

Fig. 7. The temperature dependence of the maximum torque measured for (121) as the plane of rotation. The maximum occurs at an angle of -45° from [111].

axis. In all, there may exist domains of 12 kinds. In order to derive theoretical formula for the torque, we may first write out the formula of the (Gibbs) free energy per unit volume of each subdomains. Let the direction cosines of the spin axis be (α, β, γ) and the direction cosines of the applied magnetic field (a, b, c) , both referring to the cubic principal axes. Then, for sufficiently weak field intensity, H (for which the torque is proportional to H^2 and the susceptibility independent of H) the free energy per unit volume can be written

$$F = -\frac{1}{2}\chi_{//}H_{//}^2 - \frac{1}{2}\chi_{\perp}H_{\perp}^2 \\ = \frac{1}{2}(\chi_{\perp} - \chi_{//})(\alpha a + \beta b + \gamma c)^2 H^2 - \frac{1}{2}\chi_{\perp}H^2. \quad (2)$$

One may multiply this by the corresponding volume of the same kind of domains and sum over 12 kinds of domains to obtain the total free energy. The torque needed to bring the crystal back to its original position, i.e. the position in zero field, is calculated by

$$T = -\partial F_{total} / \partial \theta, \quad (3)$$

if the angle θ is measured from a fixed axis of the crystal to the direction of the magnetic

field. Equation (1) follows immediately from (2) and (3), since F_{total} is a quadratic function of a, b, c ; C and ϵ depend on the abundance ratio of different kinds of domains.

We shall specialize our problem by confining ourselves to our stress-annealed crystals which show no anisotropy within the (111) plane. For these crystals it is plausible to assume that out of four kinds of crystallographic domains one with the trigonal axis along [111] is more abundant than the remaining three (with trigonal axes along $[\bar{1}\bar{1}\bar{1}]$, $[\bar{1}\bar{1}1]$ and $[\bar{1}1\bar{1}]$, respectively) and that the three antiferromagnetic subdomains (with spin axes possibly along $[\bar{2}11]$, $[1\bar{2}1]$, $[11\bar{2}]$ or along $[\bar{1}\bar{1}0]$, $[\bar{1}01]$, $[01\bar{1}]$ in the case of the dominant kind of crystallographic domains, for instance) are equally abundant in each kind of crystallographic domains. Then we can take out the excess

volume occupied by the dominant kind over each of those occupied by the others and consider the rest of the volume of the sample to be magnetically isotropic. The total free energy effective for the torque in this case is given by

$$F_{total} = \frac{1}{3} \sum_{(\alpha\beta\gamma)} \frac{1}{2} (\chi_{\perp} - \chi_{//}) (\alpha a + \beta b + \gamma c)^2 H^2 p V, \tag{4}$$

where the summation is taken over cyclic permutations of α, β, γ , p is the fraction of the excess volume, and V the total volume. (If the susceptibilities refer to a unit mass, the volume is replaced by the total mass.) The above formula can be put into another form:

$$F_{total} = \frac{1}{3} (\chi_{\perp} - \chi_{//}) V H^2 p (\beta\gamma + \gamma\alpha + \alpha\beta) \times (bc + ca + ab), \tag{5}$$

leaving out the isotropic part. The torque

can be calculated by differentiating the last factor, $bc+ca+ab$, with respect to the angle of rotation. It has a form

$$T = C \cos 2(\theta + \varepsilon), \quad (1)$$

where

$$C = kVH^2(\chi_{\perp} - \chi_{\parallel})pS, \quad (6)$$

$$S = \beta\gamma + \gamma\alpha + \alpha\beta,$$

k and ε being certain constants which depend on the kind of the plane of rotation.

It is noted that the torque amplitude, C , is proportional to pS so that the value of S alone cannot be known from our experiment. However, that the spin axis is along $[001]$ or its equivalents is excluded, since in this case S vanishes. The analysis of our experimental results with the use of the above formulas shows that S is negative and most probably $-1/2$ which corresponds to spin axis being in the (111) plane. Measurement of the anisotropy of the susceptibility should in principle also be unable to yield the values of p and S separately, since the formula of it can be derived from the same free energy (5).

Comparison of our formulas (1) and (6) with the results described in the preceding paragraph is very satisfactory, as one sees in Table I. The relative magnitudes of the torque amplitudes and the values of the phase constant, ε , measured for different planes of rotation agree within experimental errors with those calculated theoretically. For these values of ε the theoretical k values are negative (see Table 1), which implies that S is negative, since C is positive. The absolute measurements of the torque yield a value of pS for each sample, and the highest value of $p|S|$ obtained was 0.38, which corresponds to $p=76\%$ if S is assumed to be $-1/2$. We can conclude at least that the spin axis lies within $\pm 16^\circ$ from the (111) plane, since $p < 1$ and so $|S| > 0.38$ ($[(1+2S)/3]^{1/2}$ is the sine of the angle between the spin axis and the (111) plane). An example of evaluating pS is shown in Table II.

§ 5. Further Experimental Facts and Discussion

We have seen at the end of the preceding paragraph that the torque measurements yield the product pS . The maximum attainable absolute value of this quantity should be $1/2$, whereas the highest value actually attained

was 0.38. Attempts were made to elevate the absolute value of pS , by varying the condition of stress-annealing and growing the crystals from seeds. Crystals of kind B were most suitable for this purpose. In the meanwhile, it happened when a crystal was dropped carelessly on the floor that a considerable reduction in torque amplitude took place. Also, when the (111) surfaces of a crystal were polished by sand paper, a marked increase in torque amplitude was observed. These indicate that mechanical shocks at room temperature alter the twin structure of the crystal. Therefore we applied ultrasonic oscillations of 27 kc/sec in the direction normal to the (111) surfaces applying simultaneously a pressure on these surfaces and could even more efficiently increase the torque amplitude for samples annealed without stress. With stress-annealing only the value of $p|S|$ could not exceed approximately 0.25 in most cases but with supersonic it could be elevated to 0.38 in the best case.

Effect of a magnetic field on the alignment of domains was not much studied. Application of a high magnetic field should turn the magnetizations in the easy plane so as to bring them perpendicular to the field, overcoming a small anisotropy energy (of sixfold symmetry) in that plane and the resistances of magnetic domain boundaries. One may except a departure from the proportionality between the torque and H^2 and a hysteresis effect, i.e. a change in the magnetic anisotropy of the sample after the application of the field. There were a few examples in which a sort of these effects was observed above 10000 oe but they were not fully investigated. We hope to study them further. Antiferromagnetic resonance experiments in the region of far infra-red will give informations of the magnetic anisotropy in NiO, and this will be our next program.

It is the authors' pleasure to acknowledge the warm encouragement given by Professor Y. Mashiyma of the University of Osaka Prefecture. They also appreciate the assistance of Messrs. M. Kojima and S. Saito in the X-ray study and N. Fukuoka in the magnetic measurements. Thanks are due to the member of Azuma Precision Metal Pattern Works in Osaka for their kind help in preparing a precision pressing apparatus. A part of the present investigation was supported by the

Scientific Research Expenditure of the Education Ministry.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 13, No. 6, JUNE, 1958

Fine Structures of X-ray K Absorption Spectra of Nickel in Oxides of Nickel

Kenjiro TSUTSUMI

Department of Physics, Faculty of Science, Osaka University

(Received December 5, 1957)

The fine structures of X-ray *K* absorption spectra of nickel in metallic nickel, NiO, Ni₂O₃ and NiO₂·nH₂O were photographed by a bent crystal spectrograph. The fine structures of absorption spectra of metallic nickel and NiO agree well with those published by previous authors, but those of Ni₂O₃ do not coincide with those reported by Hayasi and Cauchois. Also Cauchois' data of Ni₂O₃ do not coincide with Hayasi's data. This seems to be due to doubtful chemical structures of Ni₂O₃ and it is supposed that the three specimens used by the three authors might have different chemical structures. The first absorption maxima *A* are much more pronounced with increasing oxygen proportion and the general features of α , β , *C* and γ of the absorption spectra of oxides are similar respectively. However, the second small absorption maxima *B* are less pronounced with increasing oxygen proportion. These facts are expected from Coster and Kiestra's and Cauchois' considerations. It may be considered from the comparison of the present curves of absorption spectra only that nickel sesquioxide is a mixture of NiO and NiO₂·nH₂O.

§ 1. Introduction

An investigation into the fine structures of the X-ray absorption spectra of metallic oxides may be of interest to obtain some information about solid state problems. Coster and Kiestra¹⁾ investigated the various oxides of Mn, Fe and Zn and concluded that the fine structure at a shorter distance from the main edge depended not so much on the crystal

structure but it seemed to be chiefly determined by the field in a closer neighborhood of the atom in question. Cauchois,^{2,3,4)} in her experiments on the fine structures of the absorption spectra of some oxide of copper and nickel, investigated the white line (R.B.) which occurred immediately on the high frequency side of *K* absorption edge. As it has been reported that there exists a series of

nickel oxides with various proportions of oxygen, the author investigated the fine structures of X-ray absorption spectra of nickel in metallic nickel (Ni), nickel monoxide (NiO), nickel sesquioxide (Ni_2O_3) and nickel dioxide hydrate ($\text{NiO}_2 \cdot n\text{H}_2\text{O}$).

§ 2. Experiments

The nickel foil was prepared by electrolysis. Its thickness was about 8μ . The oxides

were supplied by Hutaba Chemical Industry. NiO, Ni_2O_3 and $\text{NiO}_2 \cdot n\text{H}_2\text{O}$ respectively were 96.21, 99.58 and 97.57% in purity, and were grey green, grey black and green.

The X-ray diffraction patterns of all the samples were photographed. They are reproduced in Photo. 1. The diffraction pattern of $\text{NiO}_2 \cdot n\text{H}_2\text{O}$ shows only amorphous halos, and that of Ni_2O_3 is not a superposition of those of NiO and $\text{NiO}_2 \cdot n\text{H}_2\text{O}$. The diameter

Photo. 1. X-ray diffraction patterns of metallic nickel and its oxides on about 1/1 of original size.

Photo. 2. Ni K absorption spectra of metallic nickel and its oxides on about 3.7/1 of original size.

of the powder camera was 7.03 cm. The X-ray tube with a copper target was loaded with 20 kV and 20 mA. The time of exposure was about 1.5 hours.

The fine structures of X-ray K absorption spectra of nickel in Ni, NiO, Ni₂O₃ and NiO₂·nH₂O were taken with a bent crystal spectrograph of transmission type having a focusing circle of diameter of 20 cm. The second

order reflection from (1 0 0) plane of a quartz crystal was used, and the dispersion in the region of Ni K absorption edge was about 18.9 $\text{\AA}$. per mm on the photographic plate. The gas ion X-ray tube with a molybdenum target was used to avoid W $L\alpha$ emission lines and was loaded with 14 kV (peak) and 8 mA. The time of exposure was varied 15 to 20 hours. In the case of oxides the ab-

sorbers were made by mixing a small amount of grease with the finely pulverized specimen and spreading the mixture on a thin paper up to the required amount 7 mg/cm² to 20 mg/cm². The microphotometric traces with the dispersion of about 2.5 *x.u.* per cm were taken (case A), and in the case of nickel another trace with the dispersion of about 1.25 *x.u.* per cm was taken to see the details of the fine structures near the absorption edge (case B). The spectrograms and correspond-

ing microphotometer traces are reproduced in Photo. 2 and Photo. 3. The measurements of wavelengths were carried out referring to the Ni $K\alpha_1$, Cu $K\alpha_1$, Mo $K\alpha_1$ and Cu $K\beta_1$ photographed on the same plate. Table I shows the wavelength values of the fine structures of K absorption spectra of nickel in Ni, NiO, Ni₂O₃ and NiO₂·nH₂O respectively, and Table II shows their energy separations from the Ni K absorption edges of these substances.

§ 3. Discussions

The wavelength values of the fine structures of Ni K absorption spectra of metallic nickel and NiO agree well with those already published by Cauchois²⁾ (Ni and NiO) and Hayasi^{6,9)} (Ni) within the limit of experimental errors, but those of Ni₂O₃ do not coincide with those obtained by Hayasi⁹⁾ and Cauchois²⁾. Also the values of Ni₂O₃ given

by Cauchois do not agree with those obtained by Hayasi. This seems to be due to some doubtful chemical structures of Ni₂O₃. Several reports⁷⁾ hitherto made on the chemical structures of nickel sesquioxide indicate that Ni₂O₃ may be a mixture of NiO and amorphous NiO₂, that even the ordinary anhydrous substance may contain some water molecules, and that anhydrous Ni₂O₃ may not

exist. It is considered that the specimens used for the above three experiments might have different chemical structures owing to the different procedure of their preparation.

The first absorption maxima A are more pronounced with increasing oxygen proportion. Absorption maximum A corresponds to the transition of the K electron to the $4p$ -level. According to Coster and Kiestra¹⁾ the atomic wave-functions are much more maintained as more oxygen is added and the metal ions are located apart from each other. This implies that the width of the p -band becomes smaller and then the fine structure is more pronounced.

The general features of the small absorption minima α , large minima β , maxima C and minima γ of absorption spectra of these oxides are similar respectively. Coster and Kiestra^{1,8)} considered that in these regions the fine structures were determined by immediate surroundings of the atom in question. This consideration is well supported by the present experimental results. However, the second small absorption maxima B are less pronounced with increasing oxygen proportion. This seems to be due to the coordinations of oxygen atoms which become more complex with increasing oxygen proportion.

It is believed that the fine structure, in the high energy region from the main edge, is determined by the type of the crystal lattice. Nickel crystallises in the face centered cubic lattice and NiO also crystallises in nearly the face centered cubic lattice. However, recent-

ly it is reported that the NiO crystallises in the rhombohedral lattice⁹⁾ at the room temperature. Moreover, because of the large difference of structure factors of nickel and NiO, the comparison of the fine structures of these two substances was not made.

Finally it may be considered only from the comparison of the present curves of absorption spectra of NiO, Ni₂O₃ and NiO₂·nH₂O that nickel sesquioxide is a mixture of NiO and NiO₂·nH₂O. In conclusion the author well supports Coster and Kiestra's^{1,8)} and Cauchois's⁴⁾ considerations.

The author express my sincere thank to Professor M. Sawada for his encouragement to this work.

Fine Structures of the X-ray Absorption by the Single Crystal of Germanium

Kenjiro TSUTSUMI* and Masayoshi OBASHI**

**Department of Physics, Faculty of Science, Osaka University*

***North College, Osaka University*

(Received February 23, 1958)

The fine structures of X-ray absorption by single crystals of germanium were investigated. These crystals were used as an analysing crystal of a spectrometer and at the same time as an absorber. The intensities of general radiation reflected from (1 0 0), (1 1 0) and (1 1 1) planes were investigated. The fine structures of intensities reflected from these planes were in agreement with those of absorption spectrum reported by Doran and Stephenson obtained by the transmission method using a single crystal as an absorber. However, they reported that they observed a weak fine structure near the absorption edge which was not observed by us. The observed fine structure of the absorption can be interpreted in terms of Kronig's theory, while the absence of the fine structure near the absorption edge is due to the anomalous scattering of germanium on the one hand and to the thickness effect reported by Parratt, Hempstead and Jossem on the other.

§ 1. Introduction

A convenient technique to measure the fine structure of the absorption spectrum using a single crystal has been proposed by Stephenson¹⁾ and Krogstad, Nelson and Stephenson²⁾ who used a single crystal as an analysing crystal and at the same time as an absorber. They claimed that the results obtained by this technique were in agreement with those obtained by the transmission method in the cases of KBr¹⁾, KCl and NaCl²⁾. However, Nelson³⁾ could not obtain by this technique any fine structure of absorption with germanium which was reported by Hulbe and Cauchois⁴⁾.

As good single crystals of germanium were available, we investigated the fine structures of the absorption of germanium by this technique and compared these with those given in the literature³⁾.

§ 2. Experiments

By using the North American Philips Diffraction Unit and Wide Range Spectrometer, modified to a tube spectrometer described by Coster and De Lang⁵⁾, we recorded automatically the fine structures of absorption by single crystals of germanium. The details of our modified method have been published in our previous papers⁶⁾. The maximum divergence of the slit system is about 0.0004

radians. As the analysing crystals we used germanium single crystals of N type which contained arsenic as impurity and the faces parallel to (1 0 0), (1 1 0) and (1 1 1) were used. The number of etch pits by CP-4 was about $10^4/\text{cm}^2$.

The reflections of the fourth order from (1 0 0) plane, the second order from (1 1 0) plane and the first order from (1 1 1) plane were used. The perfectness of the crystals was examined by recording Mo $K\alpha_{1,2}$ emission lines reflected from these planes. They are reproduced in Photo. 1. The same emission lines reflected from a good calcite crystal were also recorded for comparison. They are reproduced in Photo. 2. The widths of the half maxima of the lines by germanium are slightly wider than those given by calcite, but the crystals of germanium can safely be used as analysing crystals.

The general radiation was analysed by these crystals of germanium in the region of Ge K absorption edge. They are reproduced in Photo. 3. The X-ray tube with a molybdenum target was loaded with 15–20 mA at 20 kV. The scanning speed of the Geiger-Müller tube was $1/8^\circ$ per minute and the time constant of the rate-meter was 8 seconds. The intensities on the long and the short wavelength sides of Ge K absorption edge were not recorded on one and the same chart, be-

cause the number of counts was too few to detect the fine structure of the reflected intensity on the short wavelength side when the intensities of both sides were so recorded as to avoid the dead time correction of the counter.

Table I shows the wavelength values (in Å) of the fine structures of reflected intensities

and Table II shows their energy separations (in eV) from the Ge K absorption edge. The last columns of the both tables show the wavelength values and the energy separations measured by Doran and Stephenson³⁾, who investigated the fine structure of the absorption spectrum using a single crystal absorber of germanium by the transmission method.

Photo. 1. Mo K_{α_1, α_2} emission lines reflected from various planes of germanium crystals.

Photo. 2. Mo K_{α_1, α_2} emission lines reflected from a good calcite,

Photo. 3. Fine structures of reflected intensities from various planes of germanium single crystals.

§ 3. Discussions

By comparing Table I and II it will be seen that the fine structures of intensities reflected from the various planes of germanium single crystals and those given by Doran and Stephenson agree well with each other, except near the absorption edge. The weak

fine structure within 50 eV from the absorption edge which was observed by Doran and Stephenson is not observed in our reflected intensity curves. In this region our results coincide with those of Nelson.

These facts are considered to be due to the following:

Fig. 1. Magnitudes of absorption discontinuities of germanium *vs* energies.

1. If we assume that the fine structure of the reflected intensity is caused by absorption by the analysing crystal itself, the fluctuations (discontinuities) in the absorption coefficient will occur at the enery values⁷⁾

$$W = \frac{h^2}{8md^2}(h^2 + k^2 + l^2), \tag{1}$$

as measured from the mean potential of the crystal since it belongs to the cubic system, where *d* is the lattice constant, *m* the electron mass and (*h*, *k*, *l*) are Miller-indices. The magnitudes of discontinuities are proportional to

$$I_{hkl} = H_{hkl}(V_{hkl})^2, \tag{2}$$

where *H_{hkl}* is the abundance factor of the (*hkl*) planes and *V_{hkl}* is the Fourier coefficient of the potential in the crystal. According to

Table III. Separations of gravity centers of absorption discontinuities of germanium. (in eV.)

Group	Theoretical	Present experiments	Doran and Stephenson
<i>α</i>	13		15.7
<i>B-β</i>	29		29
<i>C-γ</i>	62	65	55
<i>D-δ</i>	98	98-102	97
<i>E-ε</i>	177	173	167
<i>F-ζ</i>	248	246-253	247

Kronig's simplified method⁷⁾, however, *I_{hkl}* is considered to be proportional only to *H_{hkl}*. We plotted this quantity, *I_{hkl}*, against energy value given by (1) for the case of germanium (Fig. 1). One can distinguish groups *A-α*, *B-β*, *C-γ*, *D-δ*, *E-ε* and *F-ζ*. Their

centers of gravity agree with those of the observed structures as seen in Table III. In our case reflected X-rays are partially polarized, so that when these polarized X-rays are absorbed by a single crystal all photoelectrons are not uniformly ejected in all directions, and therefore some planes do not contribute to the discontinuities. This effect is more influential near the absorption edge than in the high energy region, because in Fig. 1 the abundance factor and the number of overlapping planes with different Miller-indices are small in this region. Thus the fluctuations in the absorption coefficient are less pronounced in this region than those when unpolarized X-rays are absorbed by a polycrystalline absorber.

2. The total energy I diffracted from a face of a single crystal, according to kinematical theory, is given by

$$\frac{I}{I_0} = \frac{1}{2\mu} \left(\frac{N\lambda_i^3 e^4}{Zm^2 c^4 \sin 2\theta} \cdot \frac{1 + \cos^2 2\theta}{2} \right) |F|^2 \\ \equiv \frac{Q'}{2\mu} |F|^2, \quad (3)$$

where I_0 , μ , N , Z , λ_i , θ , F and e are the power of the incident radiation, atomic absorption coefficient, number of unit cells per unit volume, number of atoms per unit cell, wavelength of the incident radiation, Bragg angle, structure factor and the charge of an electron, respectively. In the case of germanium the structure factor becomes

$$F = f(1 + e^{(\pi i/2)(h+k+l)})(1 + e^{\pi i(h+k)} + e^{\pi i(h+l)} + e^{\pi i(k+l)}) \equiv f \cdot p, \quad (4)$$

f being the atomic scattering factor of germanium. We must consider the anomalous scattering in the present case because the frequency ω_i of the incident radiation is near the frequency ω_k of the absorption edge of the scattering atom. In this case f is written as

$$f = f_0 + f' + if'',$$

where f_0 is the atomic scattering factor for frequencies high in comparison with the atomic absorption frequency ω_k and for a particular reflection it is independent of the incident wavelength itself, and f' and f'' are the real and imaginary parts of f which depend on the frequency. Then equation (3) can be written

$$I = \frac{I_0 Q' p^2}{2\mu(\omega_i)} \{ (f_0 + f')^2 + f''^2 \}, \quad (5)$$

in which I_0 , f_0 and p are independent of frequency and Q' varies monotonically with frequency. From the classical theory⁸⁾ of dipole-oscillator f' and f'' are expressed as

$$f' = \frac{mc}{2\pi^2 e^2} \int_{\omega_k}^{\infty} \frac{\omega^2 \mu(\omega)}{\omega_i^2 - \omega^2} d\omega, \quad (6)$$

$$f'' = \frac{mc}{4\pi e^2} \omega_i \mu(\omega_i) \equiv g' \mu(\omega_i), \quad \omega_i > \omega_k, \quad (7)$$

$$f'' = 0, \quad \omega_i < \omega_k.$$

When $\mu(\omega)$ varies monotonically with frequency the general features of f' and f'' , as functions of frequency, are shown in Fig. 2.

Fig. 2. General features of f' and f'' against frequency.

It is estimated* from equation (6) that the maximum magnitude of fluctuation $\Delta f'$ depending on the small fluctuation $\Delta\mu$ in μ is nearly equal to that of $g'\Delta\mu$ when $\Delta\mu$ varies sinusoidally. The fluctuation $\Delta f''$ depending on $\Delta\mu$ is $g'\Delta\mu$ from equation (7). Table IV shows the values of f_0 , f' and f'' when the damping constant of oscillators is taken to be 10^{-4} .

From equation (5) the fluctuation in I depending on $\Delta\mu$ is

* From equation (6) it can be shown that only the following integral contributes to the fluctuation in f' .

$$\frac{mc}{2\pi^2 e^2} \cdot \frac{\omega_i}{2} \int_{\omega_k}^{\infty} \frac{\Delta\mu}{\omega - \omega_i} d\omega = \Delta f'(\omega_i),$$

where $\Delta\mu$ is a fluctuating part in μ . If we assume that $\Delta\mu = a \cdot \sin m\omega$, then the maximum magnitude of $\Delta f'(\omega_i)$ can be given approximately as

$$\frac{mc}{2\pi^2 e^2} \cdot \frac{\omega_i}{2} \cdot 4 \cdot \frac{a\pi}{2} = 2ag.$$

Table IV. Values of f_0 , f' and f'' .

λ/λ_K	λ (Å)	f_0			f'	f''
		(400)	(220)	(111)		
1	1.117 ₀	18.4	21.7	26.2	-9.77	3.74
0.995	1.114 ₄				-7.17	3.70
0.99	1.105 ₈				-4.57	3.66
0.985	1.100 ₂				-4.06	3.63
0.98	1.094 ₇				-3.72	3.59
0.975	1.089 ₁				-3.44	3.55

$$\Delta I = \frac{I_0 Q' p^2}{2\mu^2} [- \{ (f_0 + f')^2 - f''^2 \} \Delta\mu + 2(f_0 + f')\mu\Delta f'] . \quad (8)$$

The maximum magnitude of $\mu\Delta f'$ is nearly equal to that of $g'\mu\Delta\mu \equiv f''\Delta\mu$, and the fluctuation $\Delta f'$ shows quite a different variation with ω_i from that of the fluctuation $\Delta\mu$. As can be seen in Fig. 2 and Table IV, $(f_0 + f')^2 - f''^2$ and $2(f_0 + f') \cdot f''$ near the absorption edge are much smaller than their respective values in the high frequency region. Thus the fluctuations in the reflected intensity are less pronounced near the absorption edge than in the high energy region. Besides, $\Delta\mu$ cannot affect I near the absorption edge as $(f_0 + f')^2$ is comparable to f''^2 . It is supposed that the maximum magnitude of the small fluctuation $\Delta f'$ is actually smaller than that of $g'\Delta\mu$ because in our experimental results the fluctuations in the reflected intensity in the high energy region from the absorption edge are similar to those of the absorption spectrum by the transmission method and therefore are not affected by $\Delta f'$. Therefore the influence of $\Delta f'$ on the reflected intensity is considered to be very small in the whole frequency region. When the magnitudes of f' and f'' become small with increasing frequency, $\Delta\mu$ much affect the reflected intensity and then the fluctuations in the reflected intensity become more pronounced.

3. The effect similar to the thickness effect in the absorption spectrum which was investigated by Parratt, Hempstead and Jossem⁹⁾ by the transmission method is considered to

occur in our case, particularly in the case of low dispersion of the spectrometer. In their investigation they concluded that the fine structure of the absorption spectrum near the absorption edge became less pronounced with increasing absorber thickness on account of the tail of the spectral window (the tail of the focal spot of the X-ray tube in our case) and the enormous asymmetric shape of the absorption edge. Therefore, in our case also, the fluctuations in the reflected intensity are less pronounced near the absorption edge than in the high energy region.

We express our sincere thanks to Professor M. Sawada for his encouragement in this work.

Nuclear Magnetic Resonance Experiment on Metal Cadmium. II

Yoshika MASUDA

Department of Physics, Kobe University

(Received December 12, 1957)

The spin-lattice relaxation time, T_1 and the spin-spin relaxation time, T_2 , of the resonance line in metal cadmium were measured by use of a nuclear magnetic resonance technique. The contribution of p -character in the conduction electron to the relaxation was estimated. The line width was measured at a temperature between the room temperature and 250°C. It was shown that the exchange broadening between unlike spins underwent a motional narrowing. The inverse line width or spin-spin relaxation time, T_2 , was interpreted in terms of the lattice diffusion theory. These analyses yielded for the coefficient of self-diffusion D the value $0.05 \text{ cm}^2/\text{sec} \exp(-17.6 \text{ kcal/mol-RT})$.

§ 1. Introduction

Nuclear magnetic resonance measurements in metal cadmium have already yielded significant results for the interpretation of its metallic properties¹⁾. The line shape, line-width, and Knight shift of the resonance line have given much informations concerning the properties of the conduction electrons.

The nuclear relaxation in metals is usually determined by the interaction of nuclear spins and conduction electron spins. When one takes into account only the Fermi-interaction, the relation between the spin-lattice relaxation time and the Knight shift is well known as the "Korringa relation"²⁾. From the fact that the isotropic shift in metal cadmium is 0.43 per cent, we determined the s -content ξ of the wave function to be about 20 per cent. The resonance line is asymmetric indicating an anisotropy of the Knight shift. From the analysis of these line profiles we estimated the asymmetry in p -character of the conduction electron. The anisotropic shift, $(\Delta H_{//} - \Delta H_{\perp})/H_0$, is 0.039 per cent, where $\Delta H_{//}$ and $\Delta H_{\perp}$ are the shifts parallel and perpendicular to the c -axis, respectively. The symmetric line broadening, $\delta_{\text{max. sl.}} = 1.5$ gauss, was originated from the indirect exchange coupling between neighboring nuclei which involves conduction electrons¹⁾. The deviation of the measured relaxation time T_1 from the Korringa time may be due to the contribution of p -electron to the relaxation.

Owing to the local magnetic field at a resonating nucleus produced by its neighbors,

nuclear magnetic resonance line in solids usually has a width of several gauss. It is well known that sufficiently rapid motion of the nuclei can reduce the effective local field, so that the onset of such motion can be observed as a reduction in line width. In metals, where the possibility of any rotational motion is excluded, the motion is presumably connected with a diffusion process. A general theory on the T_1 's and T_2 's which result from interactions of the nuclei with fluctuating local magnetic fields has been given by Bloembergen, Purcell, and Pound³⁾ and Kubo and Tomita⁴⁾. The BPP theory deals with nuclear dipolar-dipolar interactions and the effects of diffusional motion of the nuclei. Line width transition in solid alkali metals^{5), 6)} and in aluminum⁷⁾ have been reported and interpreted to be due to self-diffusion. But we must concern with the effect of nuclear motion on the exchange interaction as the line width are related in this case, to the exchange interaction between unlike spins^{8), 9)}.

We shall discuss the motional narrowing in this case. From the analysis of this narrowing, the self-diffusion coefficient will be estimated.

§ 2. Experiment

The experimental procedures and equipments employed for the measurement were described previously¹⁾. The samples were consisted of foil rolled to a thickness of about 15μ . Layers of foil were separated by mica. To avoid oxidation, the metal sample was sealed at

reduced pressure into a thin-walled glass tube. The specimen was annealed at 300°C for two hours to eliminate the effects of grain boundary diffusion.

The specimen with its coil was mounted inside a Dewar vessel, into which the heated air was blown by an air compressor through a small electric furnace. A chromel-alumel thermocouple was attached to the sample vial. The temperature inhomogeneity in the vessel was found not to exceed 1°C. The experiment was performed on the Cd¹¹³ (abundance ratio 12.34 per cent) at the field of 3900 gauss with a permanent magnet using a resonance frequency of 3.71 Mc/sec. For the measurement of the relaxation time we employed the ordinary saturation method.

§ 3. Results and Discussion

a) The Spin-Lattice Relaxation Time.

For the evaluation of T_1 from saturation factor $(\gamma H_1)^2 T_1 T_2$, we employed the T_2 as determined from the symmetric line broadening δ and not from the overall width which is of the inhomogeneous type. It results in T_1 of 0.5×10^{-3} sec. for Cd¹¹³ which is one half of the Korringa time of 1.1×10^{-3} sec. estimated from the measured shift. We shall consider this deviation.

The Hamiltonian for the nuclear spin-electron spin interaction is given by

$$\mathcal{H} = \frac{8\pi}{3} g\beta g_N \beta_N \mathbf{I}_i \cdot \mathbf{S} \delta(\mathbf{r}_i) + g\beta g_N \beta_N \mathbf{I}_i \cdot \{S r_i^{-3} - 3r_i^{-5}(\mathbf{S} \cdot \mathbf{r}_i) \mathbf{r}_i\}, \quad (1)$$

where $\mathbf{r}_i$ is the radius vector of the electron with the nucleus at the origin and β is the Bohr magneton. The electron in the solid may be adequately described by one-electron wave function of Bloch type,

$$\left. \begin{aligned} \Psi_k &= e^{i\mathbf{k} \cdot \mathbf{r}} u_k(\mathbf{r}), \\ V^{-1} \int \Psi_k^* \Psi_k d\tau &= 1, \end{aligned} \right\} \quad (2)$$

where V is the volume of the metal under consideration. $u_k(\mathbf{r})$ has the periodicity of the lattice, and within the atomic polyhedron, it is assumed to be a mixture of s - and p -functions. Bardeen¹⁰⁾, Silverman and Kohn¹¹⁾, and Kohn¹²⁾ have shown that the periodic function $u_k(\mathbf{r})$ in the Bloch wave function (2) can be

expanded in a fairly rapidly converging power series in $\mathbf{k}$. This is an expansion in spherical harmonics containing the angle θ_1 between $\mathbf{r}_i$ and $\mathbf{k}$,

$$u_k(\mathbf{r}) = c_0 u^0(r) + i k c_1 u^1(r) P_1(\cos \theta_1), \quad (3)$$

where $u^0(r)$ is the normalized s -solution of the Schrödinger equation, the $u^1(r)$ is the radial part of the p -solution. The c_1 and $u^1(r)$ are independent of k . The coefficient c_1 may be determined by the boundary conditions of the wave function on the Wigner-Seitz sphere. The c_1 was evaluated accurately in case of lithium and sodium¹¹⁾¹²⁾. In cadmium, however, it was estimated from the shift in reference 1, since we have no accurately calculated value.

The first term of the Hamiltonian (1) represents the hyperfine interaction and the second term the dipolar interaction between two dipoles. It is well known that the diagonal elements of the hyperfine interaction produce an isotropic Knight shift, whereas the off-diagonal elements contribute to the relaxation time T_1 . The expression of relaxation time first presented by Korringa²⁾ is as follows:

$$\left(\frac{1}{T_1}\right)_s = \frac{4\pi k T}{\hbar} \Omega^2 N(E_0)^2 \left(\frac{\Delta E_s}{2I+1}\right)^2 \xi^2, \quad (4)$$

where Ω is the atomic volume, $N(E_0)$ the number of states, for a unit volume of the metal, per unit energy interval, $(\Delta E)_s$ the h.f.s. splitting of the atom with one s -electron outside closed shells, and ξ the s -content of the conduction electron.

Actually the part of the electronic wave function with non s -character (p -, d -, etc.) will also contribute to the relaxation time, but not to the shift in the absence of the asymmetry in p -character of electron at the top of the conduction band. We shall consider the relaxation time originated from the p -part of the electronic wave function.

Consider the dipolar part of the Hamiltonian (1). Since the nuclear- and electron-spins are quantized with respect to the external field $\mathbf{H}$, the dipolar interaction between nuclear spin $\mathbf{I}_i$ and electron spin $\mathbf{S}$ can be expanded in spherical harmonics containing the polar angle θ and ϕ in the $\mathbf{r}_i$ space, where the polar axis is in the direction of $\mathbf{H}$,

$$\mathcal{H}_{dip} = g\beta g_N \beta_N r_i^{-3} \left[\left(-2I_z S_z + \frac{1}{2} I_+ S_- + \frac{1}{2} I_- S_+ \right) P_2(\cos \theta) \right]$$

$$\begin{aligned}
& -\frac{1}{2} (I_+S_z + I_zS_+)P_2^1(\cos\theta)e^{-i\phi} - \frac{1}{2} (I_-S_z + I_zS_-)P_2^1(\cos\theta)e^{+i\phi} \\
& -\frac{1}{4} I_+S_+P_2^2(\cos\theta)e^{-2i\phi} - \frac{1}{4} I_-S_-P_2^2(\cos\theta)e^{+2i\phi} \Big]. \quad (5)
\end{aligned}$$

I_z and S_z are the components of spin parallel to the magnetic field $\mathbf{H}$; I_+ , I_- , S_+ , and S_- are the usual spin raising and lowering operators. The state of a nucleus of spin I is characterized by the quantum number m and $s = \pm \frac{1}{2}$ is the spin quantum number of the electron.

The energy exchange between a nucleus and a conduction electron is due to their magnetic interaction and is determined by the matrix elements $\langle \Psi_k; m, s | \mathcal{H}_{k'}, m', s' \rangle$ of the Hamiltonian (5). They are

$$\begin{aligned}
& \left(m, s \left| -2I_zS_z + \frac{1}{2} I_+S_- + \frac{1}{2} I_-S_+ \right| m', s' \right) \Delta k k' c_1 c_1' \int P_1(\cos\theta_1)P_1(\cos\theta_2)P_2(\cos\theta)d\omega \\
& -\frac{1}{2} (m, s | I_+S_z + I_zS_+ | m', s') \Delta k k' c_1 c_1' \int P_1(\cos\theta_1)P_1(\cos\theta_2)P_2^1(\cos\theta)e^{-i\phi}d\omega \\
& -\frac{1}{2} (m, s | I_-S_z + I_zS_- | m', s') \Delta k k' c_1 c_1' \int P_1(\cos\theta_1)P_1(\cos\theta_2)P_2^1(\cos\theta)e^{+i\phi}d\omega \\
& -\frac{1}{4} (m, s | I_+S_+ | m', s') \Delta k k' c_1 c_1' \int P_1(\cos\theta_1)P_1(\cos\theta_2)P_2^2(\cos\theta)e^{-2i\phi}d\omega \\
& -\frac{1}{4} (m, s | I_-S_- | m', s') \Delta k k' c_1 c_1' \int P_1(\cos\theta_1)P_1(\cos\theta_2)P_2^2(\cos\theta)e^{+2i\phi}d\omega, \quad (6)
\end{aligned}$$

where

$$\Delta = g\beta g_N \beta_N \int_0^{r_s} u^{1*}(r_i) u^1(r_i) r_i^{-1} dr_i \quad (7)$$

and θ_2 is the angle between $\mathbf{r}_i$ and $\mathbf{k}'$. The integration over r_i is extended only over the Wigner-Seitz sphere with radius $r_s = \left[\frac{3}{4\pi} \frac{\Omega}{2} \right]^{1/3}$. Carrying out the integral over the solid angle $d\omega$, the matrix elements take the forms

$$\begin{aligned}
& \left(m, s \left| -2I_zS_z + \frac{1}{2} I_+S_- + \frac{1}{2} I_-S_+ \right| m', s' \right) \Delta k k' c_1 c_1' \frac{4}{15} \pi \{ 3P_1(\cos\theta_1)P_1(\cos\theta_2) - P_1(\cos\chi) \} \\
& -(m, s | I_+S_z + I_zS_+ | m', s') \Delta k k' c_1 c_1' \frac{2}{5} \pi \{ P_1(\cos\theta_2)P_1^1(\cos\theta_1)e^{-i\varphi_1} + P_1(\cos\theta_1)P_1^1(\cos\theta_2)e^{-i\varphi_2} \} \\
& -(m, s | I_-S_z + I_zS_- | m', s') \Delta k k' c_1 c_1' \frac{2}{5} \pi \{ P_1(\cos\theta_2)P_1^1(\cos\theta_1)e^{+i\varphi_1} + P_1(\cos\theta_1)P_1^1(\cos\theta_2)e^{+i\varphi_2} \} \\
& -(m, s | I_+S_+ | m', s') \Delta k k' c_1 c_1' \frac{2}{5} \pi P_1^1(\cos\theta_1)P_1^1(\cos\theta_2)e^{-i(\varphi_1+\varphi_2)} \\
& -(m, s | I_-S_- | m', s') \Delta k k' c_1 c_1' \frac{2}{5} \pi P_1^1(\cos\theta_1)P_1^1(\cos\theta_2)e^{+i(\varphi_1+\varphi_2)}, \quad (8)
\end{aligned}$$

where k_1 , θ_1 , φ_1 are the polar coordinates in the $\mathbf{k}$ space and k_2 , θ_2 , φ_2 in the $\mathbf{k}'$ space, the polar axis being in the direction of $\mathbf{H}$. χ is the angle between $\mathbf{k}$ and $\mathbf{k}'$. Picking up the non-secular parts of Eq. (8), which are responsible for the relaxation time, we obtain

$$\begin{aligned}
(\mathcal{H}_{kk'})_{rel} = & (I_+S_- + I_-S_+)W_B(kk') + (I_+S_z)W_C(kk') + (I_-S_z)W_D(kk') \\
& + (I_+S_+)W_E(kk') + (I_-S_-)W_F(kk') \quad (9)
\end{aligned}$$

with

$$\begin{aligned}
 W_B(kk') &= \Delta k k' c_1 c_1' \frac{2}{15} \pi \{ 3P_1(\cos \theta_1)P_1(\cos \theta_2) - P_1(\cos \chi) \}, \\
 W_G(kk') &= \Delta k k' c_1 c_1' \frac{2}{15} \pi \{ P_1(\cos \theta_2)P_1^1(\cos \theta_1)e^{-i\varphi_1} + P_1(\cos \theta_1)P_1^1(\cos \theta_2)e^{-i\varphi_2} \}, \\
 W_D(kk') &= \Delta k k' c_1 c_1' \frac{2}{15} \pi \{ P_1(\cos \theta_2)P_1^1(\cos \theta_1)e^{+i\varphi_1} + P_1(\cos \theta_1)P_1^1(\cos \theta_2)e^{+i\varphi_2} \}, \\
 W_E(kk') &= \Delta k k' c_1 c_1' \frac{2}{5} \pi P_1^1(\cos \theta_1)P_1^1(\cos \theta_2)e^{-i(\varphi_1+\varphi_2)}, \\
 \text{and} \quad W_F(kk') &= \Delta k k' c_1 c_1' \frac{2}{5} \pi P_1^1(\cos \theta_1)P_1^1(\cos \theta_2)e^{+i(\varphi_1+\varphi_2)}.
 \end{aligned} \tag{10}$$

The change of $N(m)$, the number of nuclear spins in the state m , due to the interaction with the conduction electrons is calculated with time dependent perturbation theory, using the Fermi-statistics for the electrons²⁾. Then we obtain

$$\begin{aligned}
 \frac{\partial N(m)}{\partial t} &= U_B \{ N(m+1)C_m - N(m)(C_m \exp \gamma + C_{m-1}) + N(m-1)C_{m-1} \exp \gamma \} \\
 &\quad + (U_G + U_G') \{ N(m+1)C_m - N(m)(C_m + C_{m-1}) + N(m-1)C_{m-1} \} \\
 &\quad + U_E \{ N(m+1)C_m \exp \gamma - N(m)(C_m + C_{m-1} \exp \gamma) + N(m-1)C_{m-1} \}
 \end{aligned} \tag{11}$$

with

$$\begin{aligned}
 U_B &= \frac{2\pi}{\hbar} \frac{\Omega^2}{(2\pi)^6} \int d\mathbf{k} \int d\mathbf{k}' |W_B(kk')|^2 \delta(E_{k'} - E_k - g_N \beta H) \\
 &\quad \times \{ 1 + \exp(-\alpha) \}^{-1} \{ 1 + \exp(\alpha + \gamma) \}^{-1}, \\
 U_G &= \frac{2\pi}{\hbar} \frac{\Omega^2}{(2\pi)^6} \frac{1}{4} \int d\mathbf{k} \int d\mathbf{k}' |W_G(kk')|^2 \delta(E_{k'} - E_k - g_N \beta H) \\
 &\quad \times \{ 1 + \exp(-\alpha) \}^{-1} \{ 1 + \exp \alpha \}^{-1}, \\
 U_G' &= \frac{2\pi}{\hbar} \frac{\Omega^2}{(2\pi)^6} \frac{1}{4} \int d\mathbf{k} \int d\mathbf{k}' |W_G(kk')|^2 \delta(E_{k'} - E_k - g_N \beta H) \\
 &\quad \times \{ 1 + \exp(-(\alpha + \gamma)) \}^{-1} \{ 1 + \exp(\alpha + \gamma) \}^{-1}, \\
 \text{and} \quad U_E &= \frac{2\pi}{\hbar} \frac{\Omega^2}{(2\pi)^6} \int d\mathbf{k} \int d\mathbf{k}' |W_E(kk')|^2 \delta(E_{k'} - E_k - g_N \beta H) \\
 &\quad \times \{ 1 + \exp(-\alpha) \}^{-1} \{ 1 + \exp(\alpha + \gamma) \}^{-1},
 \end{aligned} \tag{12}$$

where $\alpha = (E_k - E_0)/kT$, $\gamma = g_N \beta_N H/kT$, $|(I_-)_{mm'}|^2 = C_m \delta(m, m' + 1)$, $|(I_+)_{mm'}|^2 = C_{m-1} \delta(m, m' - 1)$, and $S_{\pm} = \delta(s, s' \pm 1)$. The spin-lattice relaxation time is given by $1/T_1 = U_B + 2U_G + U_E$. This gives,

$$\left(\frac{1}{T_1} \right)_p = \frac{304}{135} \frac{\pi^3 k T}{\hbar} \Omega^2 N(E_0)^2 \Delta^2 k_m^4 c_1^4, \tag{13}$$

where k_m is the value of the wave number at the Fermi level E_0 . The quantity Δ calculated from Eq. (7) is related to the atomic p -type hyperfine splitting $(\Delta E)_p$:

$$\Delta = \frac{(\Delta E)_p}{2I+1} (1 - \xi).$$

We estimated the relaxation time by p -electrons, by Eq. (13), using the value of c_1 determined from the shift obtained in reference 1, as

$$(1/T_1)_p = 0.43 \times 10^3 \text{ sec}^{-1}.$$

On the other hand, employing the values obtained in reference 1, we estimated the relaxation time by Eq. (4),

$$(1/T_1)_s = 1.1 \times 10^3 \text{ sec}^{-1}.$$

Defining the resultant relaxation time as, $(1/T_1) = (1/T_1)_s + (1/T_1)_p$, we get

$$T_1 = 0.65 \times 10^{-3} \text{ sec}.$$

Comparing this value with the experimental one of $0.5 \times 10^{-3} \text{ sec}$, we see a good agreement which may partly be accidental. We may, however, conclude that at least a part of the deviation from Korringa time is due to the contribution of p -electron to the relaxation.

As an example other than cadmium, we apply Eq. (13) to lithium and sodium employing the value of s -content calculated by Jones and

Schiff¹³⁾, Kohn¹⁴⁾, and Kjeldaas and Kohn¹⁵⁾. Jones and Schiff estimated the *s*-content in lithium to be 25 per cent and that in sodium 65 per cent. In the case of sodium, calculations show that the Fermi energy, E_0 is almost exactly the value given by free electron approximation. In the case of lithium, however, where the conduction electrons behave very differently from free electrons, the value of E_0 is not so certain. Schiff¹⁶⁾ found $E_0=2.69$ eV but free electron approximation gives $E_0=4.72$ eV. The interaction of the *p*-part would reduce the relaxation time calculated from the Korringa relation by about 2 per cent in lithium. But there is a negligible contribution to the relaxation in sodium. Although the hyperfine interaction of *p*-orbitals is usually much smaller than that of *s*-orbit, being only 6 per cent of that in the *s*-state in the case of lithium, it becomes dominant in the case of a heavier element.

This effect of *p*-electrons on the relaxation must be further examined in heavier elements.

b) The Spin-Spin Relaxation Time

The experimental data are the values of T_2 , the inverse line width or spin-spin relaxation time, measured at a temperature between a room temperature and 250°C. Figure 1 shows the variation of the overall width with temperature. As the observed anisotropy in line profile is proportional to the magnetic field as stated in reference 1, the line becomes nearly symmetric with the anisotropic shift $\Delta H_{//}-\Delta H_{\perp}=1.52$ gauss which is comparable to $\delta_{\text{max. sl.}}=1.5$ gauss, at the low field employed in the present experiments. Accordingly, δ has a considerable contribution to the line broadening in this case. δ was proved to originate from the indirect exchange coupling between neighboring nuclei which involves conduction electrons. As an anisotropic Knight shift is produced by the nuclear spin-electron spin dipolar coupling when the charge distribution of electron deviates from spherical symmetry about the nucleus, we can consider that the asymmetry of *p*-electron will be unchanged by the atomic self-diffusion process. We consider that only the symmetric line broadening δ can undergo a motional narrowing, keeping the value of $(\Delta H_{//}-\Delta H_{\perp})/H_0$ constant. The variation of the overall width with temperature was converted to the varia-

tion of the symmetric line broadening δ . It is shown in Figure 1 by notation δ .

The diffusion may also have an effect on T_1 , the spin-lattice relaxation time. Because of a poor signal-to-noise ratio we could not measure the temperature dependence of the spin-lattice relaxation time. But it has presumably a negligible contribution to the line width. If the asymmetry in *p*-character of

Fig. 1. Line width data.

conduction electrons is unchanged by the diffusion process, the asymmetry of line profile must become more striking as the diffusion progresses. But, unfortunately, we could not observe the variation with temperature of line profile and Knight shift.

δ is seen to decrease as the temperature is increased over about 80°C, and it narrows out at about 200°C. The ambiguity of measurements is rather large in high temperature region, since the resonance line becomes much less intense and reliable measurements become increasingly difficult. Though it was desirable to make measurements in rather high temperature region where the melting phenomenon heralds the breakdown of the forces which holds the lattice rigid, we could not detect the resonance line in such region.

We shall be interested in the effect of nuclear motion on the exchange interaction as the line width are related to exchange interaction between unlike spins. A pure rotation, leaving the internuclear distance between the two nuclei unchanged, has no effect because the exchange interaction has no angular dependence. Unlike the dipolar interaction, it does not average out on rotation. An analysis

of this motional narrowing of exchange broadening will be given next.

Ramsey and Purcell⁸⁾, and Ruderman and Kittel⁹⁾ have shown that the nuclear spin-electron spin interaction will in second-order perturbation theory give rise to an exchange type of coupling between nuclear spins in molecules or in metals.

The Hamiltonian for the nuclear spin-electron spin interaction is given by Eq. (1), and the electronic wave function by Eq. (2). Ruderman and Kittel⁹⁾ found the exchange interaction in a metal to be of the form

$$\mathcal{H}^{exch} = \sum_{i>j} \sum_j A_{ij} \mathbf{I}_i \cdot \mathbf{I}_j, \quad (14)$$

where

$$A_{ij} = -2^{-5} (|\Delta_{ij}|^2)_{Av} m' \pi^{-3} \hbar^2 R_{ij}^{-4} \\ \times [\sin(2k_m R_{ij}) - 2k_m R_{ij} \cos(2k_m R_{ij})]. \quad (15)$$

A pair of nuclear spins is introduced at positions $\mathbf{R}_i$ and $\mathbf{R}_j$ in the lattice, and one writes $\mathbf{R}_{ij} = \mathbf{R}_i - \mathbf{R}_j$, and m' is the effective mass. The average over k and k' is introduced,

$$(|\Delta_{ij}|^2)_{Av} = \langle \Delta_i(kk') \Delta_j(kk') \rangle_{eff}, \quad (16)$$

where

$$\Delta_i(kk') = (8\pi/3) g\beta g_N \beta_N u_k(\mathbf{R}_i) u_{k'}^*(\mathbf{R}_i). \quad (17)$$

If we assume that the spin $\mathbf{I}_i$ only interacts with a spin $\mathbf{I}_j$ in the nearest neighbor sites, the exchange interaction is modified as follows

$$\mathcal{H}^{exch} = \sum_{i>j} \sum_j A \mathbf{I}_i \cdot \mathbf{I}_j \delta(|\mathbf{R}_{ij}(t)| - a). \quad (18)$$

It is necessary to sum over all spins $\mathbf{I}_j$, because of the self-diffusion. $\delta(|\mathbf{R}_{ij}(t)| - a)$ is unity when $\mathbf{I}_i$ and $\mathbf{I}_j$ are in the nearest neighbor sites, otherwise zero, where a is the nearest neighbor distance. But the summation over j may be restricted to the nearest neighbor because of the nearest neighbor interaction only. Hamiltonian, Eq. (18), can be written as¹⁷⁾

$$\mathcal{H}^{exch} = \sum_{j=1}^n A \mathbf{I}_i \cdot \mathbf{I}_j e^{i\phi_j(t)} = \sum_{j=1}^n A(t) \mathbf{I}_i \cdot \mathbf{I}_j, \quad (19)$$

where $\phi_j(t)$ is the phase which varies in a random manner with the exchange of unlike spin in the nearest neighbor sites and n is the number of nearest neighbor sites. The correlation function of $A(t)$ is

$$\langle A(t) A^*(t+\tau) \rangle = A^2 e^{-\tau/\tau_e}, \quad (20)$$

where τ_e is the correlation time for an indirect exchange coupling. Using this correlation function, we can calculate the transition probabilities by Solomon's procedure¹⁸⁾ and these

results will give the spin-spin relaxation time T_2 . If we consider only spins of value $\frac{1}{2}$, we obtain

$$\frac{1}{T_2} = \frac{A^2 n f}{4\hbar^2} \left[\tau_e + \frac{\tau_e}{1 + (\omega_{I_i} - \omega_{I_j})^2 \tau_e^2} \right], \quad (21)$$

where f is the abundance ratio of unlike spins. In the extremely narrow case, the spin-spin relaxation time is given by

$$\left(\frac{1}{T_2} \right)_{ex} = \left(\frac{A}{\hbar} \right)^2 \frac{\tau_e}{2} n f. \quad (22)$$

Fig. 2. Plot of ν_e against reciprocal temperature, obtained from analysis of line width data.

Turning to the line width data, we can calculate the frequency of exchange motion ν_e at a given temperature. The equation $\nu_e = \nu_{e0} \exp(-E_D/RT)$ is then employed to find the activation energy E_D for self-diffusion. As Eq. (22) is valid only in the case of the extremely narrow condition $(\omega_{I_i} - \omega_{I_j})^2 \tau_e^2 \ll 1$, it cannot be applied to the early stage of narrowing under consideration. Fig. 2 shows the frequency of exchange ν_e as a function of $1/T$, obtained from the analysis of the line width data¹⁹⁾. The data are fitted by an exponential formula, corresponding to a ν_{e0} value of $1.3 \times 10^{12} \text{ sec}^{-1}$, and $E_D = 17.6 \text{ kcal/mole}$. The observed atomic diffusion coefficients are usually expressed in terms of two constants, D_0 and E_D , as follows:

$$D = D_0 \exp(-E_D/RT). \quad (23)$$

The theoretical diffusion coefficient for translational diffusion has a form

$$D = \frac{a^2}{12\tau_D}. \quad (24)$$

Here a is the lattice constant and τ_D is the mean time-of-stay in one nearest neighbor position between jumps. As the mean time-of-stay τ_D has the heat of activation, we obtain

$$\tau_{D_0} = \tau_D \exp(-E_D/RT). \quad (25)$$

The constant τ_{D_0} is found by a crude approximation to be given by

$$\tau_{D_0}^{-1} = \frac{n(2\pi\nu_{e0})}{f}. \quad (26)$$

Upon comparing above equations, we obtain for D_0 the following theoretical equation

$$D_0 = \frac{n\pi a^2 \nu_{e0}}{6f}. \quad (27)$$

This equation gives the result as follows:

$$D_0 \sim 0.05 \text{ cm}^2/\text{sec}.$$

The experiment of self-diffusion by the radioactive tracer method gave the bulk and grain boundary diffusion coefficient²⁰⁾. The bulk diffusion constants as measured in single crystals are given by

$$D_{v//} = 0.05 \text{ cm}^2/\text{sec} \exp(-18.2 \text{ kcal/mol} - RT)$$

and

$$D_{v\perp} = 0.10 \text{ cm}^2/\text{sec} \exp(-19.1 \text{ kcal/mol} - RT),$$

where $D_{v//}$ and $D_{v\perp}$ refer to diffusion parallel and perpendicular to the hexagonal axis respectively. These values are not much different from our value of D_0 . The thermodynamical relation of Nachtrieb et al.²¹⁾ gives

$$E_D = 16.5 L_m,$$

where L_m is the latent heat of melting. Introducing the observed value of latent heat for cadmium, $L_m = 13.2 \text{ cal/gr.}$, it predicts E_D to be 10.5 kcal/mole . Employing the Van Liempt relation²²⁾

$$E_D = 32 \times (\text{melting temperature}),$$

it predicts 19 kcal/mole . These values of activation energy are consistent with the value obtained in our experiment 17.6 kcal/mole . Also, inserting the observed value of $E_D = 17.6 \text{ kcal/mole}$ into the Dashman-Langmuir's relation²³⁾,

$$D_0 = E_D d^2 / Nh,$$

where d is the atomic distance and N is the Avogadro's number, D_0 is estimated to be $0.17 \text{ cm}^2/\text{sec}$.

Because of a poor sensitivity of the experiment and a crude approximation made in analysis there may be an appreciable error in our diffusion constant. We can not say so much about the quantitative result. Finally, it may be noted that we can not hope to detect the variation of diffusion with direction by nuclear resonance study, even if the single crystal is employed.

Acknowledgements

The author wishes to thank Professor T. Kanda for his continued help and encouragement throughout the progress of this work. Particular thanks are due to Professor T. Nagamiya and Professor J. Itoh for many helpful discussions and advice. This work has been supported in part by the Scientific Research Expenditure of the Ministry of Education.

Effects of Ionizing Radiations on Polyethylene

By Kenichi SHINOHARA,

Scientific Research Institute, Tokyo

Ayao AMEMIYA and Akibumi DANNO*

Faculty of Engineering, University of Tokyo, Tokyo

(Received January 28, 1958)

Polyethylene films were irradiated in the air by deuterons accelerated by a cyclotron and by gamma rays from cobalt-60 source. Gel fraction, swelling ratio, weight changes and infrared absorption spectra of irradiated specimens were measured. It was found that the specimen irradiated by deuterons was cross-linked and became insoluble in xylene. The effects of deuteron irradiation seem almost the same as those of other ionizing radiations such as pile or gamma rays. Infrared absorption spectra reveals some difference in that the ratio of E_{00}/E_{∞} is 0.65 in the deuteron irradiation and is smaller than the value of 14.0 resulting from gamma ray irradiation, where E_{00} is the optical density of carbonyl groups and E_{∞} that of unsaturation. Some considerations are given on the possible explanation of this difference.

§ 1. Introduction

Many studies have been made on the irradiation of polyethylene by ionizing radiations. Charlesby and his coworkers¹⁾⁻⁴⁾ have investigated the rod-shaped polyethylene irradiated in a pile and observed the liberation of gas, the changes in weight, density, solubility and in melting point. Infrared absorption spectra have also been investigated by Dole and his coworkers⁵⁾, Ballentine et al⁶⁾ and Miller, Lowton and Balwit⁷⁾ for polyethylene films irradiated in a pile, or irradiated by the gamma rays from cobalt-60 or by high energy electrons. Their results suggest that the production of unsaturated bonds in polyethylene is important among other radiation effects.

In the present paper, some results will be presented on the radiation effects on polyethylene which are dependent on the character of ionizing radiations, especially on the in-

frared absorption spectra of polyethylene films irradiated by deuterons and gamma rays from cobalt-60.

§ 2. Experimental Procedure

Deuteron beam produced by the cyclotron at the Scientific Research Institute was applied for polyethylene with the dimension shown below. Deuterons were extracted from the cyclotron at the exit port covered with aluminum foil approximately 28 μ in thickness. The energy of the beam was 3.8 MeV after acceleration, and about 2 MeV after passing through the aluminum window. The beam bombarded a sample after travelling through 1.5 cm in the air, with the energy of about 1.4 MeV.

The irradiation of the sample was carried out using an aluminum rotating-drum as shown in Fig. 1. The rotating-drum was 50 mm in diameter and 50 mm in height. The film to be irradiated was mounted on the surface of this drum. The drum was rotated while mov-

* Present address; Japan Atomic Energy Research Institute, Tokyo.

ing up and down in order to irradiate the sample uniformly. The revolution rate of the drum was variable in the range from 20 to 100 rpm, so that the absorbed dose can be adjusted from 4.2×10^7 to 22.5×10^7 rads per one exposure during one course of up and down. Dose applied to the sample during one

which had been attached on the surface of the sample.

In the second experiment, the films of polyethylene were irradiated by gamma rays from cobalt-60 source of about 120 curies. The dose rate in the center of the source cylinder was 7.5×10^4 r/hr as measured by the ferrous sulphate dosimetry.

The samples of polyethylene were the films commercially obtained with the thickness of 0.03 mm. The size of the specimen was 150 mm in length and 38 mm in width. The average molecular weight was determined as 5.15×10^4 by the measurement of viscosity.

§ 3. Experimental Results

(i) Formation of cross-links and the change of weight

Irradiation of polyethylene by deuterons caused a similar change in its character as by the pile radiation or gamma rays. The polymer cross-linked and formed an insoluble gel in organic solvents such as xylene or benzene. The analysis of the swelling experiments revealed that the number of cross-links increased linearly with absorbed dose.

Changes of weight caused by irradiation also showed a similar behaviour to the results obtained by Charlesby¹⁾. The weight at first increased, reaching a maximum at the absorbed dose of 4.2×10^8 rads and then decreased. Fractional increase of the weight at the maximum, however, only about 2% and was smaller than the value of 8% obtained by Charlesby for the pile irradiation. The

Fig. 1. Schematic diagram of irradiation experiment.

course was defined as one exposure, for instance, when the rate of revolution was 60 rpm and the deuteron current was $10 \mu\text{A}$, one exposure was equivalent to 7.0×10^7 rads. Total amount of the dose applied to the sample was, also measured independently by the activity of ^{24}Na produced in NaCl crystal

Fig. 2. Infrared absorption spectra of irradiated polyethylene.

thickness of the samples were of the same order of magnitude in both cases.

(ii) *Infrared absorption spectra*

Infrared absorption spectra of irradiated films of polyethylene were measured by the

Baird Model B Double Beam Infrared Spectrophotometer. The films were held in place in the cell with a holder and compared against air.

Fig. 2 shows the infrared absorption spectra of polyethylene irradiated in the air by deu-

Fig. 3. Optical densities at 1720 cm^{-1} (C=O) and at 964 cm^{-1} (C=C).

terons. Curve A is that for an unirradiated sample and curves B, C and D are those for the samples irradiated by deuterons. The number of exposures given to those specimens were 2, 6 and 12, and the absorbed dose given by the specimens were estimated as about 1.4×10^8 , 4.2×10^8 and 8.4×10^8 rads, respectively. In these curves the characteristic band at 964 cm^{-1} arises from the absorption by the unsaturation of the type of $\text{PHC}=\text{CHR}$ trans, the band at 1720 cm^{-1} by the carbonyl groups and the band 3450 cm^{-1} by the hydroxyl groups. The absorption at these characteristic bands increases with the absorbed dose showing that the unsaturations, carbonyl groups and hydroxyl groups had been produced in the irradiated samples. This is in accord with the results obtained in the experiments of pile irradiation carried out by Dole, Keeling and Rose⁶⁾, and also, of gamma ray irradiation by Ballentine et al⁶⁾.

The optical density at 1720 cm^{-1} increased

with the number of exposures but the increase is not linear as shown in Fig. 3*. The optical density at 964 cm^{-1} also increased with the number of exposures. Moreover, the ratio of optical density of carbonyl groups, E_{CO} , to that of unsaturation, E_{CO} , at a given absorbed dose was found to be approximately constant and its mean value was 0.65, as seen in Table I. If it is assumed that the molar extinction coefficients of carbonyl group and unsaturation are 188 and 85.4 mol/l/cm^2 , respectively, the ratio of the yield of carbonyl groups to that of unsaturations turns to be 1:3. From this result, the yield of unsaturations is three times larger than that of carbonyl groups in the polyethylene irradiated by deuterons.

Results of gamma ray irradiation is given in Fig. 4. The dose rate used was 7.5 r/hr . The change in optical density at unsaturation

* In the calculation of optical density, a base line was selected as to connect the both tails of the absorption peak by a straight line.

81.1	1.029	0.067	15.2

produced by gamma ray irradiation is smaller than that of deuteron irradiation. The change at carbonyl groups, on the other hand, produced by the former is larger than the by the latter. Hence, the ratio of $E_{c=O}/E_{C=C}$ in the gamma ray irradiation is much larger as seen in Table I.

This result may be compared with the result obtained by Ballentine, Dienes, Manowitz, Ander and Mesrobian⁶⁾, that the value of $E_{c=O}/E_{C=C}$ was 0.65 when irradiated by electrons of 2 MeV and was 4.5 by gamma rays from cobalt-60 with dose rate of 2.5×10^{-6} r/hr.

§ 4. Discussion

It is seen above that there is some difference in $E_{c=O}/E_{C=C}$ between deuteron and gamma ray irradiation, gamma ray giving a larger value of $E_{c=O}/E_{C=C}$ and also of $E_{c=O}$. Since the oxidation of polyethylene was not observed in the irradiation in vacuum⁹⁾, the presence of oxygen in polyethylene resulting from the diffusion from the surrounding atmosphere must be related to the oxidation process, i.e. the formation of carbonyl groups¹⁰⁾. The concentration of oxygen in polyethylene in air at one atmosphere is calculated to be about 2.2×10^{-4} mol/cc, when the permeability constant of oxygen in the sample is taken as 40×10^{-10} cc/cm²/sec/cm in Hg at 20°C¹¹⁾. On the other hand, the consumption of oxygen during the irradiation of deuterons can be estimated as 2×10^{-6} mol/cc per 2.3×10^7 rads from the number of carbonyl groups formed. The amount of consumption of oxygen is, therefore, only a small fraction of oxygen in polyethylene, in both deuteron and gamma ray irradiation. This shows that the process of diffusion is not important in giving the

Fig. 4. Infrared absorption spectra of polyethylene irradiated by deuterons and gamma rays.

- unirradiated sample
- irradiated by deuterons
- irradiated by gamma rays

difference in the effect between the deuteron and gamma ray irradiation.

The difference of E_{co}/E_{γ} between deuterons and gamma ray irradiation may be explained in the following way by considering the character of radiations. The chemical changes produced in polyethylene by ionizing radiations may be interpreted in general, by postulating primary processes and secondary processes⁽¹²⁾⁻⁽¹⁴⁾. One of the primary processes is the rupture of side-bonds giving rise to the formation of polymer radicals and liberation of free hydrogen atoms. The secondary processes will include the recombination of these radicals and free hydrogen atoms and other entities. Also, the dihydrogenation process will cause the formation of unsaturations as follows,

In the samples irradiated by deuterons, the specific ionization along the track is very high compared with that due to the secondary electrons from gamma rays from cobalt-60. The density of polymer radicals and free hydrogen atoms will also be very high, and their mutual recombination will occur so frequently, that the formation of unsaturation will be very prominent. In the case of irradiation by gamma rays, the specific ionization is low, and radicals and hydrogen atoms will be distributed some distance apart from each other. Therefore, their chance of mutual recombination will be much less than in the case of deuteron irradiation. The chance of reaction of polymer radicals with oxygen atoms, on the other hand, will be about the same resulting in the relative increase of the formation of carbonyl groups.

The experiment of Ballantine et al, also give a similar tendency for E_{co}/E_{γ} , i.e. a lower value for electron beams which, most probably, will have a much larger density of ionization than gamma rays, though the numerical values do not coincide with ours. In this case, if the radicals formed in the samples have life time not very short compared with the time required for the irradiation, the average density of radicals will be rather high, giving rise to smaller value for E_{co}/E_{γ} .

Effects of ionizing radiations on polyvinyl alcohol

I. Breakdown of main-chain and formation of carbonyl groups

Akibumi DANNO*

Faculty of Engineering, University of Tokyo, Tokyo.

(Received February 1, 1958)

Polyvinyl alcohol in the form of film and powder were irradiated in the air by gamma rays from cobalt-60 source, and by deuterons accelerated by a cyclotron. Weight changes, viscosity, solubility and infrared absorption spectra of irradiated samples were measured as a function of absorbed dose. The reduction of the molecular weight of the irradiated specimens was observed suggesting that the effect was one of degradation. Infrared absorption spectra showed the formation of the carbonyl groups in the irradiated specimen.

§ 1. Introduction

It has been shown that the chemical changes produced by ionizing radiations on long-chain polymers bring about either cross-linking or degradation depending on the chemical structure of the material and on the mode of irradiation^{1,2,3}. For example, cross-linking has been observed for polyethylene⁴, natural rubber⁵ and polystyrene⁶, while degradation for polymethyl methacrylate⁷ and polytetrafluoroethylene⁸.

The physical properties of the irradiated polyvinyl alcohol have not been reported in detail. The only article referring to it is the general review of Charlesby¹. In this article, polyvinyl alcohol was classified in the group of polymer which crosslinks.

In the present experiment polyvinyl alcohol was irradiated in the air by deuterons accelerated by the cyclotron at the Scientific Research Institute, and also by gamma rays from cobalt-60. After irradiation the sample turned brittle and became easily soluble in water. The molecular weight of the irradiated specimen decreased with the absorbed dose.

§ 2. Experimental

Deuteron irradiation was carried out on the films of polyvinyl alcohol. The film to be irradiated was mounted on the surface of an aluminum rotating-drum as reported in the previous paper⁹. The drum was rotated while moving up and down in order to radiate

the sample uniformly. The rate of revolution of the drum was variable in the range from 20 to 100 rpm, so that the absorbed dose can be adjusted from 4.2×10^7 to 22.5×10^7 rads per one exposure during one course of up and down.

Gamma rays from cobalt-60 of about 120 curies were used to irradiate, both, films and powder of polyvinyl alcohol. The dose rate in the center of the source cylinder was 7.5×10^4 r/hr as measured by ferrous sulphate dosimetry.

Films used for the experiment were of the thickness of 0.02 mm and 0.04 mm. The thinner one was used for the measurement of infrared absorption spectra, and the thicker one for the measurement of the weight change and solubility. Viscosities and solubilities were also measured for powdered samples irradiated by gamma rays. The degree of polymerization of the samples were as follows,

polyvinyl alcohol	degree of polymerization
film-A	780
film-B	1670
film-C	2680
powder-A	760
powder-B	1660
powder-C	2680

§ 3. Experimental results

(i) *Changes in weight in polyvinyl alcohol films*

Changes of weight in the films of polyvinyl alcohol irradiated in the air, by deuterons were measured as a function of the number

* Present address; Japan Atomic Energy Research Institute, Tokyo.

of exposures. The behaviour of this change was different from that of polyethylene. In the latter case the sample increases its weight at first, to reach a maximum value, and then decreases gradually. The weight of irradiated polyvinyl alcohol decreased exponentially with the number of exposures as shown in Fig. 1.

Microchemical analysis was carried out for the irradiated films. The percentages of carbon and hydrogen in weight were calculated by the carbon dioxide and water formed on combustion. According to the results of analysis, the weight fraction of carbon in the

gen atoms to that of carbon atoms, O/C, remained almost constant. From these results, it was assumed that the gases evolved by the irradiation in the air was mostly hydrogen.

Direct analysis of the gas evolved by the irradiation was also carried out as follows. Powdered sample of polyvinyl alcohol was sealed in an evacuated glass tube and irradiated to about 10^7 rads by gamma rays from cobalt-60. The gases evolved by the irradiation were analyzed by a mass-spectrometer. Table I shows the result of the analysis. Small amount of carbon-monoxide and -dioxide were also liberated.

Table 1. Results of mass-spectrographic analysis of gases liberated by the irradiation of polyvinyl alcohol in vacuum.

molecules	H ₂	CO	O ₂	CO ₂
volume %	91.0	6.2	0.8	1.5

(ii) Viscosity measurement

Powdered sample of polyvinyl alcohol irradiated by gamma rays in the air, was found to be more easily soluble in water compared with unirradiated specimen. The molecular weight of these samples were obtained by viscosity measurement using the the formula (1)¹⁰,

[η]=8.87×10⁻⁴P^{0.62} (1)

where [η] is the intrinsic viscosity and P the

Fig. 1. Weight changes of polyvinyl alcohol films irradiated by deuterons.

Fig. 2. The results of the Micro-chemical analysis of polyvinyl alcohol films irradiated by deuterons.

unirradiated specimen was slightly smaller than that of the theoretical value calculated from the chemical formula. This may be due to the water adsorbed in the sample, since the polyvinyl alcohol is very hygroscopic. This adsorbed water turned out to be 3.7% in weight. As shown in Fig. 2, the ratio of the number of hydrogen atoms to that of carbon atoms, H/C, decreased with the absorbed dose, but the ratio of the number of oxy-

Fig. 3. The relation between the degree of polymerization, P , and the absorbed dose, R .

degree of polymerization. Viscosity average molecular weight, M_v is calculated as wP , where w is the mass of monomer unit ($\text{C}_2\text{H}_4\text{O}$). For the Poisson distribution of molecular weight, number average molecular weight, M_n can be derived from the viscosity average molecular weight⁷,

$$M_n = M_v / ((\beta + 1) \Gamma(\beta + 1))^{1/\beta}, \quad \beta = 0.62 \quad (2)$$

where β is the power of Staudinger's law unused in equation (1), and is equal to 0.62.

Linear relation is obtained between $1/P$ and the absorbed dose, R , as shown in Fig. 3. In this figure, results of the measurements for different initial degree of polymerization were listed. This linear relationship between $1/P$ and R can be expressed by

$$1/P_r - 1/P_0 = \alpha R \quad (3)$$

where P_0 and P_r are the degree of polymerization of initial and the irradiated specimen, respectively. As all three curves in Fig. 3 are nearly parallel, we may be taken a single value for α , i.e.

$$\alpha = 4.5 \times 10^{-11} / \text{rad} \quad (4)$$

(iii) Change of the infrared absorption spectra

Infrared absorption spectra of irradiated

Fig. 4. Infrared absorption spectra of polyvinyl alcohol irradiated by deuterons and cobalt-60 gamma rays.

films of polyvinyl alcohol were measured by the Perkin-Elmer Model 21 infrared spectrophotometer. Results are shown in Fig. 4. Curve-A in this figure is the absorption spectra of the unirradiated sample, curve-B that of the sample irradiated by cobalt-60 gamma rays, the absorbed dose being 6.0×10^7 rads and curve-C that of the sample irradiated by deuteron, the absorbed dose being about 14×10^7 rads. In both irradiated specimens the prominent absorption is observed at $1710\text{--}1720\text{ cm}^{-1}$, which was scarcely detectable in the initial specimen.

It is known that¹¹) a carbonyl group situated in saturated open chain ketones always exhibit a strong band near $1725\text{--}1705\text{ cm}^{-1}$, while nor-

Fig. 5. Change of optical density at $1720\text{--}1710\text{ cm}^{-1}$ divided with the thickness of the sample.

mal unconjugated alkyl aldehyde shows their carbonyl band at slightly higher frequency than the corresponding ketones in the range of $1740\text{--}1720\text{ cm}^{-1}$. On the other hand, non-basic aliphatic acids shows the absorption band in the range between $1725\text{--}1715\text{ cm}^{-1}$, when examined in the solid or liquid state. Therefore, the absorption spectra observed at $1720\text{--}1710\text{ cm}^{-1}$ shows the formation of ketonic and acidic type carbonyl.

The number of carbonyl groups in the sample produced by the radiation may be estimated from the optical density. As shown in Fig. 5, the relation between the optical density of carbonyl groups and the absorbed dose is approximately linear in the specimens irradiated by cobalt-60 gamma rays.* The

* In the calculation of optical density, a base line was selected as to connect the both tails of the absorption peak by a straight line,

carbonyl concentration in the sample was obtained from the value of optical density by dividing it by the molar extinction coefficient. The value of the latter was given as 188 mol/l/cm by Cross, Richard and Willis^{12,13}. Fig. 5 gives the increase of the optical density with absorbed dose can be used to get the rate of formation of carbonyl group in a given monomer unit. The result obtained is

$2.6 \times 10^{-10}/\text{rad}$.

§ 4. Discussions

It is seen above when polyvinyl alcohol is irradiated by ionizing radiations in the air, breakdown of main-chain and formation of carbonyl groups take place. One possible mechanism for such a breakdown of main-chain and formation of acidic carbonyl groups by the irradiation in the air is

The formation of ketonic carbonyl groups and the liberation of hydrogen molecules may be explained as

If the distribution of molecular weight of the unirradiated specimen could be expressed by an exponential law, and if the breakdown of the main-chain bond occurs at random along the chain and is proportional to absorbed dose, R , then the probability of a given bond between monomers being broken by the radiation, μ , is obtained by the slope of the molecular weight *vs* dose curve (Fig. 3). The relation between the viscosity average molecular weight of irradiated specimen, M_r , and the number average molecular weight M_n , obtained by the theoretical calculation⁷, may be written for polyvinyl alcohol as $M_r = 1.8 M_n$. Thus

$$1/M_r - 1/M_0 = \mu R / 1.8 w \quad (8)$$

where M_0 is the viscosity average molecular weight of unirradiated specimen and w the mass of monomer unit.

This relation can also be written as

$$1/P_r - 1/P_0 = \mu R / 1.8 \quad (9)$$

where p_r and P_0 are the average degree of polymerization of irradiated and unirradiated specimen, respectively, which can be determined by the viscosity measurement.

It was already stated above that the result of experiment can be expressed as

$$1/P_r - 1/P_0 = 4.5 \times 10^{-11} R \quad (4')$$

Comparing (4') with the theoretical formula (9), the value of μ may be determined as $\mu = 8.1 \times 10^{-11}/\text{rad}$. Therefore, the absorption of the dose of 10^8 rads will result in the breakdown of 0.8% of the bonds in the main-chain skeleton. There are 1.36×10^{22} monomer units in one gram of polyvinyl alcohol, so that 11.0×10^{11} main-chain bonds between these monomers will be fractured by one rad. By definition, one rad of absorbed dose liberates 6.2×10^{13} eV per gram of the substance irradiated. Therefore, the energy expenditure per main-chain fracture is 56 eV.

As was seen above, the probability of formation of carbonyl groups in a given monomer unit was estimated as $2.6 \times 10^{-10}/\text{rad}$ from the infrared analysis. Thus 10^8 rads results in the formation of carbonyl groups of 2.6% of total monomer units. Comparing this value with the probability of breakdown of main-chain, it is seen that the probability of formation of carbonyl groups is three times larger, and the energy expenditure per carbonyl formation is 18 eV.

§ 5. Acknowledgement

The author wishes to express his sincere thanks to Dr. K. Shinohara of the Scientific Research Institute, Dr. A. Amemiya of Faculty of Engineering, University of Tokyo and Dr. A. Harashima of Tokyo Institute of Technology for their constant encouragement and also to Dr. M. Tomonari of the Kurashi-

ki Rayon Company for kindly preparing the samples of polyvinyl alcohol. He also wishes to thank the Tokyo Polymer Irradiation Group for their helps in the experiment.

Effects of Ionizing Radiation on Polyvinyl Alcohol

II. Changes of Physical Properties of the Irradiated Specimen Caused by Heat Treatment

By Akibumi DANNO*

Faculty of Engineering, University of Tokyo, Tokyo,

(Received February 1, 1958)

The physical Properties of polyvinyl alcohol irradiated by deuterons or gamma rays were found to change remarkably by heat treatment. Irradiation causes the decrease of the molecular weight and the increase of the carbonyl groups. When these specimens are heated above 120°C, however, the solubility diminishes considerably and even gel formation occurs for highly irradiated ones. Infrared absorption spectra revealed that the number of carbonyl groups formed by the irradiation decreased greatly as a result of heat treatment. Some discussion are given on the process of gel formation.

§ 1. Introduction

It is usually believed that physical properties of polymers irradiated by ionizing radiations remain unchanged after irradiation¹⁾.

In polyvinyl alcohol, it was found, in the previous paper²⁾, that considerable number of carbonyl groups are formed by the irradiation. Since carbonyl groups are rather active, the sample were subjected to heat treatment and the resulting changes of properties, which, it is thought, might arise from the action of carbonyl groups, were investigated. Two effects of heat treatment have been observed; gel formation and the disappearance of carbonyl groups.

§ 2. Experiment

Films of polyvinyl alcohol were irradiated by deuterons accelerated by a cyclotron³⁾. Polyvinyl alcohol in the form of films and powder were also irradiated by gamma rays from cobalt-60 as reported in the previous paper²⁾.

Films of thickness of 0.02 mm and 0.04 mm were used. The thinner one was used for the measurement of solubility. Solubility and gel fraction were also measured for the powdered sample irradiated by gamma rays.

Heat treatment was carried out by keeping irradiated samples at a certain temperature above 120°C for more than ten minutes in a thermostat. The samples were kept in air during the heat treatment.

* Present address; Japan Atomic Energy Research Institute, Tokyo.

§ 3. Experimental Result

(i) *Changes of weight in heat treatment*

Weight changes of polyvinyl alcohol due to irradiation by deuterons or gamma rays and also by subsequent heat treatment were measured. As reported in the previous paper²⁾, weight of irradiated specimens decreased with increasing radiation dose. A further change of weight in these specimens were observed after heating for one hour at 150°C. The relation between the decrease of weight and the absorbed dose is given in Fig. 1.

Fig. 1. Weight change of irradiated polyvinyl alcohol after heated at 150°C for one hour.

A set of micro-chemical analysis of heat treated specimens was carried out. The results are shown in Fig. 2. The ratio of num-

ber of hydrogen atoms to that of carbon atoms, H/C , decreases from 1.97 in the unirradiated specimen to 1.86 for highly irradiated specimen. On the other hand, the ratio of number of oxygen atoms to that of carbon atoms, O/C , decreases from 0.50 in the unirradiated specimen to 0.48 for highly irradiated specimen.

Fig. 2. Micro-chemical analysis of heat treated polyvinyl alcohol (0.02 mm in thickness).

Since the slope of the curve of H/C is greater than that of $2 \times O/C$, the liberation of hydrogen in the process of irradiation and heat treatment is more predominate than that expected from the liberation of H_2O . Since the liberation of H_2O is known to occur for unirradiated polyvinyl alcohol by heat treatment, the change of weight of the irradiated specimen by the heat treatment may be attributed to the liberation of H_2 and H_2O .

(ii) *Gel formation of irradiated specimen caused by heat treatment*

When the powder of polyvinyl alcohol irradiated by gamma rays was heated to a temperature above 120°C for over ten minutes after irradiation, considerable fraction of the powder became insoluble in boiling water. Films of polyvinyl alcohol which were irradiated by deuterons and were heated above 120°C , also, became insoluble in hot water above 150°C in an autoclave, and swelled to an extent depending on the amount of absorbed dose.

Gel fractions of the powdered polyvinyl alcohol after heat treatment were measured. The results are given in Fig. 3. In this figure, the ordinate in the gel fraction and abscissas

gives r/i , where $i=1/P_i$ and $i+r=1/P_r$. P_i and P_r are the average degree of polymerization of initial and irradiated specimens measured by viscosity. r/i gives, therefore, the ratio of the number of molecules fractured to that of molecules which existed before irradiation. When the value of r/i was smaller

● Experimental point
— Theoretical curve

Fig. 3. Gel fraction of irradiated polyvinyl alcohol powder after heat treatment.

than 0.6, the heat treated specimen was also completely soluble, and gel formation first occurred when r/i became about 0.6. This indicates that at $r/i=0.6$ the linkage between molecules which are caused by heat treatment became so abundant that they finally form an infinite network.

(iii) *The change of infrared absorption spectra due to heat treatment*

Infrared absorption spectra of films of polyvinyl alcohol irradiated by deuterons and subjected to heat treatment were measured. Results are shown in Fig. 4 and Fig. 5. Fig. 4 is that of unirradiated specimen which is heated at 150°C for one hour. Fig. 5 is that of a film subjected to the same treatment after irradiation of 6.5×10^7 rads.

In the unirradiated specimen, no significant change on the infrared absorption spectra was observed before and after heat treatment. In the irradiated specimen, however, the absorption at $1720\text{--}1710\text{ cm}^{-1}$ due to carbonyl groups is considerably diminished after the heat treatment. These specimen did not di-

solve as was stated above in boiling water.

It may be not unreasonable to conclude from these facts that carbonyl groups produced by

the radiation disappear during the heat treatment, and this disappearance has some connection to the formation of intermolecular linkages which are formed.

§ 4. Discussion

It is known that some intermolecular linkages are produced by heat treatment⁽⁴⁾, in ordinary polyvinyl alcohol which is not irradiated but contains carbonyl groups. The irradiation of polyvinyl alcohol in air causes the main-chain bond fracture and the decrease in molecular weight as shown by our experiment. Large number of carbonyl groups, however, are formed in this process and the heat treatment, carried out after the irradiation, produces so many intermolecular linkages that even an infinite net-work is formed when the absorbed dose is high.

Following tentative explanation may be given to the process of forming an intermolecular linkage, i.e. the reaction of the carbonyl group reacts with a neighbouring molecule to form a ketale linkage;

In order to make some calculation on the condition of gel formation by main-chain bond fracture of polyvinyl alcohol, it is assumed that the molecular weight distribution of the unirradiated specimen follows an exponential law, and the breakdown of the main-chain bond occurs at random along the chain. The number of molecules existing in the initial and irradiated specimen are given by the following formula,

$$n(P_i) = N_0/P_i = N_0 i$$

$$n(P_r) = N_0/P_r = N_0(i+r)$$

Where N_0 is the total number of monomer units in the specimen. The difference r ($=1/P_r - 1/P_i$) represents the probability of a fracture of the bond between two adjacent monomer units due to radiation. A calculation giving gel point was published by Charlesby⁽⁵⁾ for the case, when the active groups are produced at the ends of fractured mole-

Fig. 4. The change of infrared absorption spectra of unirradiated specimen by the heat treatment.

Fig. 5. The change of infrared absorption spectra of irradiated specimen by the heat treatment.

cules. In this calculation, it was assumed that only a certain proportion σ of the end-groups become active. In the case of polyvinyl alcohol, active groups seem to be formed in the intramolecular site and not at the ends as shown in the previous paper. However, a similar calculation can be carried out. In this case, if the number of these active groups are σ times the number of fractured molecules, the gel point is given as the point where the ratio r/i becomes

$$r/i = 1/(4\sigma - 1)$$

The sol fraction can be given by

$$S = \left\{ \frac{1-i/r}{2} - S \right\}^2$$

In this treatment, it is assumed that active groups are never produced at fractured end, but are always produced in the middle part of molecules only, and the end groups of the fractured molecules do not make linkages. Notwithstanding this difference, the same results was obtained for the gel point as that

given by Charlesby⁶⁾.

Experimentally, gel point obtained was at $r/i = 0.6$, so that the efficiency of formation of active groups, σ , is about $2/3$. Therefore, at least $4/3$ carbonyl groups are produced per one fractured molecule.

§ 5. Acknowledgement

Nuclear Quadrupole Resonances in Arsenic and Antimony Trihalides and Sulphur Molecular Addition Compounds

By Shizuko OGAWA

Department of Physics, Faculty of Science, Ochanomizu University, Tokyo

(Received February 8, 1958)

Nuclear quadrupole resonances of I, Br, Cl, As and Sb isotopes in solids AsCl_3 , SbCl_3 , SbBr_3 , AsI_3 , SbI_3 , $\text{AsI}_3 \cdot 3\text{S}_8$, $\text{SbI}_3 \cdot 3\text{S}_8$, SnI_4 , $\text{SnI}_4 \cdot 2\text{S}_8$ and $\text{SnI}_4 \cdot 4\text{S}_8$ have been measured systematically. The newly obtained coupling constants eQq and asymmetry parameters η of the I^{127} resonances at 77°K are as follows: $eQq=1383.03$, 1402.68 Mc; $\eta=0.002$, 0.039 in $\text{SnI}_4 \cdot 2\text{S}_8$, $eQq=1364.3$, 1368.3 , 1405.0 Mc and $\eta=0.00$, 0.00 , 0.03 in $\text{SnI}_4 \cdot 4\text{S}_8$. In $\text{SnI}_4 \cdot 4\text{S}_8$ an additional line was observed at 219.04 Mc corresponding to the first resonance. The second resonance of SbI_3 was at 254.637 Mc with $eQq=895.83$ Mc and $\eta=0.565$. Resonance frequencies of As^{75} in AsI_3 and $\text{AsI}_3 \cdot 3\text{S}_8$ at 77°K were 29.338 and 49.501 Mc, respectively. The first resonance of Sb^{121} in SbI_3 was 25.406 Mc at 77°K and the corresponding resonance in $\text{SbI}_3 \cdot 3\text{S}_8$ was 37.461 Mc at 297°K. SbBr_3 showed two crystal forms which gave Sb^{121} coupling constants of 319.920 and 316.02 Mc and asymmetry parameters of 0.082 and 0.182 at 304°K, respectively. On the Br resonances of SbBr_3 three resonance lines instead of two hitherto reported were observed in both crystal forms.

Coupling constants of trihalides were compared with their chemical bond properties. The constants of AsI_3 and SbI_3 are different from those of other compounds, while their sulphur molecular addition compounds are in rather good agreement.

AsI_3 showed positive temperature dependency for arsenic isotope as for the case of iodine isotope.

§ 1. Introduction

The nuclear quadrupole resonances of I^{127} in AsI_3 were first observed by Kojima, Tsukada, Ogawa, Shimauchi and Abe¹⁾. On the I^{127} resonance in SbI_3 only the lower frequency line was reported by Schawlow²⁾ and Barnes and Bray³⁾, while on the resonances in the sulphur molecular addition compounds, $\text{AsI}_3 \cdot 3\text{S}_8$ and $\text{SbI}_3 \cdot 3\text{S}_8$, the lower and higher frequency lines were measured at 77°K by Robinson, Dehmelt and Gordy⁴⁾. They also mentioned the resonance of I^{127} in $\text{SnI}_4 \cdot 4\text{S}_8$. The resonance frequency, however, was not reported.

Two resonance lines of each Br isotope in SbBr_3 which come from the nonequivalent positions of atoms were reported by Robinson, Dehmelt and Gordy⁴⁾ at 77°K, while earlier Schawlow²⁾ observed only one resonance line in Br^{81} at room temperature. On AsBr_3 three resonance lines of each Br isotope were observed by Kojima *et al.*¹⁾. Three lines were also observed on Cl^{35} resonance in AsCl_3 by Livingston⁵⁾. The Cl isotope in SbCl_3 exhibited

two resonance lines^{6),7)}, one of which had double the intensity of the other. Since the crystal structure of SbBr_3 seems to be similar to AsBr_3 , AsCl_3 and SbCl_3 , three resonance lines of Br isotope corresponding three nonequivalent positions of atoms in a molecule should be expected.

The resonance of As^{75} in AsBr_3 was measured by Kojima *et al.*¹⁾ and the resonances in AsCl_3 , AsBr_3 , AsI_3 were measured by Barnes and Bray⁸⁾. Among these resonance frequencies the frequency of AsI_3 is unreasonably high as expected from the nature of the chemical bond.

The resonances of Sb isotopes in SbCl_3 were studied by Dehmelt⁹⁾, Wang⁷⁾ and Ogawa⁹⁾, and Wang also measured the resonance in SbBr_3 at room temperature. The Sb resonance in SbI_3 , however, had not been reported.

The present measurements have been made on the isotopes, of As, Sb, Cl, Br, and I in trihalides and sulphur molecular addition triiodides in the temperature range between 77°K and room temperature. A systematic

relation between the nuclear quadrupole coupling and the nature of chemical bond was obtained. SnI_4 and its sulphur molecular addition compounds were also investigated.

§ 2. Experimental Procedure

The frequencies to be observed cover a very wide frequency range from about 20 Mc to 450 Mc. Four superregenerative oscillators were used for the detection. A tuned type transmission line which was described by Kojima *et al.*¹⁰⁾ was used above 100 Mc frequency range. In the frequency region below 100 Mc, LC tuned push pull feed back oscillators were used, which were described in detail in the previous paper⁹⁾. The frequency range from 20 Mc to 70 Mc was covered with one oscillator by using coils of various dimensions. Reactions in the oscillator coils produced by resonating nuclei were amplified by three stage audio amplifier and displayed on an oscilloscope.

While the nuclei whose spin number is 3/2 have only one resonance line, the nuclei having spin of 5/2 have two resonances, i.e., the first resonance ν_1 ($3/2 \leftrightarrow 1/2$) and the second resonance ν_2 ($5/3 \leftrightarrow 3/2$). When the both resonances are measured, the asymmetry parameter of the field gradient tensor, η , can be determined. For the determination the two resonances must be measured at the same temperature of the sample. Otherwise the error in η calculated from ν_1 and ν_2 will be large because of the difference in temperature at the sample. This precaution is essential when the asymmetry parameter has small value. In those cases a similar measuring procedure as previously described⁹⁾ was used. For a sample which has a large asymmetry parameter the above mentioned difference of temperature did not lead to a significant error in the calculation of the asymmetry parameter.

The frequency between 10 Mc and 200 Mc was measured by the aid of an oscillator of the frequency range from 10 Mc to 15 Mc which was calibrated by standard frequency of JJY. For measurements above 200 Mc, a single generator of the frequency range from 30 to 300 Mc was used as a marker, and this marker frequency was measured with the frequency meter.

§ 3. Resonances of Cl and Br Isotopes

The nuclei Br^{79} , Br^{81} and Cl^{35} have a spin of 3/2. Nuclear quadrupole resonances of these nuclei exhibit only one resonance line, whose frequency is expressed as follows:

$$\nu = \frac{1}{2} eQq_{zz} \left(1 + \frac{1}{3} \eta^2 \right)^{1/2}, \quad (1)$$

where Q is nuclear quadrupole moment of nucleus. The asymmetry parameter, η , is defined by $|q_{xx} - q_{yy}/q_{zz}|$ where q_{zz} is field gradient tensor component along the principal axis. Although asymmetry parameter is not obtained, nuclear quadrupole coupling constant eQq can be obtained by doubling the observed frequency unless the asymmetry parameter is large.

The resonance frequencies of Cl^{35} in AsCl_3 and SbCl_3 were measured. The results are listed in Table I. AsCl_3 is liquid at room temperature and freezes about -16°C . Below this temperature three resonance lines were always observed. The obtained values are consistent with Livingston's results at 77°K . Since the As resonance in AsCl_3 showed only one resonance line as described below, the three Cl resonance lines must belong to the same molecule. Cl^{35} in SbCl_3 shows two resonance lines, one of which has a large intensity of about twice of the other. This arises from the fact that there are two nonequivalent sites of the chlorine atoms of the molecule in crystal lattice.

		77	133.499±0.005	141.923±0.003	142.622±0.002

The measured resonance frequencies of Br⁷⁹ and Br⁸¹ in SbBr₃ as listed in Table II. SbBr₃ (Crystal form I) was obtained by slow heating of mixture of bromine dissolved in carbon disulphide and antimony powder. After distillation of the solution the crystal of SbBr₃ was deposited. Results in Table II show three lines. The measured resonance frequencies agree partially with the results of Schawlow indicating 135.56 Mc in Br⁸¹ at 24°C and with those of Robinson *et al.* indicating 137.428 Mc and 144.490 Mc at 77°K, the latter is higher about 1 Mc than the highest line in the present experiment. The existence of three resonance lines, however, differs from their results. The samples which were obtained in commercial (Crystal from II) exhibited different three resonance lines. The observation of the resonance frequencies in the temperature from 77°K to room temperature indicated that these two forms of crystals did not interchange from one another by varying the temperature. Some informations about these crystal forms might be obtained with a Zeeman analysis.

Temperature variations of the resonance frequencies for these crystals are shown in Fig. 1 together with the values of other observers. The ratio of the coupling constants of Br⁷⁹ to that of Br⁸¹ is equal to the ratio Q^{79}/Q^{81} and has an average value of 1.19713 ± 0.00008 at the temperature used.

§ 4. Resonances of I¹²⁷ Isotope

The isotope I¹²⁷ has a spin of 5/2 and the resonance frequencies of it expressed by the following equations;

$$\left. \begin{aligned} \nu_1 &= \frac{3}{20} eQq_{zz} \left(1 + \frac{59}{54} \eta^2 - \frac{11093}{17496} \eta^4 \right), \\ \nu_2 &= \frac{3}{10} eQq_{zz} \left(1 - \frac{11}{54} \eta^2 + \frac{2837}{17496} \eta^4 \right). \end{aligned} \right\} \quad (3)$$

If these two frequencies can be observed, the asymmetry parameter, η , is determined. The equations are approximate solutions of the

Fig. 1. Temperature dependency of the resonance frequencies of Br⁸¹ in SbBr₃. Solid line shows crystal form I and dotted line shows crystal form II. It also shows the measured values by Robinson, Dehmelt and Gordy. (×), and by Schawlow (Δ).

secular equations¹¹. The higher terms of η^2 are required when η is larger than about fifteen percents.

S_8 compounds were made by distillation or crystallization from a carbon disulphite solution containing iodide and sulphur. $AsI_3 \cdot 3S_8$ is a very stable compound and forms a large orange crystal. Resonance is also observed in the compound made by mixing melted iodide and sulphur.

The resonance of I^{127} in AsI_3 , the first resonance of SbI_3 and the resonances in the corresponding sulphur molecular addition compounds, $AsI_3 \cdot 3S_8$ and $SbI_3 \cdot 3S_8$, at 77°K were reported by several investigators. In the present experiment these resonance frequencies were also measured from 77°K to room temperature to compare the tri-iodides with the corresponding sulphur molecular addition compounds. The resonance frequencies of I^{127} in iodides are listed in Table III.

The second resonance of I^{127} in SbI_3 was first looked for by Schawlow unsuccessfully. He interpreted this result by supposing that the frequencies ν_1 and ν_2 coincided so that only one resonance would be observed. The present survey at 77°K from about 350 Mc to the lower frequencies, however, revealed the existence of the resonance at the unexpectedly low frequency of about 260 Mc. It yielded an asymmetry parameter of 0.565. The iodine resonance of SbI_3 could not be observed at room temperature. At about -30°C a broad weak line appeared, and then the intensity increased and the line width seemed to become narrower as the temperature was decreased. At 77°K the signal to noise ratio of ν_1 was as large as twenty. The signal to noise ratio of ν_2 at 77°K was about four, so that it was difficult to observe this resonance at the higher temperature. The deep red crystal at room temperature changed to a yellow

low one at low temperature. This seems to indicate some gradual phase change or rotation of the molecule.

SnI_4 is one of the substances which produces sulphur molecular addition compounds. As a comparison, the resonance of the pure single crystal of SnI_4 was measured, although it had already been measured by Dehmelt¹³⁾ and others^{4),14)}. The results are also included in Table III. On account of the large asymmetry parameter of SbI_3 the equations containing the terms up to η^8 were used for the determination of eQq .

§ 5. Resonances in As and Sb Isotopes

The measured resonance frequencies of As^{76} in arsenic compounds are shown in Table IV.

Table IV. As^{76} resonances in arsenic compounds.

Compound	Temp. (°K)	Resonance Frequency ν (Mc/sec)

	213	31.079 ± 0.003
	77	29.338 ± 0.005
	303	47.545 ± 0.003
$\text{AsI}_3 \cdot 3\text{S}_8$	217	48.398 ± 0.005
	72	49.501 ± 0.005

* high temperature phase.

The resonance in AsCl_3 was observed at all range of temperature up to the melting point, -16°C . Although it was observed at 77°K by Barnes and Bray⁸⁾, the resonance at higher temperature has not been observed. The resonance frequency at 77°K obtained in the present experiment is lower about 80 kc than the value reported by them. The signal to noise ratio was rather good so that the measured value at 77°K will be more reliable than their value. Resonance of As^{76} in AsI_3 was observed about 32 Mc at room temperature but in powdered sample the signal to noise ratio was very poor. In the single crystal, of about 3 cm^3 , the signal to noise ratio was only about four and the line width was about 20 kc. Resonance of As^{76} in AsI_3 was also reported by Barnes and Bray⁸⁾, however, their value of 116 Mc seems very high. The reso-

nance frequency may be roughly estimated by using the equation of $(1/2) \cdot 3 \cos \theta (1+2\beta)eQq_{\text{atom}}$, where 2β is 0.5 being electronegativity difference between As and I and θ is the angle of I-As-I which is known to be about 87° from the asymmetry parameter of the iodine resonance¹⁾ or crystal structure¹⁰⁾. The estimated resonance frequency is about 48 Mc. The present result is reasonable from this estimation. The As^{76} resonance of $\text{AsI}_3 \cdot 3\text{S}_8$ was 47.5 Mc at room temperature having more good signal to noise ratio.

As^{76} whose spin number is $3/2$ has one resonance, therefore η is not determined. But since AsCl_3 exhibits three Cl resonance lines corresponding to three nonequivalent Cl atoms in a same molecule and the latter two samples show only one I resonance line, it is supposed that the asymmetry parameter of AsCl_3 is finite and those of AsI_3 and $\text{AsI}_3 \cdot 3\text{S}_8$ are zero.

The measured resonance frequencies of Sb in antimony compounds are shown in Table V. Abundances of two isotopes Sb^{121} and Sb^{123} are about 57 and 43 percent respectively. For the resonance frequencies of Sb^{121} having a spin of $5/2$, the equations (2) are applicable and for Sb^{123} having a spin of $7/2$ the resonance frequencies are expressed by following equations:

$$\left. \begin{aligned} \nu_1 &= \frac{1}{14} eQq_{ss} \left(1 + \frac{109}{30} \eta^2 - \frac{196093}{27000} \eta^4 \right), \\ \nu_2 &= \frac{2}{14} eQq_{ss} \left(1 - \frac{17}{30} \eta^2 + \frac{50207}{27000} \eta^4 \right), \\ \nu_3 &= \frac{3}{14} eQq_{ss} \left(1 - \frac{1}{10} \eta^2 - \frac{487}{27000} \eta^4 \right). \end{aligned} \right\} \quad (3)$$

The Sb resonance in SbBr_3 occurs at two different frequencies corresponding to bromine resonances in two crystal forms. The reported frequencies of Sb in SbBr_3 by Wang⁷⁾ corresponds to crystal form I. In crystal form II the Sb atom has a large asymmetry parameter of about 18 percent. These samples gave so large electric loss on the oscillator coil that the resonance frequency of Sb^{123} could not be measured accurately. In the case of SbI_3 the line was very broad and the side bands of the line which shifted by the quenching frequency are overlapped each other. Only the first resonance of Sb^{121} was observed. The Sb atom has a axially symmetric field gradient with respect to the three I atoms similar to AsI_3 , so the second resonance could

		250	37.77 ±0.06	—		251.8	0*

* The value are assumed from the crystal structures.

be expected to be twice the first resonance. However, the resonance could not be found in the frequency range between 45 Mc to 52 Mc. It is probably due to a small signal to noise ratio.

SbI₃·3S₈ which was studied at room temperature, exhibited some spurious lines with intensities comparable to the true resonance line. Therefore, it was necessary to verify this resonance line by smearing it out with a magnetic field. The spurious resonances were more abundant in the frequencies below 30 Mc. They probably originate from electric vibrations in the crystal domains¹⁶⁾. A few spurious lines were also observed in AsI₃·3S₈.

§ 6. Discussion on Sulphur Molecular Addition Compounds

Several iodides have been known to have sulphus molecular addition compounds which are composed of its original compounds and definite multiples of the sulphur molecule¹⁷⁾. Robinson, Dehmelt and Gordy⁴⁾ considered the quadrupole coupling constants of AsI₃ and SbI₃ to be approximately equal to those of 3S₈ compounds by the reason that the observed resonance frequency of SnI₄·4S₈ was near that of SnI₄.

As shown in Fig. 3, AsI₃ has a structure of macromolecular sheets and not molecular structure. On the other hands AsI₃·3S₈, investigated by Hertel, has a single molecular structure, where the molecule AsI₃ is surrounded with six sulphur ring molecules as shown in Fig. 4¹⁷⁾. The effect of the sulphur molecules is to decrease the intermolecular bonds between the molecules of AsI₃. In

fact, the observed coupling constant of the I¹²⁷ resonance increased by about twenty megacycles indicating stronger covalent structure. For SbI₃ the same interpretation is true. Small intermolecular bonding results in a large amount of covalent structure. The observed

Fig. 2. Crystal structure of AsI₃. $a=7.187$ Å. It shows a sheet in a unit cell which is normal to c axis of crystal.

Fig. 3. Crystal structure of AsI₃·3S₈. $a=14.2$ Å. Bond angle I-As-I is 101.7°¹⁸⁾

asymmetry parameters are large in AsI_3 and SbI_3 , but their S_8 compounds have very small values. Indeed an accurate relative measurements of the first and the second resonances of $\text{AsI}_3 \cdot 3\text{S}_8$ at room temperature yielded zero asymmetry parameter. The measurement at 77°K gave a small asymmetry parameter which came partially from unavoidable temperature difference between two samples in the separate detectors. The resonance in I^{127} in $\text{SbI}_3 \cdot 3\text{S}_8$ has less signal to noise ratio. However, it seems that asymmetry parameter is finite.

Sulphur molecular addition compounds of SnI_4 showed resonances which has less signal to noise ratio and broader width than those of pure SnI_4 . Robinson *et al.* indicated the structure of 4S_8 but Hertel showed 2S_8 . Indeed the amount of sulphur played a complex role in the present experiment. Fig. 4 shows

Fig. 4. Splitting of the I^{127} resonance lines in SnI_4 (a), $\text{SnI}_4 \cdot 2\text{S}_8$ (b) and $\text{SnI}_4 \cdot 4\text{S}_8$ (c).

the resonance frequencies of SnI_4 as the amount of sulphur is increased. 2S_8 and 4S_8 might give the different type of crystals. When the mixing of sulphur was insufficient the resonance lines of two types were often observed. When SnI_4 was mixed with more than 4S_8 the intensity of resonance line decreased abruptly. The samples of SnI_4 used to make those compounds were single crystals and powder which was not applied to special purification. Powder material easily gave $\text{SnI}_4 \cdot 2\text{S}_8$ and $\text{SnI}_4 \cdot 4\text{S}_8$. Pure single crystals, however, yielded $\text{SnI}_4 \cdot 2\text{S}_8$ but not $\text{SnI}_4 \cdot 4\text{S}_8$. Crystal structures of sulphur molecular addition compounds of SnI_4 have not been reported.

The resonance frequencies of $\text{SnI}_4 \cdot 2\text{S}_8$ and

$\text{SnI}_4 \cdot 4\text{S}_8$ were plotted against the temperature. The results are reproduced (in Fig. 5). Two lines of $\text{SnI}_4 \cdot 2\text{S}_8$ have the same intensities. This fact indicates that these lines are due to two pairs of iodine atoms in one molecule. The splitting of multiplet in $\text{SnI}_4 \cdot 4\text{S}_8$ was about 20 Mc. It shows that the intermolecular bonding is larger than SnI_4 and the asymmetry of molecule is disturbed.

Fig. 5. Temperature dependency of first resonance of I^{127} in SnI_4 (dotted line), $\text{SnI}_4 \cdot 2\text{S}_8$ (○) and $\text{SnI}_4 \cdot 4\text{S}_8$ (●). Points at 257°K in SnI_4 was measured by A. Schimauchi and S. Hagiwara.

The line widths in $\text{AsI}_3 \cdot 3\text{S}_8$ and $\text{SbI}_3 \cdot 3\text{S}_8$ were narrower than those of AsI_3 and SbI_3 . It seems that the intermolecular interaction between AsI_3 molecules is reduced by the presence of sulphur molecules. On the other hand, addition of sulphur molecule in SnI_4 reduced the intensity of resonance by a factor of a few tenths and broadened the widths of resonance line. The effect of S_8 molecule is opposite in both cases.

§ 7. The Quadrupole Coupling and the Electronegativity

The coupling constant is related with the

number of unbalanced *p* electrons U_p and with the coupling constant for a pure *p* electron which is twice that of free atom.

$$eQq_{\text{obs.}} = |U_p \cdot eQq_{\text{pure } p}|. \tag{4}$$

U_p is a quantity depending upon electronic structure of the molecule.

The molecules of interest here are type MX_3 , i.e., arsenic and antimony trihalides and sulphur molecular addition compounds of triiodides. When double bond character and *d* hybridization are not considered for simplicity, the atom M has *s-p* hybridized orbitals which form three covalent bonds and an unshared pair. On account of electronegativity difference between M and X atoms, M is positively charged in these cases. U_{pM} is expressed by Gordy as follows¹⁹⁾;

$$U_{pM} = -3\alpha_M \{1 - 3\beta + 4\beta(1+c)\}, \tag{5}$$

where α_M represents percent *s* character of the bonding orbitals, β is ionic character of

bond angle, of X-M-X, θ , in the following relation

$$\alpha = \cos \theta / (1 - \cos \theta), \tag{6}$$

This angle is approximately same in these molecules²⁰⁾²¹⁾. For the atom X, a single bond is formed to complete its octet. The principal axis of the field gradient tensor is along the bond direction. U_{pX} is as follows;

$$U_{pX} = (1 - \alpha_X)(1 - \beta). \tag{7}$$

where α_X represent percent *s* character of X atoms.

The atomic coupling constants for iodine, bromine and chlorine atoms are now known accurately by the results of the atomic beam experiments²²⁾⁻²⁴⁾. The values of 2292, 769 and 109.6 Mc were used for I^{127} , Br^{79} and Cl^{35} . For arsenic and antimony atoms the atomic couplings were calculated with the values of 426 and 734 Mc respectively which are estimated from the values of electric field gradient *q* obtained from optical hyperfine structure²³⁾ and the values of nuclear quadrupole moment $Q^{26)}$.

Table VI shows the values of U_p and the differences of the electronegativities of the bonded atoms²⁷⁾. Molecular coupling constants investigated here and by other references are shown together in this table. $1 - |U_p|$ is the deviation of the coupling from that of pure covalent *p* bond and gives a measure of the ionic character. Figs. 6 and 7 show the plots

each bond, and *c* is a correction for the change in screening caused by the charge. In this expression the *s* character is depends on the

Fig. 6. The values of $1 - |U_{pM}|$ versus electronegativity difference $|x_M - x_X|$ in M atoms. ● is As compound and ○ is Sb compound.

of $1 - |U_p|$ against the electronegativity difference. Except for AsI_3 and SbI_3 these plots are represented by the following equations.

$$|U_{pM}| = 0.08 + 0.37|x_M - x_X|, \quad (8a)$$

$$|U_{pX}| = 0.86 - 0.38|x_M - x_X|. \quad (8b)$$

The relation (8b) is considered as expressing qualitatively the dependency expected from Eq. (7), since the s character, α_X , is about 14 percent and the ionic character of each bond, β , is nearly a half of the electronegativity difference between bonded atoms. The relation (8a), however, results very small value of s character for M atom adopting the same value of ionic character β for X atom. The smallness of s character contradicts with the result calculated from the bond angle $X-M-X$. The assumption of s - p hybridized configura-

Fig. 7. The values of $1 - |U_{pX}|$ versus electronegativity difference $|x_M - x_X|$ in X atoms. ● is As compound and ○ is Sb compound.

tion alone is insufficient to interpret the experimental result, therefore d hybridization or double bond character should be considered together with s - p hybridization.

The coupling constants for both M and X atoms in AsI_3 and SbI_3 are obviously apart from the linear relation (8). This fact indicates that the crystal structures of these molecules are quite different from those of others and these molecules deform appreciably in the crystalline state. In fact, AsI_3 and SbI_3 do not form molecular crystals. On the other hand, sulphur molecular addition compounds of AsI_3 and SbI_3 satisfy the linear relation.

In the compounds the molecules of AsI_3 and SbI_3 are remained without large change.

§ 8. Temperature Dependency

Generally, the frequency of nuclear quadrupole resonance line decreases with increasing temperature. This character was interpreted by Bayer²⁸⁾ with the concept of the effective field gradient which is averaged field gradient for the thermal vibrations whose frequencies are large compared to the quadrupole resonance frequency. The effective field gradient and consequently observed frequency decreased when temperature increased. The observed resonance frequencies of Cl^{35} in AsCl_3 are plotted in Fig. 8, which also includes the

Fig. 8. Temperature dependency of the Cl^{35} resonance frequency in AsCl_3 . Open circles show Livingston's measurement.

low temperature values obtained by Livingston. Since the vibrational effect is diminished at low temperature frequency change of resonance line becomes very small at low temperature.

In Table VII the calculated values of logarithmic temperature coefficient $1/\nu \cdot \partial \nu / \partial T$ at 77°K is shown. From these figures it is concluded that the temperature dependency of M atom in MX_3 type molecule is about two or three times larger than X atoms.

In the case of AsI_3 the observed frequency changes of both the nuclei As and I were positive, that is, decreasing temperature decreases the resonance frequency. Fig. 9 shows the temperature changes of As resonance frequencies in AsI_3 and $\text{AsI}_3 \cdot 3\text{S}_8$. Positive temperature coefficient could not be interpreted

with Bayer's theory. Kushida, Benedeck and Bloembergen²⁹⁾ studied the pressure effect for quadrupole resonances. The variable quantity of nuclear quadrupole frequency with temperature is expressed

Table VII. Logarithmic temperature coefficients
 $1/\nu \cdot \partial \nu / \partial T$ ($10^4/^\circ\text{K}$).

Fig. 9. Temperature dependency of the As⁷⁶ resonance frequency in AsI₃ (●) and AsI₃·3S₈ (○).

$$\begin{aligned} \frac{1}{\nu} \left(\frac{\partial \nu}{\partial T} \right)_p &= \frac{V}{\nu} \left\{ \frac{\partial \nu}{\partial q_0} \frac{dq_0}{dV} + \frac{\partial \nu}{\partial \eta_0} \frac{d\eta_0}{dV} \right. \\ &+ \sum_i \frac{\partial \nu}{\partial \xi_i^0} \left(\frac{\partial \xi_i^0}{\partial V} \right)_T \left. \right\} \frac{1}{V} \left(\frac{\partial V}{\partial T} \right)_p \\ &+ \frac{1}{\nu} \sum_i \frac{\partial \nu}{\partial \xi_i^0} \left(\frac{\partial \xi_i^0}{\partial T} \right)_p. \end{aligned} \quad (9)$$

The first term represents the volume dependency of quadrupole resonance frequency and the second term is the Bayer's term. ξ_i^0 is the amplitude of the normal modes of the vibration. In the case of AsI₃, η in I¹²⁷ resonance increased with decreasing temperature. This term gives a decrease of coupling when temperature is decreased. However, in As⁷⁵ resonance η would be very small, probably

zero, for the links of six iodine atoms. Therefore the second term in the bracket has a small effect. The first term in bracket indicates a volume effect. The volume of AsI₃ decreases with decreasing temperature. This may produce a decrease of the p character of the field gradient and an increase of the hybridization of the intramolecular bond by increase bonding to surrounding molecules. Probably, the hybridization in AsI₃ has some d character and produces large ionic character which is expected from Figs. 6 and 7. Thus, in the case of AsI₃ the first term in bracket which shows volume effect is predominant and over-compensates the effects of the other terms in above equation.

The As resonance in AsI₃ indicates a phase change at about 92°C which is shown in Fig. 10. It corresponds to that the iodine reso-

Fig. 10. Temperature dependency of As⁷⁶ resonance frequency in AsI₃ at above room temperature. Phase transition was observed at about 90°C.

nance in AsI₃ split into three multiplets above 90°C¹⁾. Smallness of deviation of the resonance frequency at this phase change indicates that the crystal structure is not affected so much.

A Torsion Magnetometer for Determining Free Radicals in Some Organic Solutions

By Hideo TAKAKI, Naoto KAWAI, Chie MIYAKE and Tadasuke MORITA

Faculty of Science, Kyoto University

(Received February, 14, 1958)

A torsion pendulum magnetometer whose sensitivity is 1×10^{-10} c.g.s.e.m.u./division was made with fused silica. By using this, a process in which the free radicals appear and disappear was traced magnetically from time to time during the reduction of duroquinone with glucose, and the result showing a fair agreement with Michaelis' was obtained. Secondly, we examined similar reactions by changing reducing agents, their concentrations and the temperature. Finally, the mean life time of free radicals was calculated from the observation. Then it was found to be shown as an exponentially decreasing function with temperature, and to be about 20 minutes at room temperature.

§ 1. Introduction

For several decades free radicals have been one of the leading subjects of investigation in the field of organic chemistry. A series of experiments have been made and a number of hypotheses have been set up severally on the nature, behavior and kinetics of what is called the radical reaction. On the other hand, the free radicals, having been found in most of all the living matters, have accentuated the attention of many biologists, biochemists and biophysicists. For instance, Bauer¹⁾ has found in the living cells a plenty of free radicals which disappear with the death of the cells, suggesting that life depends on an excited state of protein molecules in the protoplasm.

Of all the characteristics the said radicals possess, the most remarkable property is their magnetism. Since they always contain odd or unpaired electrons, they reveal themselves to be paramagnetics in a magnetic field. Consequently, the free radicals are the subjects to be investigated preferably by the magnetic measurement. By any other method the way of detection itself is extremely difficult. It is indeed Bauer and Michaelis who first introduced the magnetic method into this investigation. Michaelis²⁾ studied in detail the reducing or oxidizing process of dyestuff in 1938.

In recent years much has been studied on them by the resonance absorption experiments. B. Commoner, J. Townsend and G.E. Pake³⁾ have proved that the concentration of free

radicals abundant in living cells, such as leaves, roots, rabbit tissue, carrots, frog egg, etc. is in the range from about 2 to 200 ($\times 10^{-8}$)

Fig. 1. Apparatus.

moles per gram; while H. M. McConnell,⁴⁾ R. Bersohn,⁵⁾ J. E. Wertz,⁶⁾ etc., we learn, are going to further determine the hyperfine structure of semiquinone group.

Thus, the investigators' interest has so largely been focused upon the problems involving the radical reactions that it seems to be of fundamental importance to set up a sensitive apparatus capable of measuring the magnetic susceptibility of organic substances from time to time during the reaction, and then to infer how the free radical arises, reacts and disappears in the course of the radical reaction. The following is the descriptions of the magnetometer newly designed by us, together with some of the results.

§ 2. Apparatus

A sensitive torsion magnetometer was made with fused silica in the following way. As shown in Fig. 1, pendulum system of the magnetometer (*C*, *M*, *B* and *B'*) is fixed to a tripod through a thin quartz fiber (*A*) in such a way that the center of gravity of the whole pendulum system may be higher than the fulcrum. The solution to be measured is placed into a reaction vessel (*B*) and a suitable solution into a compensating vessel (*B'*). By placing the above-mentioned vessel symmetrically on either side of the truncated pole pieces of the electromagnet (*N*), the basic diamagnetism of both the two kinds of solution can completely be offset and only susceptibility change related with the reaction can be taken out. The amounts of the change can be measured directly from the deflection angle of the pendulum with the aid of a lamp-scale and a reflecting mirror (*M*). As already mentioned, the center of gravity (*G*) of the pendulum system is located higher than the torsion wire, so the restoring couple vector due to the torsion wire, is much reduced by the couple vector of the gravity, which, acting at the center of gravity of pendulum system downward, will rotate the system in the opposite direction to that of the former. The situation may be expressed by

$$\frac{\theta}{f} = \frac{r}{\tau - mgl}$$

where θ , represents the deflection angle; f , horizontal component of paramagnetic attraction between the magnetic field and the solution; τ , torsion constant of the torsion

wire; l and r , the distance from the foot of pendulum to *G* and to center of cylindrical vessel respectively; m , the total of the pendulum system; and g , the force of gravity.

Fig. 2. Scheme of magnetometer.

Sensitivity of our apparatus can be raised, when by adding suitable mass to the top of the pendulum (*C*) we elevate its center of gravity, because $\tau - mgl$ can be decreased. Hence a very sensitive magnetometer is to be attained, so far as $\tau - mgl$ is kept positive. The highest sensitivity ever reached by this adjustment was 1×10^{-10} c.g.s.e.m.u. volume susceptibility per division. It is one of the characteristics of the equipment that the samples, however large the charge may be, can be measured without changing the sensitivity.

The calibration of our magnetometer is carried out in the following way; first, a small counter weight, say, 1 mg is mounted upon the dish attached to the *B*, the resultant deflection is determined, and then the scale constant per unit force (dyne/div) is calculated. The attraction between total paramagnetics in the reaction vessel and the magnetic field is further expressed by

$$f = A\chi \int H \frac{\partial H}{\partial x} dx$$

where A is the cross sectional area of the vessel, and χ the paramagnetic volume susceptibility of the solution which varies with time.

§ 3. Determination of free radicals

One of the results we obtained by using

Fig. 3. Solution of 0.020 g. of duroquinone; 1 cc. of 1.0-N sodium hydroxide and 1 cc. of pyridine, mixed with water up to 5 cc., and 20 mg of glucose added.

this apparatus is given in Fig. 3. In the present experiment, we took up the reaction system containing H_2O , NaOH , pyridine, duroquinone and glucose, in which process there arises the free radical in question, as

Fig. 4. Durosemi-quinone radical.

Fig. 5. Monosaccharides concentration dependency of reaction.

Fig. 6. Temperature dependency of reaction.

an intermediate product of semiquinone, having paramagnetism as shown in Fig. 4. The positive shift of magnetometer in the Fig. 3, therefore, corresponds to the free radical accumulation.

Fig. 7. Temperature dependency of mean lifetime of free radical.

We further examined the process of reactions by various monosaccharides, such as glucose, fructose, mannose, etc.. The results can be summarized in the following items in descending order:

That, if the temperature under which the reaction proceeds is kept constant, the velocity

is the fastest in fructose, the slowest in mannose and the intermediate in glucose, respectively.

That, in every monosaccharide, both the rate of production of free radicals and that of their decay are strictly in proportion to the concentration of monosaccharide, (see Fig. 5), while Fig. 6 shows the temperature dependency of the reaction, citing, as a representative case, that of glucose.

Order of magnitude estimation of the mean life time of free radicals: The mean life time of semiquinone radicals was determined by integrating the concentration curve (represented in fractions) with respect to time, and them by dividing it by the total number of molecules. Thus, the obtained temperature dependency of the life time in the case of fructose is shown in a semilogarithmic diagram Fig. 7. The life time of radicals depends upon the temperature, the concentration of monosaccharide and the kind of monosaccharide. It is worth while to note here that the life time is remarkably prolonged as temperature falls. Extrapolate the line at the boiling temperature of liquid oxygen, then the life time will amount up to about 10^{17} years.

We wish to express our thanks to Professor R. Goto for his encouragement and assistance in preparing duroquinone.

On the Flow of a Viscous Fluid past a thin Screen at Small Reynolds Numbers

By Hidenori HASIMOTO

Department of Aeronautical Engineering, Faculty of Engineering, Kyoto University

(Received February 12, 1958)

The slow steady flow of a viscous incompressible fluid past a thin screen with holes or slits is investigated on the basis of the Stokes equations of motion. It is found that the flow conductance σ of the holes or slits (i.e. the ratio of the total flow Q to the pressure drop P) is given by

$$\sigma = \frac{Q}{P} = \frac{M}{8\rho\mu},$$

where ρ is the density of the fluid, μ the viscosity, and M the virtual mass of disks or strips which are congruent with the holes or slits, moving broadside-on in a perfect fluid. The drag D acting on a part of the wall δW of the screen is also given by

$$D = Pq_p,$$

where q_p is the total flow of the perfect fluid through δW in this movement with unit velocity.

As examples, the cases of a single elliptic hole, a single slit, two parallel equal slits, and a series of parallel equal and equidistant slits are considered. Especially, in the last case, the total drag for an intervening strip is shown to be $4\pi\mu U / \log |\cos(\varepsilon\pi/2)|$ where U is the velocity of the viscous fluid at infinity, and ε the relative aperture of the screen ($0 < \varepsilon < 1$).

§ 1. Introduction

The flow of a fluid through an orifice or orifices in a screen is very important from the practical view-points, and many classical works are known, especially for the case of the perfect fluid.

When the area of the orifice and the rate of flow through it are small, the effect of viscosity is so great that we must in general appeal to the Navier-Stokes equations for the theoretical study.

However, the Stokes approximation seems to be adequate and useful in many cases, if we take into account the small Reynolds numbers of the flow field in the neighbourhood of an orifice.

In this paper the flow of a viscous incompressible fluid through an orifice or orifices in an infinitely thin screen is investigated from a general view-point, on the basis of the Stokes equations of motion.

It is found that the flow conductance of the orifice and the drag on a part of the wall are proportional respectively to the virtual mass and the rate of flow induced by

the movement of the disks or strips congruent with the orifices in a perfect fluid.

About ten years ago Roscoe¹⁾ studied the three dimensional flow past a plane obstacle and related its drag to its electrostatic capacity. Our studies owe greatly to his idea and may be regarded as the complement to his study in this respect. He confined his study to the case of three dimensions, perhaps being afraid of the failure of the Stokes equations in the case of the two-dimensional flow. The existence of the solution is ascertained, however, in the case of the flow past a screen, having pressure difference between its two sides. The presence of this pressure difference seems to be an essential feature of our problem.

As examples, the cases of a single elliptic hole, a single slit, two parallel and equal slits, and a series of parallel equal and equidistant slits are discussed. The first example is considered by Roscoe without noticing our relation (3.9). He also estimated the conductance of a slit (which is two-dimensional) making a limiting process, which is shown in

our second example to be erroneous unfortunately.

Recently, many studies have been made on the flow of a viscous fluid past an obstacle in the presence of other obstacles, e.g. walls or the same kind of obstacles, on the basis of the Oseen or the Stokes equations of motion. Most of these investigations must appeal to an expansion method assuming the ratio d/l to be small, where d is the representative length of obstacles (such as the diameter of a circular cylinder), and l is the distance between them. Our second and third examples, being the exact solutions of the Stokes equations, may be useful to fill up the deficiency of them, especially in the case of small aperture $d \gg l$. Tamada and Fujikawa²⁾ investigated in detail the flow past a lattice of circular cylinders on the basis of the Oseen equations. Kuwabara³⁾ also discussed the flow past a lattice of parallel flat plates. Their formulae for the drag on a cylinder agree with the result of the fourth example qualitatively in the limit of small Reynolds numbers and small d/l .

§ 2. Fundamental Equations

We take the x -axis perpendicularly to the plane of the screen, denoting unit vector parallel to the x -axis by $\mathbf{i}$. The pressure p of the fluid at $x = \pm\infty$ is taken to be $p = \mp P/2$ without loss of generality. Let us consider the motion of the fluid induced by this pressure difference P .

The Stokes equations for the steady slow motion of an incompressible viscous fluid are written as

$$\mu \Delta \mathbf{V} = \text{grad } p, \quad (2.1)$$

$$\text{div } \mathbf{V} = 0, \quad (2.2)$$

where Δ stands for

$$\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2},$$

$$\mathbf{V} = (u, v, w)$$

is the velocity vector, and μ is the coefficient of viscosity.

Our problem is to solve (2.1) and (2.2) under the boundary conditions

$$\text{i) } p \rightarrow \mp P/2 \text{ as } x \rightarrow \pm\infty, \quad (2.3)$$

$$\text{ii) } \mathbf{V} = 0 \text{ on the wall of the screen } W \\ \text{at } x = 0, \quad (2.4)$$

$$\text{iii) } p \text{ and } \mathbf{V} \text{ are regular, one-valued and finite (or zero) throughout the field of flow including infinity.} \quad (2.5)$$

We have only to consider the positive half space $x > 0$, because the symmetry of (2.1)–(2.5) allows a solution in which u is even and v, w, p are odd with respect to x :

$$\begin{aligned} u(x, y, z) &= u(-x, y, z), \\ v(x, y, z) &= -v(-x, y, z), \\ w(x, y, z) &= -w(-x, y, z), \\ p(x, y, z) &= -p(-x, y, z). \end{aligned} \quad (2.6)$$

On account of continuity of $\mathbf{V}$ and p we can conclude from (2.6) that

$$v, w, p = 0 \text{ on the holes } H \text{ at } x = 0. \quad (2.7)$$

The boundary value problem of this type in the positive half-space is quite similar to the stamp problem in the elasticity, and has the following solution

$$\mathbf{V} = \mathbf{i}\phi - x \text{ grad } \phi, \quad (2.8)$$

$$p = -2\mu \frac{\partial \phi}{\partial x}, \quad (2.9)$$

which satisfy (2.1)–(2.5) and (2.7) provided that ϕ is a harmonic function:

$$\Delta \phi = 0 \quad (2.10)$$

and satisfy the following boundary conditions

$$\phi = 0 \text{ on the wall } W \quad (2.11)$$

$$\partial \phi / \partial x = 0 \text{ on the holes } H, \quad (2.12)$$

$$\text{grad } \phi \rightarrow \frac{P}{4\mu} \mathbf{i} \text{ as } x \rightarrow \infty, \quad (2.13)$$

grad ϕ being one-valued and regular throughout the field of flow including infinity. H must not contain the element whose area is ∞^2 . This exceptional case corresponds to the flow past a disk etc., which should be excluded from our problem. (2.8)–(2.10) are essentially the same formulae already used by Roscoe in the study of the flow past a plane obstacle.

The quantity of practical interest is the flow conductance of the holes:

$$\sigma = Q/P, \quad (2.14)$$

where

$$Q = \int_H u \, dS \quad (2.15)$$

is the total flow through the holes H . By making use of (2.8) Q is represented in terms of ϕ as follows:

$$Q = \int_H \phi \, dS. \quad (2.16)$$

The drag on a part of the wall ∂W is also expressed in terms of ϕ as

$$D = -2 \int_{\delta W} p \, dS = 4\mu \int_{\delta W} \frac{\partial \Phi}{\partial x} dS, \quad (2.17)$$

where use is made of (2.6) and (2.9).

§ 3. Flow of a Perfect Fluid past Complementary Disks or Strips

Let us consider the velocity potential Φ_p for the flow of a perfect fluid with uniform velocity U_p at $x = \pm\infty$, past disks or strips H which are congruent with the holes under consideration. It is well known that Φ_p satisfies the following equations and boundary conditions

$$\Delta \Phi_p = 0, \quad (3.1)$$

$$u_p = \partial \Phi_p / \partial x = 0 \quad \text{on } H, \quad (3.2)$$

$$\text{grad } \Phi_p \rightarrow iU_p \quad \text{as } x \rightarrow \infty, \quad (3.3)$$

and $\text{grad } \Phi_p$ is regular and one-valued throughout the flow field including infinity.

It will be seen that (3.1)–(3.3) are perfectly equivalent to (2.10)–(2.13) provided that U_p and Φ_p satisfy

$$U_p = P/4\mu, \quad (3.4)$$

and

$$\Phi_p = 0 \quad \text{on } W. \quad (3.5)$$

The condition (3.5) may be easily satisfied by taking a suitable additive constant in Φ_p if there is no circulation for each element of H . Thus if we know the velocity potential of a perfect fluid past H which is the complement of W , our problem is solved.

We next proceed to find a formula which expresses the flow conductance of holes for a viscous fluid in terms of a quantity which is familiar in the case of a perfect fluid. For this purpose we consider the motion of H with velocity iU_p broadside-on in a perfect fluid. The velocity potential induced by this motion is evidently given by

$$\Phi_p - U_p x \quad (3.6)$$

using Φ_p determined by (3.1)–(3.3). The virtual mass M of H is defined

$$\begin{aligned} MU_p^2 &= 2T \\ &= \rho \int [\text{grad} (\Phi_p - U_p x)]^2 dV \end{aligned} \quad (3.7)$$

and is independent of U_p , where T is the induced kinetic energy of the fluid, ρ is the density, and dV the volume element of the flow field external to H .

Making use of Green's theorem and taking into account the relations (3.1)–(3.5) and the

symmetry of the flow field, we have

$$\begin{aligned} MU_p^2 &= -2\rho \int_H (\Phi_p - U_p x) \frac{\partial}{\partial x} (\Phi_p - U_p x) dS \\ &= 2\rho U_p \int_H \Phi_p dS, \end{aligned} \quad (3.8)$$

assuming that the surface integral over a sphere of infinite radius tends to zero. This assumption is allowed unless the total area of H is infinite as in the case of an infinite series of slits. In such a case (3.7) becomes infinite and (3.8) loses its meaning. However it is convenient to define a partial virtual mass of a hole of area δH , taking δH instead of H as the domain of integration in (3.8).

Introducing (3.4) and (3.8) into (2.14) and (2.16) we obtain for Q and σ

$$Q = \frac{MU_p}{2\rho} = \frac{MP}{8\rho\mu}, \quad \sigma = \frac{M}{8\rho\mu}. \quad (3.9)$$

When M denotes the partial virtual mass, Q gives of course the total flow through δH .

In addition, making use of (2.17) and (3.4), the drag D on a part of the wall δW is given by

$$D = 4\mu \int_{\delta W} u_p dS = \frac{P}{U_p} \int_{\delta W} u_p dS = Pq_p, \quad (3.10)$$

where q_p is the total flow of the perfect fluid through δW with uniform velocity i at infinity.

Equations (3.9) and (3.10) are the required results, and complement Roscoe's formula which relates the viscous drag D_a of a disk with its electrostatic capacity C by

$$D_a = 8\pi\mu CU, \quad (3.11)$$

where U is the normal velocity of the disk.

§ 4. Examples

1) A single elliptic hole.

The virtual mass of an elliptic disk H is known to be

$$\begin{aligned} M &= \frac{4\pi}{3} \rho b^2 c^2 \int_0^{\pi/2} \sqrt{b^2 \sin^2 \theta + c^2 \cos^2 \theta} d\theta \\ &= \frac{16\rho S^2}{3\pi s}, \end{aligned} \quad (4.1)$$

$$S = \pi bc, \quad s = 4 \int_0^{\pi/2} \sqrt{b^2 \sin^2 \theta + c^2 \cos^2 \theta} d\theta,$$

where b and c are the semi-axes, S is the area and s the periphery of H . Introducing (4.1) into (3.9) the conductance of the elliptic hole H is given by

$$\sigma = \frac{2S^2}{3\pi\mu S}, \quad (4.2)$$

which is the formula obtained by Roscoe without noticing the relation to M .

For the sake of reference the velocity distribution on the hole is found to be

$$V = \frac{SP}{\pi\mu S} \sqrt{1 - \frac{y^2}{b^2} - \frac{z^2}{c^2}} i. \quad (4.3)$$

(2) A single slit of width $2h$.

For a strip or a flat plate of width $2h$, M is known to be

$$M = \pi\rho h^2. \quad (4.4)$$

This gives for the conductance of a slit of width $2h$:

$$\sigma_{2h} = \frac{\pi}{8\mu} h^2 \doteq 0.3927 \frac{h^2}{\mu}. \quad (4.5)$$

Roscoe estimated this value to be $4h^2/(3\pi\mu) \doteq 0.4244 h^2/\mu$ assuming (4.2) to be valid for a rectangle of width $2h$ and making its length L infinitely large. This interesting discrepancy seems to be due to the edge effect of the elliptic hole which becomes important as its thickness becomes small.

Now, according to classical results, the velocity potential of a perfect fluid past a strip $x=0$, $|y| \leq h$ is given by

$$\begin{aligned} \phi_p &= U_p \operatorname{Re} f(\zeta), \\ f(\zeta) &= \sqrt{\zeta^2 + h^2}, \\ \zeta &= x + iy. \end{aligned} \quad (4.6)$$

Introducing this into (2.8) and (2.9) we obtain for the velocity and pressure distribution on H and W

$$\begin{aligned} V = i\phi &= \begin{cases} \frac{Ph}{4\mu} \sqrt{1 - \frac{y^2}{h^2}} i, & |y| \leq h, \\ 0, & |y| \geq h. \end{cases} \\ p &= \begin{cases} 0, & |y| \leq h, \\ \mp \frac{P}{2} \sqrt{1 - \frac{h^2}{y^2}}, & |y| \geq h, \end{cases} \quad x = \pm 0, \end{aligned} \quad (4.7)$$

$$\begin{aligned} \frac{dp}{dx} &= -2\mu \frac{\partial^2 \phi}{\partial x^2} = 2\mu \frac{\partial^2 \phi}{\partial y^2} = 2\mu \frac{\partial^2 |V|}{\partial y^2} \\ &= \begin{cases} -\frac{P}{2h} \sqrt{\left(1 - \frac{y^2}{h^2}\right)^3}, & |y| \leq h, \\ 0, & |y| \geq h. \end{cases} \end{aligned} \quad (4.9)$$

u - y curve is an ellipse in contrast with a parabola in the case of the Poiseuille flow.

The behaviour of the flow at a great distance r from the slit is also given by

$$V \sim \mp \frac{Ph^2}{8\mu} x^2 \cdot \operatorname{grad} \left(\frac{1}{r^2} \right), \quad \text{as } x \rightarrow \pm\infty \quad (4.10)$$

and

$$p \sim \mp \frac{P}{2} \left[1 - \frac{h^2(x^2 - y^2)}{2r^4} + O\left(\frac{1}{r^4}\right) \right], \quad (4.11)$$

making use of

$$\begin{aligned} \phi &\sim \pm \frac{P}{4\mu} \operatorname{Re} \left(\zeta + \frac{h^2}{2\zeta} + \dots \right) \\ &= \pm \frac{Px}{4\mu} \left[1 + \frac{h^2}{2r^2} + \dots \right]. \end{aligned} \quad (4.12)$$

3) Two parallel slits of equal breadth

Let us consider two parallel slits $h > y > a$ and $-h < y < -a$ whose width l and distance d are $l = h - a$ and $d = 2a$ respectively. In this case ϕ is given by

$$\phi = \operatorname{Re} f(\zeta),$$

$$f(\zeta) = U_p \int_0^\zeta \frac{\zeta^2 + m^2}{\sqrt{(\zeta^2 + a^2)(\zeta^2 + h^2)}} d\zeta, \quad (4.13)$$

which satisfies (2.11)–(2.13) provided that

$$\frac{\Gamma}{2} = U_p \int_a^h \frac{m^2 - y^2}{\sqrt{(y^2 - a^2)(h^2 - y^2)}} dy = 0 \quad (4.14)$$

or

$$m^2 = h^2 E(\sqrt{1 - k^2}) / K(\sqrt{1 - k^2}), \quad k = a/h, \quad (4.15)$$

where K and E are the complete elliptic integrals of the first and the second kind respectively. $f(\zeta)$ is the complex velocity potential of a two-dimensional perfect fluid past two flat plates ($x=0$, $a < |y| < h$) with uniform velocity iU_p . (4.14) is nothing but the condition of zero circulation around each plate, and is seen to assure (2.11), if we take into account that the integrand of (4.13) is real for $\zeta = iy$ in the intervals $|y| < a$ or $|y| > h$, and its contribution to (4.13) is purely imaginary.

Putting $\zeta = iy$ in (4.13) and substituting in (2.16) the total flow Q past a hole is given by

$$\begin{aligned} Q &= \int_a^h \phi dy = y\phi \Big|_a^h - U_p \int_a^h \frac{y(m^2 - y^2)}{\sqrt{(y^2 - a^2)(h^2 - y^2)}} dy \\ &= \frac{\pi P}{8\mu} \left[\frac{a^2 + h^2}{2} - m^2 \right] \\ &= \frac{\pi h^2 P}{8\mu} \left[\frac{1}{2} (1 + k^2) - \frac{E(\sqrt{1 - k^2})}{K(\sqrt{1 - k^2})} \right], \end{aligned} \quad (4.16)$$

making use of $\phi(0, h) = \phi(0, a) = 0$ and introducing (3.4).

The drag D acting on a plate $|y| < a$ is given by

$$\begin{aligned} \frac{D}{P} &= \frac{2}{U_v} \int_0^a \frac{\partial \Phi}{\partial x} dy = 2 \int_0^a \frac{m^2 - y^2}{\sqrt{(a^2 - y^2)(h^2 - y^2)}} dy \\ &= 2 \left[\frac{m^2 - h^2}{h} K(k) + h E(k) \right] = \frac{\pi h}{K'}, \end{aligned} \tag{4.17}$$

where we have used the relations (3.10) and (4.13) together with the Legendre relation

$$E'K - KK' + EK' = \frac{\pi}{2}, \tag{4.18}$$

where

$$E' = E(k'), \quad K' = K(k'), \quad k' = \sqrt{1 - k^2} = \sqrt{1 - (a^2/h^2)}. \tag{4.19}$$

Fig. 1 and Fig. 2 show the values of $8\mu\sigma/(\pi h^2) = \sigma/\sigma_{2h}$ and $D/(2hP)$, where σ_{2h} is the

Fig. 1.

Fig. 2.

conductance of a single slit of width $2h$ given by (4.5). Making k ($=a/h$) or k' ($=\sqrt{1 - (a^2/h^2)} \sim \sqrt{(2l)/h}$) tend to zero we obtain

$$\frac{\sigma}{\sigma_{2h}} = \frac{1}{2} \left[1 - \frac{2}{A} + \frac{k^2}{2A} \left(2 - \frac{1}{A} \right) + O(k^4) \right] \tag{4.20}$$

$$= \frac{1}{16} k'^4 + O(k'^6) \sim \frac{l^2}{4h^2}, \tag{4.21}$$

$$A = \log \left(\frac{4}{k} \right) = \log \left(\frac{4h}{a} \right) = \log \left(\frac{8h}{d} \right),$$

$$\frac{D}{2hP} = \frac{\pi}{2[A + (A-1)k^2/4 + O(k^4)]} \tag{4.22}$$

$$= \frac{1}{1 + k'^2/4 + O(k'^4)} \sim 1 - \frac{l}{2h}. \tag{4.23}$$

According to (4.20) the blocking effect of a small intervening strip (width $d=2a$) in a slit (width $2h$) is great on account of the presence of the logarithmic term. On the other hand if we keep the width of two slits ($l=h-a$) constant and decrease the distance $2a$ between them σ increases from σ_l at $a=\infty$ to $\sigma_{2h}/2=2\sigma_l$ at $a=0$, on account of the interference between two slits.

(4.22) shows that the drag for a small obstacle in a slit experiences the force of the magnitude $\pi hP/\log(8h/d)$, and (4.23) shows that the deviation of D from $2hP$ is given by lP , being a half of $2lP$ which may be inferred from naive consideration.

4) A series of parallel equal and equidistant slits.

We now consider the case where

$$\Phi = A \operatorname{Re} F(\zeta) \quad (A = \text{real}) \tag{4.24}$$

with

$$F(\zeta) = \cosh^{-1} \left(\frac{1}{C} \cosh \frac{\pi \zeta}{h} \right), \quad C = \cos \frac{\pi l}{2h}. \tag{4.25}$$

This Φ is an even periodic function of ζ with a period ih , since $\cosh^{-1}(-|\tau|) = \cosh^{-1}|\tau| + i\pi$, and we take F to be real and positive at $\zeta=0$.

On the imaginary axis $\zeta=iy$, $\cosh(\pi \zeta/h)$ equals $\cos(\pi y/h)$, and F becomes purely imaginary at the interval W except H:

$$\text{W: } \frac{l}{2} + nh < y < -\frac{l}{2} + (n+1)h,$$

$$\text{H: } -\frac{l}{2} + nh < y < \frac{l}{2} + nh,$$

$$n=0, \pm 1, \pm 2, \dots \tag{4.26}$$

On the other hand

$$\frac{\partial F}{\partial x} = F'(\zeta) = \frac{\pi}{h} \frac{\sinh(\pi \zeta/h)}{\sqrt{\cosh^2(\pi \zeta/h) - C^2}} \tag{4.27}$$

is purely imaginary at H and real at W.

If we make x infinitely large we find

$$F = \frac{\pi}{h} \zeta - \log C + O(e^{-(2\pi/h)x}) \text{ as } x \rightarrow \infty, \quad (4.28)$$

since

$$\cosh^{-1} \xi = \log(\xi + \sqrt{\xi^2 - 1}) = \log(2\xi) + O\left(\frac{1}{\xi^2}\right). \quad (4.29)$$

These show that (4.24) and (4.25) in conjunction with (2.8) and (2.9) give the viscous flow through a series of parallel equal (width l), and equidistant (period h , distance $d = h - l$) slits, if we take

$$A = \frac{h}{4\pi\mu} P \quad (4.30)$$

according to (2.11)–(2.13).

Introducing (4.24) and (4.28) into (2.8) we obtain

$$V \rightarrow iU, \quad U = -A \log C \text{ as } x \rightarrow \pm\infty. \quad (4.31)$$

This implies the existence of the uniform flow iU at ∞ which may be expected by considering that the total flow is infinite in the present case.

Taking into account the continuity and periodicity of the flow, we obtain

$$Q = Uh = \frac{Ph^2}{4\pi\mu} \left| \log \cos \frac{\pi l}{2h} \right| \quad (4.32)$$

for the total flow past one slit, or

$$\sigma = \frac{Q}{P} = \frac{h^2}{4\pi\mu} \left| \log \cos \frac{\pi \varepsilon}{2} \right|, \quad \varepsilon = \frac{l}{h} \quad (4.33)$$

for the conductance of a slit, where ε is the relative aperture of the screen.

The force D acting on a strip, e.g.

$$\frac{l}{2} < y < -\frac{l}{2} + h,$$

is given by

$$D = Ph = \frac{4\pi\mu U}{\left| \log \cos \frac{\pi \varepsilon}{2} \right|}, \quad (4.34)$$

by use of the momentum and periodicity consideration together with (4.30) and (4.31).

Of course (4.32) and (4.34) can be obtained from (2.16) and (2.17) directly, but these integrals are reducible to the integrals at $x = \infty$ if we make use of contour integrals along a rectangle

$$-\frac{i}{2}h \rightarrow \frac{i}{2}h \rightarrow \frac{i}{2}h + \infty \rightarrow -\frac{i}{2}h + \infty,$$

and note that $\varnothing$ and $\partial\varnothing/\partial x$ are periodic harmonic functions, satisfying (2.11)–(2.12).

Fig. 3 shows the values of $D/(\mu U) = h^2/(\mu\sigma)$

$$= 4\pi \left/ \left| \log \cos \frac{\pi \varepsilon}{2} \right| \right|.$$

Making ε or $\varepsilon' = 1 - \varepsilon$ tend to zero we obtain

$$\frac{h^2}{\mu\sigma} = \frac{D}{\mu U} = \frac{32}{\pi \varepsilon^2} - \frac{4\pi}{3} + O(\varepsilon^2) \quad (4.35)$$

$$= \frac{4\pi}{\left| \log \sin \frac{\pi \varepsilon'}{2} \right|}$$

$$= \frac{4\pi}{\log \frac{1}{\tau} + \sum_{n=1}^{\infty} \frac{2^{2n-1} B_n}{n(2n)!} \tau^{2n}} \sim \frac{4\pi}{\log \frac{1}{\tau} + \frac{\tau^2}{6}}, \quad (4.36)$$

where

$$\varepsilon' = 1 - \varepsilon = \frac{h-l}{h} = \frac{d}{h}, \quad \tau = \frac{\pi \varepsilon'}{2} = \frac{\pi d}{2h}, \quad (4.37)$$

and B_n is the Bernoulli number:

$$B_1 = \frac{1}{6}, \quad B_2 = \frac{1}{30}, \quad B_3 = \frac{1}{42},$$

$$B_4 = \frac{1}{30}, \quad B_5 = \frac{5}{66}, \quad \dots \quad (4.38)$$

Fig. 3.

According to (4.35) the drag on a strip is inversely proportional to the square of the relative aperture ε , and $\sigma \sim \pi l^2/32\mu \sim \sigma_l$ (see (4.5)), provided ε is small. It is remarkable that the expansion formulae afford very good approximations even in the intermediate values of ε , if we take only the first two terms (see Fig. 3).

Recently Tamada and Fujikawa investigat-

ed²⁾ the flow past a lattice of circular cylinders (diameter d) on the basis of the Oseen equations and obtained a formula for the drag on a cylinder in the limit of small Reynolds numbers and d/h . Their values are qualitatively similar to that obtained from (4.36) and are a little larger for the same values of d/h . Kuwabara's result for a lattice of flat plates which are parallel to the main flow is also similar to (4.36) and give smaller values for the same values of d/h . These are in accordance with our intuition.

In conclusion the author expresses his hearty gratitude to Professor Ko Tamada,

Professor Isao Imai and Professor Susumu Tomotika for their continual suggestion and encouragement throughout this work. The author's thanks are also due to the Ministry of Education for a grant in aid for fundamental research.

Asymptotic Behaviour of the Response Function of an Optical System with the Primary Spherical Aberration

By HIROSI ITÔ

Department of Applied Physics, Faculty of Engineering, Osaka University

(Received April 1, 1958)

An asymptotic calculation of the response function of an optical system which has the primary spherical aberration is carried out in the presense of a defect of focus. The evaluation of the integral for the response function is calculated by the aid of the approximate formulae for Fresnel's integral when the coefficient of the spherical aberration is sufficiently large compared with the wave length of light. The response function denotes an interesting behaviour for various focal shifts even for a fixed value of the coefficient of the spherical aberration. When the shift is small, it has a strong decreasing character, and for larger values of it, the function becomes larger and begins to denote an oscillating property at last. The spatial frequency s extends from zero to 2 and the result is not valid in the neighbourhoods of the end points because of the simplification of the calculation which is used. The result is compared with an experiment.

§ 1. Introduction

Recently, many authors introduced "*information theory*" into the discussion of the characteristics of the optical systems, and some of the concepts which have prevailed up to now in this field are being reconsidered from this new standpoint. One of the most interesting new ideas which have been brought forth by this theory is that, we can assume an optical system as a kind of linear filter

which has the frequency response. The frequency response function derived from this assumption is now considered as the most powerful concept which would play an essential role in the performance test for optical systems, Duffieux¹⁾, Hopkins²⁾ and Linfoot³⁾ have introduced a reasonable definition for it. The complex amplitude in the image of a point source situated on the optical axis of an optical system can be given by the Fourier

transform of the pupil function. If we consider the frequency spectrum of the intensity in the diffraction image of the point source, it can be represented by the correlation function and is given by the formula (1) in § 2. This function has just the same form as that of the time correlation function in the theory of time series although the spatial frequency stands as time. Numerous investigations⁽⁴⁾⁽⁵⁾⁽⁶⁾ have been done about the measurement of this function for various optical systems, but there are very few about the analytical calculations. Hopkins²⁾ calculated the effect of defocussing, and De⁷⁾ did that of the function for an astigmatic optical system with defect of focus. However, any direct analysis is supposed to be difficult when the system includes every kind of aberration and even the numerical calculation seems awfully hard when the coefficients of the aberrations become large. On the other hand, it seems us that, there is a benefitable condition in case of the usual photographic lenses to try approximate calculations by it. The aberration function appears as the phase of the pupil function and includes Seidel's aberration coefficients. Although these constants are sufficiently small, the optical wave length is still smaller compared with them. We must notice that, these coefficients are considered to become smaller effectively as the aperture is reduced down smaller, and such discussion will fail for extreme cases. Taking advantage of this fact, we could expect to get some asymptotic expression for the response function. Although this thought is valid in principle, it is still difficult in general case. Fortunately, since the aberration function for the presence of the primary spherical aberration and the defect of focus is not complicated, such treatment is possible. Its calculation appears in § 3 and § 4, and the higher order approximation which gives some correction for it is in § 5. The detailed calculation of the most important integral which plays an essential role is given in Appendix. The calculated values and observed values are compared for a single lens which is assumed to have only the primary spherical aberration.

§ 2. General Formulae

The definition of the response function is given as the following when an incoherently

lit or self-luminous object is imaged through an optical system in question. Of course, we assume that the image is isoplanatic.

$$\varphi(s) = \frac{1}{\pi} \iint f\left(x + \frac{s}{2}, y\right) f^*\left(x - \frac{s}{2}, y\right) dx dy, \quad (1)$$

where

$$f(x, y) = \exp[ik W(x, y)] \cdot \begin{cases} (x^2 + y^2 \leq 1) \\ = 0. & (x^2 + y^2 > 1) \end{cases} \quad (2)$$

$W(x, y)$ is the aberration function of the optical system and $k = 2\pi/\lambda$. λ is the optical wave length. When the system has the primary spherical aberration in the presence of a defect of focus, the pupil function $f(x, y)$ is given by

$$\exp\left[ik\left\{A(x^2 + y^2) + \frac{1}{4}W_1(x^2 + y^2)^2\right\}\right]. \quad (3)$$

A represents the marginal optical distance between a reference sphere centered on the chosen focal plane and the section of the emergent wave front in the sagittal meridian. W_1 is the coefficient of the primary spherical aberration when the exit pupil is considered as a circle of which radius is 1. Using (3), the integrand of (1) is written as

$$\exp[i(p x + q x y^2 + q x^3)]. \quad (4)$$

p and q are both the functions of the spatial frequency s , and are defined by

$$\left. \begin{aligned} q &= k W_1 s \\ p &= \frac{k W_1 s}{4} \left(s^2 - \frac{1}{n} \right), \end{aligned} \right\} \quad (5)$$

where we put

$$A = -\frac{W_1}{8n}. \quad (6)$$

By proper choice of the parameter n , we can realize any focal setting for a given W_1 . n takes negative values as well as positive ones. From (5), p changes its sign from negative to positive at $s_0 = (1/\sqrt{n})$.

The region of integration for (1) is given by the shadowed region in Fig. 1 on the exit pupil plane. Then the response function is

$$\begin{aligned} \varphi(s) &= \text{real part of } \frac{4}{\pi} \int_0^{1-s/2} \exp[i(qx^3 + px)] dx \\ &\quad \times \int_0^{\sqrt{1-(x+s/2)^2}} \exp[iqxy^2] dy \end{aligned} \quad (7)$$

where the limits of integration are written explicitly.

Fig. 1. Domain of integration of (7).

§ 3. Fresnel's Integral

Instead of (7), it is more convenient to treat the integral

$$\begin{aligned} \Phi(s) = & \int_0^{1-(s/2)} \exp [i(qx^3 + px)] dx \\ & \times \int_0^{\sqrt{1-(x+s/2)^2}} \exp [iqxy^2] dy. \end{aligned} \quad (8)$$

Putting the integral related to y as

$$f(x) = \int_0^{\sqrt{1-(x+s/2)^2}} \exp [iqxy^2] dy,$$

and replacing $\sqrt{qxy}$ by a new variable σ , we get

$$f(x) = \frac{1}{\sqrt{qx}} \int_0^{\sqrt{qx[1-(x+s/2)^2]}} \exp [i\sigma^2] d\sigma. \quad (9)$$

$\sqrt{qx}f(x)$ is exactly Fresnel's integral⁸⁾ of which property is well-known. However, as the result is not represented by a simple function, we must be satisfied with its approximation. When we put

$$qx \left\{ 1 - \left(x + \frac{s}{2} \right)^2 \right\} = u, \quad (10)$$

Fresnel's integral is represented by

$$\sqrt{qx}f(x) = \begin{cases} \frac{\sqrt{\pi}}{2} e^{i\pi/4} (u \gg 0) \\ u^{1/2} e^{iu} (u \sim 0) \end{cases} \quad (11)$$

as the first approximation. These two functions are connected with each other at $\pi/4$ continuously but not smoothly. The true function oscillates around this value and the error caused by this smoothing process will be estimated later. The values of x corresponding to $u = (\pi/4)$ can be obtained by solving the equation

$$qx \left\{ 1 - \left(x + \frac{s}{2} \right)^2 \right\} = \frac{\pi}{4}. \quad (12)$$

Since p and q are very large for almost all values of s , there is a conventional method to get these values. In Fig. 2, the maximum values of u are sketched as the function of s when $kW_1 = 400$. This function is

$$M = kW_1 s \left\{ -\frac{s}{3} + \frac{s^3}{108} + \left(\frac{2}{9} + \frac{s^2}{54} \right) \sqrt{3 + \frac{1}{4} s^2} \right\} \quad (13)$$

Fig. 2. Maximum value of $qx\{1-(x+s/2)^2\}$ as the function of spatial frequency.

Except the neighbourhoods of $s=0$ and $s=2$, M is sufficiently larger than $\pi/4$. This function u is zero at the both ends $x=0$ and $1-(s/2)$, and has only one maximum between these points. From this fact, we may assume that there are two values of x which satisfy $u = (\pi/4)$, and the one is very near the point $x=0$ while the other is in the neighbourhood of $x=1-(s/2)$. These values are given approximately by

$$x_1 \sim \frac{\pi}{4q \left(1 - \frac{s^2}{4} \right)} \quad x_2 \sim 1 - \frac{s}{2} - \frac{\pi}{8q \left(1 - \frac{s}{2} \right)}. \quad (14)$$

These become infinite at $s=0$ or $s=2$, so that the result which comes from this simplification can not be applied near these points. The number of lines per millimeter on the object plane to be resolved by some optical system is too numerous for the region of s which exceeds 1, when the aberration is large. Probably, the usual lenses have no response effectively for such high values. Therefore, it will be sufficient for us not to consider the neighbourhood of $s=2$, although the divergence

near zero is undesirable and limits the application of the result. Within this reasoning, we are going to use the following representation for $f(x)$, that is

$$f(x) = \begin{cases} f_1(x) = \frac{\sqrt{\pi}}{2} e^{\pi/4 \cdot i} & (x_1 < x < x_2) \\ f_2(x) = e^{i\pi u} \left(\frac{u}{qx} \right)^{1/2} & (0 \leq x \leq x_1 \\ & (x_2 \leq x \leq 1 - (s/2)) \end{cases} \quad (15)$$

§ 4. First Approximation

Using the relation (15), the integral with respect to x is given by

$$\begin{aligned} & \int_0^{1-(s/2)} f_1(x) \exp[i(qx^3 + px)] dx \\ & + \int_0^{x_1} (f_2(x) - f_1(x)) \exp[i(qx^3 + px)] dx \\ & + \int_{x_2}^{1-(s/2)} (f_2(x) - f_1(x)) \exp[i(qx^3 + px)] dx \quad (16) \end{aligned}$$

The first term in (16) is also written as

$$\begin{aligned} & \int_0^\infty f_1(x) \exp[i(qx^3 + px)] dx \\ & - \int_{1-(s/2)}^\infty f_1(x) \exp[i(qx^3 + px)] dx. \quad (17) \end{aligned}$$

The second term of this becomes

$$\begin{aligned} & \frac{\sqrt{\pi}}{2i} \frac{\exp \left[i \left\{ q \left(1 - \frac{s}{2} \right)^3 + p \left(1 - \frac{s}{2} \right) \right\} \right]}{\sqrt{q \left(1 - \frac{s}{2} \right) \left\{ 3q \left(1 - \frac{s}{2} \right)^2 + p \right\}}} \\ & + O(q^{-5/2}) \quad (18) \end{aligned}$$

by partial integration. Note that this process also makes the result not to be applied in the neighbourhood of $s=2$. According to the definition (7), one of the necessary terms which comes from (18) is

$$I_1 = - \frac{2 \sin \left\{ q \left(1 - \frac{s}{2} \right)^3 + p \left(1 - \frac{s}{2} \right) + \frac{\pi}{4} \right\}}{\sqrt{\pi \left(1 - \frac{s}{2} \right) q \left\{ 3q \left(1 - \frac{s}{2} \right)^2 + p \right\}}} \quad (19)$$

The error is the order of $q^{-5/2}$ which is not serious unless s is very small. The first term in (17) is

$$\frac{\sqrt{\pi}}{2} \frac{e^{\pi/4 \cdot i}}{\sqrt{q}} \int_0^\infty \frac{\exp[i(qx^3 + px)]}{\sqrt{x}} dx. \quad (20)$$

By putting $qx^3 = t^3$, this becomes

$$\frac{\sqrt{\pi}}{2} \frac{e^{\pi/4 \cdot i}}{q^{2/3}} \int_0^\infty \frac{\exp[i(t^3 + \alpha t)]}{\sqrt{t}} dt, \quad (21)$$

where α is defined by $(p/q^{1/3})$ which changes its sign at $s_0 = (1/\sqrt{n})$. Apart from the coefficient, the property of this integral is closely similar to that of Airy's integral and its evaluation can be also done in the same manner as that. Its detailed calculation is shown in Appendix. The result is not unique and is divided into several cases. By the definition of p and q , α is given by

$$\alpha = \frac{(kW_1 s)^{2/3} \left(s^2 - \frac{1}{n} \right)}{4}. \quad (22)$$

For a value of s smaller than $(1/\sqrt{n})$, α takes a negative value and becomes positive for s larger than this value. This change of sign is very important, since the asymptotic behaviour of (21) for positive α is quite different from that for negative α . For a negative value of α , and for its large absolute value (21) becomes

$$\begin{aligned} I_2 = & \frac{2}{\sqrt{|p|q}} \left\{ \sin 2 \left(\frac{|\alpha|}{3} \right)^{3/2} - \frac{5}{18} \frac{\cos 2 \left(\frac{|\alpha|}{3} \right)^{3/2}}{2 \left(\frac{|\alpha|}{3} \right)^{3/2}} \right. \\ & \left. - \frac{205}{648} \frac{\sin 2 \left(\frac{|\alpha|}{3} \right)^{3/2}}{\left(2 \left(\frac{|\alpha|}{3} \right)^{3/2} \right)^2} + \dots \right\}. \quad (23) \end{aligned}$$

If α is positive and large, its asymptotic expansion is

$$\begin{aligned} I_2' = & \frac{2}{kW_1 s^2} \exp \left[- \frac{kW_1 s^4}{12\sqrt{3}} \right] \\ & \cdot \left\{ 1 - \frac{5}{18} \frac{1}{2 \left(\frac{\alpha}{3} \right)^{3/2}} + \frac{205}{608} \frac{1}{\left(2 \left(\frac{\alpha}{3} \right)^{3/2} \right)^2} - \dots \right\}. \quad (24) \end{aligned}$$

I_2' decreases exponentially as s becomes larger while the decreasing property of I_2 is not so strong. It denotes an oscillating property. When α is small, the integral (21) is represented by the following infinite series.

$$\begin{aligned} I_2'' = & \frac{2}{3\sqrt{\pi} q^{2/3}} \sum_{m=0}^\infty \frac{(\pm|\alpha|)^m}{m!} \Gamma \left(\frac{m}{3} + \frac{1}{6} \right) \\ & \times \cos 2\pi \left(\frac{m}{3} + \frac{1}{6} \right). \quad (25) \end{aligned}$$

This result is most important since α is not so large in almost all the region of s which we are interested in. It gives the largest contribution to the response function because it is the order of $q^{-2/3}$. I_1 is of the order of

$q^{-3/2}$ and any one of the other terms of which the derivation will be shown later is the order of q^{-1} or $q^{-3/2}$.

Now we are in the stage to calculate the remaining integrals which may be considered as the correction terms as well as I_1 . In the following, we take two integrals among them as the examples and show their evaluations. One of the integrals which appear in (16) is

$$\int_0^{x_1} f_2(x) \exp[i(qx^2 + px)] dx$$

$$= \int_0^{x_1} \sqrt{1 - \left(x + \frac{s}{2}\right)^2} \exp \left[i \left\{ p + q \left(1 - \frac{s}{4} \right) \right\} \right. \\ \left. \times x - iqsx^2 \right] dx. \quad (26)$$

The factor qsx^2 is quite small even at the upper limit of integration, so that we assume that

$$\exp \left[i \left\{ p + q \left(1 - \frac{s}{4} \right) \right\} x - iqsx^2 \right] \\ \sim \exp \left[i \left\{ p + q \left(1 - \frac{s}{4} \right) \right\} x \right].$$

Expanding the square root term around $x=0$, and integrating by x , we get

$$I_3 = 4\sqrt{1 - \frac{s^2}{4}} \frac{\sin \frac{\pi}{4 - s^2}}{q} + O(q^{-2}). \quad (27)$$

Another integral which is in (16) is

$$\int_{x_2}^{1 - (s/2)} \sqrt{1 - \left(x + \frac{s}{2}\right)^2} \exp \left[i \left\{ p + q \left(1 - \frac{s^2}{4} \right) \right\} x - iqsx^2 \right] dx. \quad (28)$$

We put $x = 1 - s/2 - \xi$ and take the following approximations

$$\sqrt{1 - \left(x + \frac{s}{2}\right)^2} \sim \sqrt{2\xi} \\ \exp \left[i \left\{ p + q \left(1 - \frac{s^2}{4} \right) \right\} x - iqsx^2 \right] \sim \exp \left[-iqs \left(1 - \frac{s}{2} \right)^2 + i \left\{ p + q \left(1 - \frac{s^2}{4} \right) \right\} \left(1 - \frac{s}{2} \right) \right. \\ \left. + 2iqs \left(1 - \frac{s}{2} \right) \xi - i \left\{ p + q \left(1 - \frac{s^2}{4} \right) \right\} \xi \right].$$

Inserting these results into (28), we get

$$C \int_0^{\pi/8q(1-s/2)} \sqrt{\xi} \exp \left[\left\langle 2qsi \left(1 - \frac{s}{2} \right) - i \left\{ p + q \left(1 - \frac{s^2}{4} \right) \right\} \right\rangle \xi \right] d\xi$$

where

$$C = \sqrt{2} \exp \left[i \left\langle -qs \left(1 - \frac{s}{2} \right)^2 + \left\{ p + q \left(1 - \frac{s^2}{4} \right) \right\} \left(1 - \frac{s}{2} \right) \right\rangle \right].$$

This is evaluated as the following by partial integration.

$$\sqrt{\frac{\pi}{8q \left(1 - \frac{s}{2} \right)}} \frac{\exp \left[i\pi \left\{ p + q \left(2s - 1 - \frac{3}{4}s^2 \right) \right\} / 8q \left(1 - \frac{s}{2} \right) \right]}{i \left\{ q \left(2s - 1 - \frac{3}{4}s^2 \right) + p \right\}} \\ - \frac{1}{2i \left\{ q \left(2s - 1 - \frac{3}{4}s^2 \right) + p \right\}^{3/2}} \int_0^{-\pi/4 \cdot (s-1)^2/(2-s)} \frac{e^{t}}{\sqrt{t}} dt. \quad (29)$$

The integral which appears here is also Fresnel's integral. The upper limit of this integral is not so small even if we limit the domain of s up to 1. Therefore, the first approximation which has been used before is not sufficient. Taking into account the second order approximation, this becomes

$$I_4 = \frac{1}{6\sqrt{2}} \pi \left(\frac{\pi}{q(1-\frac{s}{2})} \right)^{3/2} \cos \frac{\pi}{4} \frac{(s-1)^2}{2-s} + O(q^{-2}) . \tag{30}$$

Just the same kind of approximation is applied to the remaining two integrals in (16). The results are

$$I_5 = - \frac{2 \cos \left\{ \frac{\pi}{4-s^2} \right\}}{q \sqrt{1-\frac{s^2}{4}}} + O(q^{-3}) ,$$
$$I_6 = \frac{4 \sin \left\{ \frac{\pi}{16q} \frac{p+3q(1-\frac{s}{2})^2}{1-\frac{s}{2}} \right\} \cos \left\{ q(1-\frac{s}{2})^3 + p(1-\frac{s}{2}) - \frac{\pi}{16q} \frac{p+3q(1-\frac{s}{2})^2}{1-\frac{s}{2}} + \frac{\pi}{4} \right\}}{\sqrt{q(1-\frac{s}{2})} \pi \{ p+3q(1-\frac{s}{2})^2 \}} + O(q^{-5/2}) .$$

Now the value of the response function is given by the sum of these six terms.

$$I = I_1 + I_2 + I_3 + I_4 + I_5 + I_6 + O(q^{-2}) . \tag{31}$$

Although we use the symbol I_2 , I_2'' must be employed for small values of s , and I_2' or I_2 is applied for larger values of s . In Fig. 3, five examples are given for different values of W_1 and n by using (31). Three I_2 's should be used carefully, and I_2'' has been used actually for almost all region of s for all of them.

Fig. 3.

§ 5. Second Order Approximation

The calculation of the response function which was expounded in the foregoing sections is quite consistent so far as we take (15) as the first approximation of Fresnel's integral. As pointed out, I_2'' is the principal part and the largest correction terms are of the order of q^{-1} . If the second order contribution of Fresnel's integral is the same order, we must add this to the result. If we take into account the second term, Fresnel's integral is represented by

$$\int_0^z \frac{e^{it}}{\sqrt{t}} = \begin{cases} \sqrt{\frac{\pi}{2}} (1+i) - i \frac{e^{iz}}{\sqrt{z}} & (z \gg 0) \\ 2z^{1/2} e^{iz} - \frac{4}{3} i z^{3/2} e^{iz} & (z \sim 0) \end{cases} \quad (32)$$

$$\quad (33)$$

When we use this expression, the curve is not continuous at x_1 or x_2 if we use the original values. However, the discrepancies are not serious, so that these simple values will be still used. The integral which arises from the second term of (32) is

$$-\frac{i}{2} \frac{1}{q} \int_{x_1}^{x_2} \frac{\exp \left[i \left\{ p + q \left(1 - \frac{s^2}{4} \right) \right\} x - i q s x^2 \right]}{x \sqrt{1 - \left(x + \frac{s}{2} \right)^2}} dx,$$

where the following approximation is used.

$$\frac{1}{\sqrt{1 - \left(x + \frac{s}{2} \right)^2}} \sim \frac{1}{\sqrt{1 - \frac{s^2}{4}}} \left(1 + \frac{x}{2 \left(1 - \frac{s^2}{4} \right)} \right).$$

Then we get

$$-\frac{i}{2} \frac{1}{q \sqrt{1 - \frac{s^2}{4}}} \left(\int_{x_1}^{x_2} \frac{\exp \left[i \left\{ p + q \left(1 - \frac{s^2}{4} \right) \right\} x - i q s x^2 \right]}{x} dx \right. \\ \left. + \frac{s}{2 \left(1 - \frac{s^2}{4} \right)} \int_{x_1}^{x_2} \exp \left[i \left\{ p + q \left(1 - \frac{s^2}{4} \right) \right\} x - i q s x^2 \right] dx \right),$$

where only the first integral is necessary because the second one is of the order of q^{-2} . The first one can be rewritten as follows:

$$\int_0^\infty g(x) dx - \int_0^{x_1} g(x) dx - \int_{x_2}^\infty g(x) dx, \quad (34)$$

where

$$g(x) = \exp \left[i \left\{ p + q \left(1 - \frac{s^2}{4} \right) \right\} x - i q s x^2 \right] / x.$$

The result which comes from the second integral of (34) is

$$I_7 = -\frac{1 - \frac{1}{4n}}{2q \left(1 - \frac{s^2}{4} \right)^{3/2}} \left\{ 1 - \frac{1}{18} \left(\frac{\pi}{4} \right)^2 \left(\frac{1 - \frac{1}{4n}}{1 - \frac{s^2}{4}} \right)^2 \right\} + O(q^{-2}). \quad (35)$$

The real part of the integral

$$-\frac{i}{2} \frac{1}{q\sqrt{1-\frac{s^2}{4}}} \int_{x_2}^{\infty} \frac{\exp\left[i\left\{p+q\left(1-\frac{s^2}{4}\right)\right\}x-iqsx^2\right]}{x} dx.$$

can be easily shown to be of the order of q^{-2} . The integral which comes from the first term in (34) is

$$\frac{2}{q\pi\sqrt{1-\frac{s^2}{4}}} \int_0^{\infty} \frac{\sin\left(\left\{p+q\left(1+\frac{s^2}{4}\right)\right\}x-qsx^2\right)}{x} dx.$$

Putting $qsx^2 = \xi^2$, it becomes

$$\frac{2}{q\pi\sqrt{1-\frac{s^2}{4}}} \int_0^{\infty} \frac{\sin\left\{\sqrt{kW_1}\left(1-\frac{1}{4n}\right)\xi-\xi^2\right\}}{\xi} d\xi.$$

This integral is also evaluated by the method of the steepest descent, and its result is

$$I_8 = \frac{1}{q\sqrt{1-\frac{s^2}{4}}} \left[1 - \frac{\frac{4}{\sqrt{\pi}}}{\sqrt{kW_1}\left(1-\frac{1}{4n}\right)} \sin\left\{\frac{kW_1}{4}\left(1-\frac{1}{4n}\right)^2 - \frac{\pi}{4}\right\} \right] + O(q^{-5/2}).$$

Therefore, the correction which comes from (32) is

$$I_8 + I_7.$$

Now we consider the integrals which come from the second term of (33). The calculation is done in the same line as before, and one of the results is

$$I_9 = -\frac{2}{3} \frac{\sqrt{1-\frac{s^2}{4}}}{kW_1s\left(1-\frac{1}{4n}\right)} \cos \frac{\pi}{4} \frac{1-\frac{1}{4n}}{1-\frac{s^2}{4}}.$$

The integral

$$-i\left(\frac{4}{\pi}\right) \frac{2}{3} q \int_{x_2}^{1-\frac{s}{2}} x \left\{1-\left(x+\frac{s}{2}\right)^2\right\}^{3/2} \exp\left[i\left\{p+q\left(1-\frac{s^2}{4}\right)\right\}x-iqsx^2\right] dx$$

is of the order of $q^{-3/2}$, and is

$$\frac{2}{3} \frac{\sqrt{\frac{\pi}{4}}}{q^{3/2} \left\{2s\left(1-\frac{s}{2}\right) - \left(1-\frac{1}{4n}\right)\right\}} \cos \left\{q\left(1-\frac{s}{2}\right)^2 \left(s - \frac{1-\frac{1}{4n}}{1-\frac{s}{2}}\right) - \frac{\pi}{4} \left(s - \frac{1-\frac{1}{4n}}{2-s}\right)\right\} + O(q^{-5/2})$$

Any one of the terms which are of the order of $q^{-3/2}$ is very small in fact, so that we take

$$I_7 + I_8 + I_9$$

as the correction which comes from (32) and (33).

§ 6. Discussion and Comparison with the Experiment

The error introduced by the calculation up to now will be necessary to be explained. The absolute value of the error increases as

the spatial frequency decreases. At $s=0$, it becomes infinite and also so at $s=2$. However, if kW_1 is very large, it does not become serious even for sufficiently small values of s . For example, the orders of the error at $s=0.001$ and $s=0.1$ are 10^{-2} and 10^{-4} respectively when $kW_1=600$.

From the examples which are given in Fig. 3, several interesting features will be revealed. When kW_1 becomes larger, the response becomes smaller as we easily imagine. However, for a fixed value of W_1 , the response changes remarkably for different choice of focal shift. The curves (2) (3) (4) and (5) have the same value of kW_1 , but different n 's. $n=\infty$ means no focal shift. When n becomes smaller, magnitude of defocussing becomes larger. Of course, we are now considering only the case where n is positive. This means that, the curve of the spherical aberration and the image plane are in the same direction from the gaussian plane. Otherwise, response becomes considerably smaller than the ones given here. The behaviour of the curve is similar to the case where $n=\infty$. Among these curves, (2) has the highest response almost everywhere. Probably, it corresponds to the best focus.

The behaviour of the curve (4) is very interesting. It has an oscillating property and has several peaks. The last one is larger than the preceding ones. This phenomena has been recognized by numerical calculations⁶⁾

when the aberration is large.

In order to know the behaviour of the response function for the increase of the parameter n , we consider the first term of (23), and take the phase factor. The argument of the function

$$\frac{2}{\sqrt{pq}} \sin \frac{kW_1 s}{4 \cdot 3^{3/2}} \left(\frac{1}{n} - s^2 \right)^{3/2} \quad (36)$$

takes its maximum value

$$\mu = \frac{kW_1}{64n^2}$$

at $s_0' = (1/2\sqrt{n})$. (36) becomes zero at $s=0$ and $s=2$. However near these points, this expression is not valid because of the small values of α , so that we do not take these end points. If we assume $\mu < \pi$, there is no node. If $\pi < \mu < 2\pi$, the function (36) takes zeros two times, and the corresponding response functions crosses s -axis twice. By the rule stated above, the number of nodes of the curve (4) must be four while the true number is six. The calculated value of μ is 9.375 and is nearly equal to 3π . If μ is a little larger than 3π , two more nodes will appear. By this fact, this example is somewhat critical and not said to be a good one. Nevertheless, this method of estimation is very convenient to know the rough behaviour of the response function. About the other cases, μ 's are all smaller than π , and this means no node for every curve as we can see from Fig. 3.

Recently, my friend, Dr. T. Suzuki designed

Fig. 4. Comparison of the calculated values and observed values of the response function for a single lens. F number is 3.67, $kW_1=174$ and $n=\infty$.

and constructed a device which measured the response of optical systems. An experiment is done for a single lens which has only the primary spherical aberration. The experimental values are shown in Fig. 4 and compared with theoretical values. The correction which is given in § 5 is now considered. The coincidence of them can be said good although the calculated values are always larger than the observed ones. We are not in the stage to analyze the errors of this experiment or to estimate the magnitude of them at present. However, since this experiment is difficult, one of them might come from some incompleteness of the instrument*. The discrepancy between them increases as s increases. However, the loss of high frequency components is always inevitable in such kind of experiments. From the comparison with the experiment, the result obtained here seems to be still good even for small values of s . By our experience, the result is not reliable when W_1 is comparable with λ . For smaller values of W_1 or s , the numerical calculation¹⁰⁾ is recommended by using a good table of Fresnel's integral.

I should like to express my gratitudes to Mr. R. Kōno and S. Lee and Dr. T. Suzuki. Kōno and Lee helped me in deriving the curves appeared here. Dr. Suzuki presented me valuable advices and data.

Appendix

Evaluation of the Integral (21)

α changes its sign at $s_0=(1/\sqrt{n})$, so that we must consider the following two integrals

$$\int_0^\infty \frac{\exp[i(t^3+|\alpha|t)]}{\sqrt{t}} dt, \quad (1)$$

$$\int_0^\infty \frac{\exp[i(t^3-|\alpha|t)]}{\sqrt{t}} dt. \quad (2)$$

1. α is sufficiently large.

Instead of the real value t , we consider a complex variable z and take the function

$$\zeta(z)=i(z^3\pm|\alpha|z), \quad (3)$$

and the following contour integral is considered. In case when positive α is taken, the path of integration on complex plane is taken in Fig. 5. The one corresponding to negative

* T. Suzuki is now planning to make a device which has better response.

sign is in Fig. 6.

$$\frac{1}{2\pi i} \int_{\Gamma} \frac{e^{\zeta}}{\sqrt{z}} dz. \quad (4)$$

The saddle points are obtained by solving the algebraic equation

Fig. 5. The contour Γ for the integral (4) when α is positive.

Fig. 6. The contour Γ for the integral (5) when α is negative.

$$\zeta'(z_0)=3z_0^2+\alpha=0, \quad (4)$$

where

$$z_0 = \begin{cases} \pm i\sqrt{\frac{|\alpha|}{3}} & (\alpha \text{ is positive} = \text{case I}) \\ \pm \sqrt{\frac{|\alpha|}{3}} & (\alpha \text{ is negative} = \text{case II}) \end{cases}$$

The path of the integration which passes through the saddle point A is given by

$$x^3 - 3y^2 + |\alpha| = 0, \quad (\text{case I})$$

$$x^3 - 3xy^2 - |\alpha|x + 2\left(\frac{|\alpha|}{3}\right)^{3/2} = 0. \quad (\text{case II})$$

The tangent line at A is parallel to x axis in case I and makes the angle $\pi/4$ with x axis in case II. The integrals along y axis are pure imaginary in both cases, so that we need only the paths which pass through A's. Expanding $\zeta(z)$ in the neighbourhood of $z=z_0$, we get

$$\zeta(z) = \zeta(z_0) + \frac{\zeta''(z_0)}{2!}(z-z_0)^2 + \frac{\zeta'''(z_0)}{3!}(z-z_0)^3.$$

where $\zeta'(z_0)=0$ since z_0 is a saddle point. After expanding $1/\sqrt{z}$ near the point $z=z_0$, we put $z-z_0=\rho$ in case I and $z-z_0=\rho e^{\pi/4+i}$ in case II. Then we integrate with respect to ρ from $-\infty$ to $+\infty$ because any one of the integrands has a sharp maximum at A if α is large. Then we get the results (23) and (25). 2. α is small.

In this case, integration is done along the path OB for both cases. Putting $z=\rho e^{\pi/6+i}$, it becomes

$$\begin{aligned} & \int \frac{\exp[i(z^3 \pm |\alpha|z)]}{\sqrt{z}} dz \\ &= e^{\pi/6+i} \int_0^\infty \frac{\exp[i(-\rho^3 \pm e^{2/3+\pi i} |\alpha| \rho)]}{\sqrt{\rho}} d\rho \\ &= e^{\pi/6+i} \sum_{m=0}^\infty e^{2/3+m\pi i} \frac{(\pm|\alpha|)^m}{m!} \int_0^\infty \rho^{m-1/2} \exp(-\rho^3) d\rho. \end{aligned}$$

Putting $\rho^3=\tau$, we can easily evaluate the integral and get the result.

Adsorption of Water Vapour on Glass and Other Materials in Vacuum

By Hiroaki OKAMOTO and Yutaka TUZI

Matsuda Research Laboratory, Tokyo Shibaura Electric Co., Kawasaki

(Received February 28, 1958)

The adsorption of water vapour on lead borosilicate glass, soda lime glass, copper, nickel and alumina ceramic in high vacuum was studied by the time lag method of molecular flow originated by Barrer. The amount of adsorption at $273^\circ \sim 403^\circ \text{K}$ and 2×10^{-6} mmHg was found to be less than 1% of a monolayer. It is suggested that the adsorption of water vapour in this pressure region will not be a simple physical adsorption.

§ 1. Introduction

One of the main components of the residual gases in vacuum apparatus is water vapour.^{1), 2)} It is often supposed that many kinds of phenomena observed in vacuum systems are

complicated due to this residual water vapour. Although the adsorption of water vapour has been extensively studied,^{3), 4), 5)} there are only a few data which will contribute to the high vacuum technique. Experimental difficulties

associated with the measurement of pressure have restricted most investigations to the high pressure region. The most sensitive pressure gauge in high vacuum technique, the ion gauge, cannot be used because of its incandescent tungsten filament.^{1),6),7)} Other instruments for pressure measurement are all insensitive for the study of adsorption in very low pressure region.

In the present paper, a preliminary study for the estimation of the rate of adsorption of water vapour on glass, copper, nickel and alumina ceramic by using the time lag method of molecular flow is described.

§ 2. Principle of the Time Lag Method

The principle of this method is similar to that of Barrer,⁸⁾ and is illustrated in Fig. 1.

Fig. 1. Principle of time lag method.

The sample is packed into a tube A connecting two vessels V_1 and V_2 . The whole apparatus is maintained at a constant temperature. At the beginning of each experiment, the apparatus is evacuated to a fine vacuum. When the pressure p_1 in V_1 is increased by introducing a gas, the pressure p_2 in V_2 also rises by diffusion of the gas through A, but the latter pressure rise takes place with a time lag behind the former. The amount of time lag depends on the adsorption of gas in A.

In the first part of this section, 2.1, we will consider the diffusion process and the time lag assuming no adsorption in A. In part 2.2, the influence of adsorption will be discussed. In part 2.3 we will finally discuss the estimation of adsorption by the time lag method.

2.1. The Diffusion Process and the Time Lag when No Adsorption Takes Place in A⁹⁾: Assuming that the flow is molecular, the transient isothermal flow along the axis of A will be expressed by the equation of diffusion

$$\frac{\partial c}{\partial t} = D \frac{\partial^2 c}{\partial x^2}, \quad (0 < x < l) \quad (1)$$

where c represents the concentration in A, D the diffusion constant and l the length of A. If c_1 , c_2 are the concentrations in V_1 and V_2 respectively and if $c=0$ at $t=0$, the approximate value of c_2 at time $t=t$ will be obtained as

$$c_2 = \frac{\pi r^2}{V_2} \int_0^t D \left(-\frac{\partial c}{\partial x} \right)_{x=l} dt, \quad (2)$$

where r represents the radius of A and V_2 represents the volume of V_2 . If $c_1 \gg c_2$ is always valid, the approximate value of the concentration gradient at $x=l$ can be obtained by solving Eq. (1) with the boundary conditions $c=c_1$ at $x=0$ and $c=0$ at $x=l$, and the initial condition $c=0$ at $t=0$ ($0 < x < l$).

The calculated variation of c_2 versus t is illustrated by the curve in Fig. 1. (b), which asymptotically approaches a straight line. If we elongate the asymptotic straight line to cut the time axis, we obtain the intercept L which is defined as the "time lag". For the system shown in Fig. 1. (a), it can be proved that

$$L = \frac{l^2}{6D}. \quad (3)$$

2.2. The Diffusion Process and the Time Lag when Adsorption Takes Place in A: The adsorption is expected to modify the rate of diffusion in the following way. If the adsorbed film is immobile as would be approximately correct at a very low pressure,

$$v \frac{\partial c_g}{\partial t} = v D \frac{\partial^2 c_g}{\partial x^2} - a \frac{\partial c_a}{\partial t}, \quad (4)$$

where c_g and c_a represent the concentration of the gas phase and the adsorbed film respectively, and v and a represent the total volume of the pores and the surface area of the adsorbent per unit length of A respectively. If one assumes that the adsorption equilibrium is reached very rapidly,

$$\frac{\partial c_a}{\partial t} = \frac{\partial f(c_g)}{\partial t} \quad (5)$$

and L can be evaluated from Eq. (4) and (5) for two limiting cases.

In the first case we assume that the amount of adsorption is proportional to the pressure. For this case Barrer⁸⁾ and Clausing¹⁰⁾ solved the problem in the following way. Namely, in this case,

$k_s c_g = c_a$ (6)

where k_s is a constant, and therefore Eq. (5) becomes

$$\frac{\partial c_a}{\partial t} = k_s \frac{\partial c_g}{\partial t} \tag{7}$$

From Eq. (4) and (7),

$$\frac{\partial c_g}{\partial t} = \frac{D}{\left(1 + k_s \frac{a}{v}\right)} \cdot \frac{\partial^2 c_g}{\partial x^2} \tag{8}$$

Thus the time lag L becomes

$$L = \frac{l^2 \left(1 + k_s \frac{a}{v}\right)}{6D} \tag{9}$$

Eq. (9) shows that L is independent of c_1 .

In the second case, it is assumed that the adsorption of the gas takes place completely in a region before the gas begins to diffuse into the next region.¹¹⁾ For this case, with an additional assumption that the diffusion constant of the adsorbing gas in A is fairly large compared to the migration velocity of the adsorbate, Clausing obtained a simplified solution in the following way.¹⁰⁾ Let the pressure at ∂x (Fig. 1 (a)) at an arbitrary moment be zero, and let N represent the number of adsorption sites per unit surface area of the adsorbent, and K the conductance

(a) Dry air

(b) Water vapour

Fig. 2. Time lag and build up of p_2 , in typical experiment.

per unit length of A. If all molecules which flow into δx during the time interval δt are adsorbed on the adsorption sites existing in δx , the following equation will hold:

$$\frac{Kc_1}{x} \delta t = Na \delta x. \tag{10}$$

Gas molecules will flow into the region next to δx only after the completion of adsorption on all sites in δx . Thus it will take a time L for molecules to occupy all sites in A before they begin to diffuse into V_2 . L can be obtained by integrating Eq. (10):

$$L = \int_0^t dt = \int_0^t \frac{Na x}{Kc_1} dx, \tag{11}$$

or

$$\begin{aligned} L &= \frac{1}{2} \frac{Na l^2}{Kc_1} \\ &= \frac{1}{2} \frac{N \times (\text{molar volume}) \times 760 \times T \times a \times l^2}{(\text{Avogadro's number}) \times 273 \times K \times p_1} \end{aligned} \tag{12}$$

where T represents the temperature of experiment in $^{\circ}\text{K}$ and p_1 is expressed in mm Hg. Eq. (12) shows that L is inversely proportional to p_1 .

2.3. *The Estimation of Adsorption by the Time Lag Method:* The time lag L' which an adsorbable gas (e.g. H_2O) of molecular weight M would show if it were non adsorbing can be estimated by the following relation, if we know the time lag L_0 of a non adsorbing gas (e.g. air) of molecular weight M_0 :

$$L' = L_0 \sqrt{\frac{M}{M_0}}. \tag{13}$$

This is because

$$D \propto \sqrt{M}. \tag{24}$$

The difference $L - L'$ will give an estimate of the amount of adsorption. As shown in Fig. 2 (a), (b), there actually is a very remarkable difference between the time lag of dry air and that of water vapour.

§ 3. Experimental

Samples used in this study are lead borosilicate glass (Nonex type), soda lime glass, OFHC copper, vacuum melted nickel and alumina ceramic (92~93 % Al_2O_3). Glass samples were crushed into 10~20 mesh particles, washed in tap water, distilled water, ethyl alcohol and ethyl ether successively. Metal samples were hacked into pieces of about 1×1 mm size, washed in water, ethyl alcohol and ethyl ether successively, and reduced in hydrogen. They were again reduced in dry hydrogen after the insertion into the apparatus. Alumina ceramic was crushed into 10~20 mesh particles, boiled in sulphuric acid for 1 hr., washed in water, and fired in a gas furnace at a temperature of 1100°C for 30 min^{*)}. The real surface area of each sample was determined by the BET method using ethylene as the adsorbate^{(12),(13)}

*) More detailed discussions of these treatments were reported in Ref. (7) and (13).

Table I. Condition of the Experiments.

Sample	Lead borosilicate glass	Soda lime glass			Copper	Nickel	Alumina ceramic
Shape	10~20 mesh particles	10~20 mesh particles			1×1 mm pieces	1×1 mm pieces	10~20 mesh particles
Weight (g)	38.5	→	23.3	25.3	93.0	56.1	33.0
Specific surface area (cm ² g ⁻¹)	67		33		6.0	40	57.5
Length of A (cm)	12.8	4.3	7.3	8.1	8.2	8.8	8.1
Radius of A (cm)	0.85	0.81	0.85	0.81	0.84	0.83	—
Conductance for dry air, K/l at 300°K (cm ³ sec ⁻¹)	14.3	60	36	29	70.7	63.2	66.7
Conductance for H ₂ O, K/l at 300°K (cm ³ sec ⁻¹)	18.1	76	45.5	36.5	89.8	80.2	84.6

(Table I). The water vapour was supplied from distilled water which had been thoroughly degassed and stored in the experimental apparatus.

The whole apparatus was constructed with Nonex type lead borosilicate glass, special taps without grease were used in high vacuum side. Details of this apparatus has been described elsewhere.⁷⁾

Prior to each experiment, the whole apparatus was baked out at 380°C in high vacuum and evacuated to a pressure of less than 1×10^{-8} mm Hg. The ion gauge with which p_2 was measured had been thoroughly processed by electron bombardment.

The pressure p_1 was kept at a constant value between 10^{-4} and 10^{-6} mm Hg by allowing the water vapour flow through a small leak into V_1 and evacuating it through a duct of appropriate conductance. p_1 was estimated by an oil manometer which was located in the high pressure side of the small leak. Throughout the time lag measurements, p_2 was maintained 10^{-7} mmHg to 10^{-8} mmHg so as to the relation $p_1 \gg p_2$ held at all times.

The water vapour which flowed into V_2 was examined by low temperature distillation. Hardly any decomposition products or impurities could be detected.

§ 4. Results and Discussions

The time lag versus pressure relation for each sample was obtained at a series of temperatures. The results for lead borosilicate

glass, soda lime glass and nickel are shown as examples in Figs. 3, 4 and 5 respectively.

The variation of time lag as a function of the tube length l was investigated for soda lime glass at 330°K and $p_1 = 2.1 \times 10^{-6}$ mm Hg, and is given in Fig. 6.

Fig. 4. Time lag of water vapour for soda lime glass.

Fig. 5. Time lag of water vapour for nickel.

Fig. 3. Time lag of water vapour for lead borosilicate glass.

The amount of adsorption at $p_1 = 2 \times 10^{-6}$ mm Hg was evaluated assuming Eq. (12). For this calculation, it is necessary to estimate K , the conductance of A. This can be carried

out in the following way: As is seen in Fig. 2, p_2 reaches a saturation value p_{2f} as time goes on because of the pumping action of the ion gauge with which p_2 is measured. In this saturation state, the following relation is known to hold:

$$\frac{K}{l} = \frac{p_{2f}S}{p_1 - p_{2f}} \quad (15)$$

In this equation, S is the rate of absorption of gas by ion gauge, which can be determined

Fig. 6. Time lag of water vapour as a function of length of A.

Fig. 7. Amount of adsorbed water vapour vs. temperature.

by the rate of pressure decrease in a known volume, and is approximately constant in this pressure region.¹⁴⁾ The values of K estimated in this way are given in Table I. The calculated amounts of adsorption for all samples investigated are illustrated in Fig. 7.

The following points can be concluded for all specimens studied: (1) The time lag L of water vapour is very much greater than the value estimated assuming no adsorption. (2) L is proportional to $\log p_1$ and l^2 (at least for soda lime glass). (3) The temperature coefficient of L is negative. (4) The $L \sim p_1$ relations are explained by neither of the assumptions in 2.2. (5) Therefore, the adsorption in this pressure region will not be a simple physical adsorption. (6) The amount of adsorption at 273°~403°K and $p_1 = 2 \times 10^{-5}$ mmHg is less than 1% of a monolayer (3.45×10^{-6} cc STP).¹⁵⁾

Barrer *et al.* elongated the $L \sim p_1$ curve (plotted to the ordinary scale) to cut the time lag axis and assumed this intercept to be the true time lag. They explained the pressure dependence of the time lag assuming that the molecules adsorbed on the completed first monolayer are mobile. In our cases, however, the above assumption is inadequate because the amount of adsorption is less than 1% of a monolayer.

The authors are indebted to Prof. K. Kinoshita for his kindness in reading the manuscript, to Prof. G. Tominaga and Prof. Y. Uemura for their kind discussions.

Specific Heats of Copper Ferrite

By Tohru INOUE and Shuhichi IIDA

*Department of Physics, Faculty of Science,
University of Tokyo*

(Received April 4, 1958)

The tetragonal distortion of the spinel structure such as CuFe_2O_4 , CuCr_2O_4 , NiCr_2O_4 , Mn_3O_4 , ZnMn_2O_4 , etc, has recently discussed. Among these, CuFe_2O_4 is the only one that is ferromagnetic at room temperature. The tetragonal distortion of CuFe_2O_4 was explained by Goodenough¹⁾ by using the idea of semicovalent bonding and recently by Dunitz et al.²⁾ by using the concept of Jahn-Teller effect. Bertaut³⁾ has found that CuFe_2O_4 becomes cubic after quenched from high temperature and concluded that the transition temperature from cubic to tetragonal is about 760°C. But this conclusion due to Bertaut is supposed to be incorrect because recently Miyahara and Ohnishi⁴⁾ showed this transition to occur about 400°C by means of X-ray high temperature camera and qualitative heat analysis. This transition temperature is below the magnetic Curie temperature. In this respect it should be noticed that Takei et al.⁵⁾ has early pointed out the existence of the anomaly at about 390°C from an abrupt change of the magnetization at constant magnetic field and Forrer et al.⁶⁾ has also pointed out the existence of the anomaly at about 360°C.

Fig. 1. Specific heats of copper ferrite

In this connection we have measured the specific heats for CuFe_2O_4 . The result is shown in Fig. 1. It shows clearly the presence of a λ -point at 390°C corresponding to transition from cubic to tetragonal. The peak at about 470°C is that associated with the magnetic transition of this material.

The apparatus used is the improved one of the Takagi Nagasaki's adiabatic calorimeter⁷⁾. The main heater which is situated outside of the copper container consists of the heating elements on the upper and lower surface of the cylinder as well as on the side, and inside of the main heater there is another outer heater for the fine adjustment.

The specimen was prepared as follows; the electrolytic iron and copper was dissolved in nitric acid, dried by infrared ray lamp, calcinated at 1000°C in air for 6 hours, and pressed into the shape of pot with lid. Then it was heated again at 1000°C for about 10 hours and annealed at about 900°C for several hours. The purpose of the last annealing is to transform all the cuprous ions into the cupric ions. The specimen was about 70 grams in weight. The measurements were performed at the pressure of about 0.04 mmHg and at the heating rate of 1.5 degrees per minute.

Inferring from the result of the measurement as high as 750°C, it is certain that there is no anomaly at 760°C. After rapid cooling in vacuum from 750°C, the anomaly at 390°C was disappeared. But it recovered again by an annealing in air at 900°C for several hours. The reason of this anomalous phenomenon might be due to the production of cuprous ions in the matrix and further study is now going on.

The Q -value for the $\text{N}^{14}(n, \alpha)\text{B}^{11}$ Reaction

Tadayoshi DOKE, Shoji SUZUKI
and Iwao OGAWA

*Department of Physics, St. Paul's
University, Tokyo*

(Received April 4, 1958)

A gridded ionization chamber, with a cylindrical

effective volume 18.5 cm. in dia. and 8 cm. in height, filled with a mixture of 1-atm. nitrogen and 3-4-atm. argon gas was irradiated by *D-D* neutrons from a Cockcroft-Walton accelerator, and the *Q*-value for the $N^{14}(n, \alpha)C^{11}$ reaction was determined from the pulse-height distribution obtained either with a single channel pulse-height analyzer or with a gray wedge analyzer. The mean deviation of positions of peaks in the measured spectra was about 20 kev.

D-D neutrons were produced by bombarding a thick heavy ice-target with 150 kev deuterons, and those neutrons which were emitted at nearly a right angle to the D^+ -beam were used to irradiate the chamber, since the neutron energy for this direction is least dependent upon deuteron energies,¹⁾ the energy in our case being $E_n = 2.40$ MeV. The distance from the ice-target to the chamber was so chosen that the energy-spread of incident neutrons due to the angular width would not exceed ± 0.05 MeV.

An example of pulse-height spectra thus obtained is shown in Fig. 1. Several peaks are clearly seen, and have been interpreted as noted in the figure.

The relationship between pulse-height and particle energy was calibrated with five natural alpha-sources having well-known particle energies²⁾ (U^{238} , U^{234} , Po, ThC and ThC'). The extrapolated pulse-height vs energy straight line crossed the energy axis at less than about 100 kev, in good accordance with Cranshaw and Harvey's results³⁾ for pure argon.

The average *Q*-value obtained from the (n, α) peak and E_n was $Q = -0.12 \pm 0.06$ Mev. On the other hand, *Q* became somewhat larger in the absolute value, when the neutrons in the 20° -direction to the D^+ -beam were used ($Q = -0.17$ Mev). This value is, however, less reliable because of the uncertainty in the estimation of neutron energies.

Also, the peak II in Fig. 1 was used tentatively to check the results above. This peak can be assumed to correspond to the well-known (n, α) resonance reaction at $E_n = 1.800 \pm 0.015$ Mev⁴⁾ caused by the stray neutrons having a continuous energy-spectrum in this energy region. Such an interpretation affords $Q = -0.18 \pm 0.05$ Mev, in agreement with the former result within the limits of probable error.

All these results give considerably smaller *Q*'s as compared with other authors'.^{5), 6)} However, ours are in fair agreement with the current mass-*Q*-value ($Q_m = -0.15 \pm 0.01$ Mev^{7, 8)}).

The reason that other authors—with the exception of Bollmann and Zünti—obtained too large values ($-0.2 \sim -0.5$ Mev) is perhaps that they did not take into proper account the appreciable in-

constancy, with respect to the particle species and energies, of the energy loss of the particle per ion pair for the undiluted N_2 -gas they used, as was pointed out by Bollmann et al.⁵⁾ To reduce this effect, Bollmann et al. used argon-diluted nitrogen,

Fig. 1. Typical Gray-Wedge Pulse-Height Spectrum. Peaks noted as I, II and III are due to the (n, α) and (n, p) resonance reactions induced by stray neutrons with certain corresponding energies.

but their figures (-0.28 ± 0.08 Mev) still exceed the current Q_m . This is probably due to the possible (systematic) error in their estimation of E_n 's, which might well become appreciable for the angle of neutron emission far different from a right angle.

J. PHYS. SOC. JAPAN. **13** (1958) 658**A Richter Type Magnetic Loss in Yttrium-Iron Garnet**

By Hisashi SEKIZAWA, Shūichi IIDA

*Department of Physics, Faculty of Science,
Tokyo University, Tokyo, Japan*
and Tomonao MIYADAI*The Electrical Communication Laboratory, Nippon
Telegraph and Telephone Public Corporation*

(Received April 4, 1958)

A magnetic loss of Richter type has been found in ferrites containing ferrous ions¹, and it is attributed to the electron diffusion, i.e. the exchange of electrons between Fe^{2+} and Fe^{3+} ions. A similar phenomenon was observed for yttrium-iron garnet $3\text{Y}_2\text{O}_3 \cdot 5\text{Fe}_2\text{O}_3$.

The specimen was prepared from 99.9% yttrium and high purity iron oxide. The constituent oxides were mixed and pressed into toroidal form about 3 cm in outer diameter. Then, it was fired at 1430°C for 6 hours in air and cooled in the furnace. X-ray diffraction pattern of the powder specimen which was prepared together with the toroidal specimen showed only the lines belonging to garnet phase with $a=12.37\text{ \AA}$. Complex permeability of the specimen at fixed frequencies (2, 1, 0.5 and 0.25 Mc/s) was measured by means of an impedance bridge varying the temperature from ca. 120°C to -180°C . The results are shown in Fig. 1. There is a distinct peak of $\tan \delta$ for each frequency which shifts to higher temperatures for higher frequencies. The logarithms

Fig. 1. $\tan \delta$ and μ' of yttrium-iron garnet.

— $\tan \delta$; after fired at 1430°C and cooled in furnace.
 --- $\tan \delta$, after heating up to 350°C .
 — μ ; (Appreciable change was not observed by the heating up to 350°C .)

of the frequency at which the maximum of $\tan \delta$ takes place were plotted against the reciprocal of the temperature and found to lie on a straight line as shown in Fig. 2. The activation energy E obtained from the slope of the line is about 0.50 eV .

Fig. 2. Plots of $\log f$ vs. $1/T$ of the maximum of $\tan \delta$ for yttrium-iron garnet.

No anomalous behaviour was found in the lower temperature range down to liquid oxygen temperature. (Another specimen with lower purity had similar peaks below liquid oxygen temperature for the same set of frequencies). The measurements were performed again after the specimen was heated in air up to about 380°C , fairly above the Curie temperature (237°C). The peaks of $\tan \delta$ vanished by this heat-treatment as shown also in Fig. 1.

Yttrium-iron garnet contains no divalent metallic ions in stoichiometric composition². But it has been found that the electrical resistivity of this garnet shows marked dependence on the firing temperature³, and it can be accounted for only by assuming the existence of ferrous ions in it. This fact points to the conclusion that the garnet can oxidize or deoxidize without accompanying any phase change but with an appearance of certain imperfections (interstitial atoms etc.), as it is the case for most of the oxides. Thus it is also possible in the garnet that ferrous and ferric ions coexist in the same crystal sites and the electron diffusion among these ions may couple with the direction of the magnetic moment, as it is in the case of ferrites. Although the value of the activation energy obtained is higher than the one observed usually in ferrites, it is too small to be accounted for by the ionic diffusion. The disappearance of loss peak upon oxydation supports the mechanism mentioned above.

On the Measurement of Isotope Abundance of Lithium with Mass Spectrometer

By Itiro OMURA and Nozomu MORITO

*Hitachi Central Research Laboratory
Kokubunji, Tokyo*

(Received April 1, 1958)

An absolute measurement of the isotope abundance ratio of lithium has been carried out with a mass spectrometer. The instrument used is the Hitachi Mass Spectrometer, RMU-5, with a single filament surface ionization source. Samples used are lithium chloride N_1 on the market (Koso Chem. Co., Inc.), and purified lithium chloride B_5 which was provided through the courtesy of Prof. Titani of Tokyo Metropolitan University. A droplet (about 0.2 cc) of aqueous solution (0.5 mg/l) is placed on the filament and dried.

The values of the ion abundance ratio ($^7\text{Li}/^6\text{Li}^+$) obtained were 12.48 ± 0.05 for the sample N_1 and 13.69 ± 0.05 for B_5 . The values which have been reported as the natural abundance ratio of lithium isotopes are scattered in a pretty wide range approximately from 11 to 13. The results for the sample N_1 lies in this range and without any correction according to the so-called isotope effect, it is equal to the value which has been believed to be the most reliable. The isotope constitution of the sample B_5 might have been changed during the purification¹⁾.

The change of the ion current and the ion abundance ratio after a sudden change of the filament temperature was observed. Other processes were tried successively after the current as the abundance ratio had become constant. In the first process the filament temperature was suddenly increased from 1025°C to 1075°C. In the second it was decreased from 1075°C to 1025°C for 30 seconds and again returned to 1075°C, while in the last process it was increased to 1175°C for 30 seconds and then reduced to 1075°C. After each of these processes, transient variation appeared not only in the current but in the abundance ratio, as is shown in Figs. 1 and 2.

The abundance ratio of potassium isotopes was measured for reference. The ratio $^{39}\text{K}/^{41}\text{K}^+$ obtained was 13.96 ± 0.05 . In this case, as well as in the case of lithium, the isotopic correction seemed to be unnecessary. Similar phenomena as shown in Figs. 1 and 2 were again observed.

The unexpected phenomena have a serious influence on the analysis, but their origin is not clear. The mechanism of surface ionization seems to be much complicated. Although there are several plausible reports published on the measurement of

Higher order Transitions in Double Nuclear Resonance Experiments in Solids

By N. Bloembergen

Harvard University, Cambridge,
Massachusetts, U. S. A.

(Received March 19, 1958)

Saito has in a recent paper¹⁾ discussed the narrowing of one nuclear (A) resonance, while the other nuclear (B) resonance is driven hard by a large radiofrequency field near the resonance frequency ω_B^0 . The experiments were conducted in TlF and TlBr. Saito mentions two observations, which remained unexplained:

(1) The A resonance becomes asymmetric, when the driving frequency ω_B is slightly off the resonance value ω_B^0 .

(2) The A resonance "collapsed" at first for intermediate values of driving field at the resonance frequency ω_B^0 , before the narrowed line appears for larger driving fields.

It is the purpose of this note to call attention to some higher order nuclear spin transitions. Their

existence has recently been demonstrated in double resonance experiments in cesiumhalides²⁾, and they may also account for the observations of Saito.

Consider for simplicity two nuclear species $I_A = I_B = \frac{1}{2}$, in a coordinate system rotating with the angular velocity ω_B . In this system of reference the B spins are quantized with respect to the effective field $H_B^{\text{eff}} = xH_B^{\text{rf}}(\omega_B) + z(\omega_B^0 - \omega_B)/\gamma_B$. The A spins are still effectively quantized in the z -direction. The magnetization of the B-spins in the ρ -direction, i.e. parallel to H_B^{eff} , which makes an angle Θ with the z -axis, can be obtained from Redfield's theory³⁾. This author also showed that the part of the interaction between a pair of A and B spins to be retained is

$$\mathcal{H}_{AB}^{\rho} = C_{AB} I_{z,A} [I_x^2, B \cos \Theta + \frac{1}{2} (I_{+,B}^2 + I_{-,B}^2) \sin \Theta] \quad (1)$$

$$C_{AB} = a_{AB} + (\gamma_A \gamma_B \hbar^2 \tau_{AB}^{-3} + b_{AB}) (1 - 3 \cos^2 \vartheta_{AB}). \quad (2)$$

Consider a radiofrequency field at the frequency $\omega_A = \omega_A^0 + \gamma_B |H_B^{\text{eff}}| = \omega_A^0 + \gamma_B H_B^{\text{rf}} \text{cosec } \Theta$. Energetically this field can induce transitions in which an A-spin is flipped from the positive to the negative z -axis ($\Delta m_A = +1$), and simultaneously a B-spin is reversed with respect to the effective field ($\Delta m_{\rho,B} = +1$). The matrix element for this double transition is by second order perturbation theory

$$\frac{(\frac{1}{2}, \frac{1}{2} | \gamma_A \hbar H_A^{\text{rf}} I_A^+ | -\frac{1}{2}, \frac{1}{2}) (-\frac{1}{2}, \frac{1}{2} | \frac{1}{2} C_{AB} I_{z,A} I_{+,B}^2 \sin \Theta | -\frac{1}{2}, -\frac{1}{2})}{\gamma_B \hbar H_B^{\text{rf}} \text{cosec } \Theta} \quad (3)$$

Since C_{AB} and $\gamma_B \hbar H_B^{\text{rf}}$ are of the same order of magnitude, this second order transition has an intensity comparable to the first order transition, in which only A spin is flipped ($\Delta m_B = 0$). Third and higher order transitions may also contribute appreciably²⁾. Clearly the inverse process has a matrix element of the same magnitude. The processes $\Delta m_A = -\Delta m_{\rho,B} = \pm 1$ also exist with a resonance frequency $\omega_A^0 - \gamma_B H_B^{\text{rf}} \text{cosec } \Theta$. The relative intensities of the three transitions are given by the following table:

Resonant Frequency	Relative Intensity
$\omega_A^0 + \gamma_B H_B^{\text{rf}} \text{cosec } \Theta$	$\{Z/(n_B^+ + n_B^-)\} (n_A^+ n_{B\rho}^+ - n_A^- n_{B\rho}^-) (C_{AB} \sin^2 \Theta / \gamma_B \hbar H_B^{\text{rf}})^2$
ω_A^0	$n_A^+ - n_A^-$
$\omega_A^0 - \gamma_B H_B^{\text{rf}} \text{cosec } \Theta$	$\{Z/(n_B^+ + n_B^-)\} (n_A^+ n_{B\rho}^- - n_A^- n_{B\rho}^+) (C_{AB} \sin^2 \Theta / \gamma_B \hbar H_B^{\text{rf}})^2$

Z is the number of nearest B neighbors to an A spin. $n_{B\rho}^+ - n_{B\rho}^-$ can be determined from Redfield's theory. It is zero exactly at resonance ($\Theta = \pi/2$), and has opposite sign on either side of ω_B^0 . $n_A^+ - n_A^-$ has the normal Boltzmann value for sufficiently weak fields $H_A(\omega_A)$.

It follows immediately that the absorption around ω_A^0 is asymmetric, and that the asymmetry should be reversed, if $\omega_B - \omega_B^0$ changes sign.

The "collapse" can be explained as a severe broadening of the line by second and higher order transitions, when $\gamma_B \hbar H_B^{\text{eff}} \leq C_{AB}$. From Fig. 2

and Table I of reference 1 it can be seen that the collapse indeed occurs in this range. For $\gamma_B \hbar H_B^{\text{eff}} > C_{AB}$ the higher transitions move away from the A resonance and become much weaker in intensity. The narrowing then becomes observable.

Polarization Reversal in Triglycine Sulphate Crystal

By Kiyasu ZEN'ITI, Kazuo HUSIMI
and Keisuke KATAOKA

Electrical Communication Laboratory,
Nippon Telegraph and Telephone
Public Corporation, Tokyo

(Received March 3, 1958)

Conventional methods for the study of switching processes in ferroelectrics use the switching current as the measure for switching of polarization. Such an observation cannot determine the absolute polarization of the crystal. We have applied the ultrasonic method¹⁾ to study the switching process of triglycine sulphate crystal and compared the results with those obtained by the conventional pulse method.

The crystals have been grown by S. Waku of this Laboratory by volatilization process. The sample used is 0.5 mm in thickness and 4 mm² in area of electrode which was prepared by vacuum evaporation of gold. The spontaneous polarization is 3.3 μc/cm², which is considerably larger than the value 2.2 μc/cm² already reported. The crystal is markedly piezoelectric in polarized state²⁾, which

makes it very favourable for the ultrasonic method.

After setting the crystal to negative

saturation by application of a field of 1.5 kV/cm for several seconds, the crystal is switched to the positive polarization step by step by successive application of voltage pulses from a pulse generator of low output impedance. The pulse widths are chosen from 10 μsec to 1 msec with logarithmically linear steps and the field strengths are from 1 kV/cm to 5.5 kV/cm with 0.5 kV/cm steps. The polarization vs. time curves are shown in Fig. 1 for the case of pulse height of 4 kV/cm.

As shown in Fig. 1 the switching velocity becomes very small near the saturation, therefore the value of switching times would depend much on its definition. We shall here define the switching time t_{α} by the equation

$$\int_0^{t_{\alpha}} i \cdot dt = (1 + \alpha) P_s$$

where i is the switching current and α is the degree of polarization on reversal measured from the depolarized point. In Fig. 2 are shown three switching times $t_{0.0}$, $t_{0.4}$ and $t_{0.8}$ as the function of the switching field.

In conventional pulse method, the switching current has a sharp peak followed by a long and gradually decreasing tail. Strictly speaking, the switching time cannot be defined unambiguously in such a case, but for convenience we determine observed switching times t_{0b} from the end of the tail, and these are also shown in Fig. 2.

The switching characteristics are influenced seriously by the crystalization conditions. The switching processes of another sample prepared in uncontrolled condition is shown in Fig. 3. Not only

is the switching time larger for this sample, but there appears an apparent saturation near 50% of the true saturation polarization. This apparent saturation occurs even in a good crystal when an unsuitable electrode material such as conductive point is used, or the sample is measured in damp environment. The apparent saturation in an uncontrolled sample may be due to the wide distribution of the polarizing rates of different parts of the crystal. In a good crystal, it is probably caused by a layer of low polarizing rate which is formed under the surface by the surface condition such as electrode material or moisture.

Preliminary Announcement of Meetings of the Physical Society of Japan

1. Annual Meeting

The Annual Meeting for 1958 of the Physical Society of Japan will be held at the University of Kyoto, Kyoto, during October 15~20, 1958. There will be the following sections:

Theory of elementary particles. Nuclear reaction and nuclear structure (theoretical and experimental). Cosmic rays. Radiation physics. Ionic crystals. Optical properties of matter. Lattice imperfections. Plastic properties of matter. Metals. Magnetism. Dielectrics. Semi-conductors. Atoms and molecules. Low temperature physics. Statistical mechanics. Biophysics. High polymer physics. Electric discharge and plasma physics. Applied mathematics and mechanics. X-rays and electron diffraction. Optics. Apparatus and techniques. Acoustics.

There will be several sessions for invited papers and general lectures besides the sessions for contributed papers.

2. Symposium on Lattice Imperfections

A Symposium on Lattice Imperfection will be held in conjunction with the Annual Meeting. English will be adopted as the formal language of this symposium. Professors Maurer and Brown of Illinois University are being invited to give lectures.

Isotope Shift in the Spectrum of W I*

By John A. VREELAND

*Westinghouse Electric Corporation, Atomic Power Department,
Pittsburgh, Pennsylvania, U.S.A.*

and

Kiyoshi MURAKAWA

*Institute of Science and Technology, University of Tokyo,
Komaba-machi, Meguro-ku, Tokyo*

(Received March 13, 1958)

By use of samples enriched in W^{183} and W^{180} respectively and of natural tungsten the isotope shift in the spectrum of W I was measured, and the ratio of the shift of the neighboring even isotopes was determined. The result is

$$\Delta\nu(186-184) : \Delta\nu(184-182) : \Delta\nu(182-180) = 83 \pm 2 : 100 : 66 \pm 5.$$

Discrepant result of other observers is considered to be due to the neglect of the disturbing effect of the W^{183} -components.

§ 1. Introduction

Using separated tungsten isotopes whose compositions are shown in Table I, Vreeland and Murakawa¹⁾ (referred to as Part I) measured the isotope shift of the even isotope in the hyperfine structure (hfs) of the spectrum

Table I. Isotopic constitution (percent) of the samples of tungsten.

Sample label	Isotope				
	180	182	183	184	186
183	0.098	4.19	86.21	7.14	2.36
180	4.95	50.75	15.28	17.89	11.14
Natural	0.14	26.4	14.4	30.6	28.4

of W I and calculated the nuclear magnetic moment of W^{183} . The isotope shift can be easily studied in the line $\lambda 4269$, owing to the large magnitude of the shift, but unfortunately this line was masked by the strong aluminum hydride band. Somewhat later, using natural tungsten, Murakawa²⁾ (referred to as Part II) studied the hfs of $\lambda 4269$ and of some other lines, and determined the ratio of the shift of the neighboring even isotopes: $\Delta\nu(186-184) : \Delta\nu(184-182) = 1 : 1.206 \pm 0.010 = 83 \pm 1 : 100$. Two years ago, using natural tungsten again, Murakawa³⁾ (referred to as Part III) detected

a component due to W^{180} in the hfs of $\lambda 4269$ and gave the ratio of the even isotope shifts: $\Delta\nu(186-184) : \Delta\nu(184-182) : \Delta\nu(182-180) = 1 : 1.206 \pm 0.010 : 0.88 \pm 0.07 = 83 \pm 1 : 100 : 73 \pm 7$. Subsequently Barr and Jenkins⁴⁾ (referred to as

Fig. 1. Enlargement of the interference patterns of the spectrum of W I.

* The work with separated isotopes was performed in the University of Wisconsin in 1950-1951 and was supported by the U.S. Office of Naval Research.

B and J), using a sample enriched in W^{180} , measured the same ratio and obtained $\Delta\nu(186-184): \Delta\nu(184-182) = 88:100:68$.

The ratio $\Delta\nu(184-182): \Delta\nu(182-180)$ given in Part III is in agreement with B and J within the experimental error of Part III, but the ratio $\Delta\nu(186-184): \Delta\nu(184-182)$ given in Part II (and also in Part III) differs from that of B and J beyond the limit of error of Part II.

The above-mentioned ratio was obtained in Parts II and III mainly by studying the hfs of $\lambda 4269$, whereas the conclusion of B and J is based on the hfs of $\lambda 5015$ and $\lambda 4983$ ⁶⁾. In order to study the hfs of $\lambda 5015$ and $\lambda 4983$, samples enriched in W^{183} and W^{180} respectively (in addition to natural tungsten) must be used. The plates that were taken previously using separated isotopes have now been re-measured, confirming Parts II and III, and a result which

is more accurate than Part III has been obtained.

§ 2. Experimental Procedure

As a light source a liquid-air cooled or water-cooled aluminum hollow-cathode discharge tube was used, whose construction was described by Arroee and Mack⁶⁾. Neon was used as carrier gas. The hfs was resolved by a silvered Fabry-Perot etalon. Some of the interference patterns are reproduced in Fig. 1.

§ 3. Result of Measurement

In each sample (see Table I) the isotope W^{183} is present and disturbs the determination of the positions of the components of W^{184} and W^{182} . On the other hand the sample W^{183} contains the isotopes W^{184} and W^{182} (in addition to W^{183} , W^{186} and W^{180}) and the

Fig. 2. Hfs of $WI \lambda \lambda 5515$, and 4983 .

determination of the positions of the components of W^{183} ($I=1/2$) is disturbed by the components of W^{184} and W^{182} .

We have therefore measured the patterns of both natural tungsten and W^{183} and adjusted the positions of the components due to

W^{184} and W^{182} , so that both sets of analysis may be consistent with each other (see Figs. 2 and 3)⁷⁾. It was assumed that the center of gravity of the W^{183} -components lies just midway between the W^{184} - and W^{182} -components (Part II).

In Figs. 2 and 3 the hfs of the term $5d^4$ ^5D was calculated assuming that the configuration $5d^4$ is of LS-coupling: Sogo and Jeffries⁸⁾ $\mu(W^{183})=0.115\pm0.001$ nm was used; Racah's value⁹⁾ $\zeta(5d)=2089$ and the effective charge¹⁰⁾ $Z^*(5d)=74-20=54$ were assumed. This calculation would be sufficient for a one-digit discussion of the hfs of $5d^4$ ^5D . In the case of $\lambda 4404.5$ (Fig. 3), the interval factor of the level $5d^4$ $^3P_2^a$ is required. Since another level with $J=2$ lies near, an assumption of pure LS-coupling would certainly be a poor approximation for $^3P_2^a$, so that we have left the hfs of $^3P_2^a$ undetermined. In adjusting the positions of the components of W^{184} and W^{182} for $\lambda 4404.5$ the component a was neglected.

Fig. 3. Hfs of W I $\lambda\lambda$ 5015, 4887, and 4404.5. A number in parentheses was calculated.

Since this has only a small intensity, it would have a small influence on the determination of these components.

The position of the component W^{180} was measured by a comparator and a microphotometer. It was found that only the distance $W^{186}-W^{180}$ can be measured accurately. From this the calculated distance $W^{186}-W^{182}$ was subtracted and the distance $W^{182}-W^{180}$ was obtained. The best accuracy was attained for $\lambda 5515$ (Figs. 1 and 2). In the case of $\lambda 4983$ the accuracy is somewhat less. The component W^{180} of $\lambda 5015$ appears over-exposed on all the plates that were taken using the sample W 180, so this was abandoned.

In our first publication (Part I) the process of obtaining the positions of W^{182} and W^{184} was somewhat different from that adopted in the present measurement, but we consider

Fig. 4. Hfs of W I λ 4269. A number in parentheses was calculated.

the distance $\Delta\nu(182-180)$ obtained in the present work to be more accurate than Part I. The ratio of the distances of the neigh-

boring isotopes that was determined from Figs. 2-4 (the hfs of $\lambda 4269$ is shown in Fig. 4 for the sake of completeness) is summarized in Table II, and the weighted mean is

$$\Delta\nu(186-184):\Delta\nu(184-182):\Delta\nu(182-180) \\ = 83 \pm 2:100:66 \pm 5.$$

Table II. Isotope shift in W I.

Line	$\Delta\nu(186-184):\Delta\nu(184-182):\Delta\nu(182-180)$			
$\lambda 5515$	84	:	100	: 66
$\lambda 5015$	83	:	100	
$\lambda 4983$	83	:	100	: 66
$\lambda 4887$	85	:	100	
$\lambda 4404$	82	:	100	
$\lambda 4269$	83	:	100	

The value of $\Delta\nu(186-184):\Delta\nu(184-182)$ given here is in agreement with Part II (and Part III), but not with the result of B and J. The value of $\Delta\nu(184-182):\Delta\nu(182-180)$ given here is in agreement with Part III and with B and J. B and J do not mention the use of separated isotope W 183. Since the isotope shift is small (of the order of 0.05 cm^{-1}) in the case of $\lambda 5015$ and $\lambda 4983$ which were studied by B and J, the effect of the presence of W¹⁸³ in the sample would certainly be not negligible. We therefore hope that by introducing correction due to the components of W¹⁸³ to the data of B and J, the ratio $\Delta\nu(186-184):\Delta\nu(184-182):\Delta\nu(182-180)$ deduced from their data would come closer to our value.

Full details concerning the hfs of W¹⁸³ (magnetic effect) will be published elsewhere.

On the Electrical Properties of Polycrystalline Boron

By Ryosei UNO

Scientific Research Institute, Komagome-Kamifujimae, Bunkyo-ku, Tokyo, Japan

(Received January 23, 1958)

Several specimens of polycrystalline boron, which have various electrical conductivities at room temperature, ranging from $8(\text{ohm cm})^{-1}$ to 5×10^{-3} or less, were obtained by reduction of distilled boron tribromide. The spectroscopic analysis and the observation by the Debye-Scherrer X-ray pattern were carried out. Some evidence was obtained showing that the conductivity at room temperature may not increase with the amount of impurities but it depends rather on the difference in the crystal structure. Assuming a simple model, carrier concentration and mobility were estimated from the data of conductivity and thermoelectric power. The result was that the carrier concentration may be nearly constant over the range from 100 to 1000°K and that the mobility may vary exponentially with the reciprocal of absolute temperature.

§ 1. Introduction

Electrical properties of bulk boron and boron films have been investigated by several workers, and an extensive survey of the experimental results together with some optical properties was given by Moss.¹⁾ Weintraub²⁾ found the specific conductivity of bulk boron, produced by reduction of boron tribromide by hydrogen using high voltage electric arc, to be $5.9 \times 10^{-7} \Omega^{-1} \text{cm}^{-1}$ at 23°C , increasing to about $1 \Omega^{-1} \text{cm}^{-1}$ at 1000°C and the thermal activation energy to be about 1.25 eV. According to Laubengayer *et al.*,³⁾ however, the increase of electrical conductivity of a single crystal of boron prepared by them was less than one hundred fold between 20 and 600°C corresponding to an activation energy of less than 0.35 eV. Moreover, a measurement carried out by Henninger⁴⁾ on the bulk boron prepared by Weintraub²⁾ suggested that the specimen might have layers of low conductivity and the true conductivity of boron might be very low and have a small dependence on temperature. Recently, Lagrenaudie⁵⁾ measured various properties of boron on three groups of samples, *viz.*, those obtained by dissociation of boron tribromide, those obtained by cracking of boron hydride on glass plate, and those obtained by fusion of amorphous boron. Samples produced by the dissociation seem to be very pure and consisted of considerably large crystalline grains. Samples

produced by the fusion were impure and those by cracking on glass were pure but amorphous. All the samples were *p*-type semiconductors, having an intrinsic activation energy of about 1.2~1.3 eV according to the measurements on electrical conductivity, optical transmission and photoconductivity. Several impurity levels, having activation energies of 0.06, 0.30, 0.40, 0.50, 0.60 and 0.84 eV, were also obtained from the gradient of curves of conductivity versus the reciprocal of absolute temperature. It was also reported that the Debye-Scherrer X-ray pattern of the sample produced by dissociation contains new lines other than those observed by Laubengayer. The rectification of boron was hardly observed, and the mobility of carrier was reported to be small because Hall effect could not be observed, and a value of $3 \text{ cm}^2/\text{volt-sec}$ was estimated from an observation of the current variation due to induced charge. It may be concluded from his experiments that the energy difference between the valence band of boron and the first excited band is about 1.2~1.3 eV. Anomaly of the reflection of light was not observed at the absorption edge and the observed difference of absorption, between samples produced by dissociation and those by fusion, could not be interpreted by the difference in the amount of impurities. Johnston *et al.*⁶⁾ measured the temperature dependency of specific heat of boron and obtained a rather high value of 1219°K as the Debye characteristic temperature, between 60 and 150°K , which may be consistent with the small mobility.

* Now at Faculty of Literature and Science, Nihon University, Kamikitazawa, Setagaya-Ku, Tokyo.

In our experiments, several specimens of boron of different impurity contents were produced by the reduction of boron tribromide using more or less different procedures. Measurements made on these samples showed that the electrical conductivity did not depend much on the amount of impurities but might depend rather on the crystal structure of the samples. Measurements of the temperature dependence of electrical conductivity, thermoelectric power and Hall constant at temperatures between 100 and 1000°K, were also carried out in order to obtain some information about carrier concentration, mobility, effective mass and energy band structure. However, our measurements of Hall voltage using both direct current and alternating current carried out over a temperature range from 150 to 600°K were unsuccessful on account of very small Hall voltage. An analysis, therefore, was carried out using the data of thermoelectric power and electrical conductivity. The result obtained using a simple model was that the carrier concentration may be nearly constant over the range from 100 to 1000°K and that the mobility vary exponentially with the reciprocal of absolute temperature.

§ 2. Preparation of Samples

The preparation of samples was described in detail in the previous paper.⁷⁾ Following the method used by Laubengayer *et al.*,³⁾ powder of boron was made from boron oxide by the reduction with magnesium, which was then changed over to boron tribromide. After the distillation, boron tribromide was thermal-

ly decomposed or reduced by hydrogen and the samples of pure boron were obtained. Five processes differing slightly from one another were used in this final procedure and samples having different properties were obtained.

In the first process, the boron was thermally decomposed in vacuum and pure boron was deposited on the filament of tantalum or tungsten. Bromine liberated was taken off by allowing it to combine with mercury. By this process, only sample No. 1 was obtained. In the second process, mixture of hydrogen and a small amount of boron tribromide vapour was allowed to flow through the reduction chamber in which the filament was held at a high temperature. Bromide was reduced at the filament and boron was deposited on it. No mercury was used except on glass taps, and blocks of boron large enough for our purposes were obtained. The reduction was carried out at a temperature of about 1300~1400°C, which was measured by an optical pyrometer looking through the glass wall of the reduction chamber. As the wall was blurred, the value of the temperature measured might have been lower than the actual temperature and could serve only as an indication. (from No. 2 to 10) By spectroscopic analysis of a sample produced by this process, some traces of mercury and beryllium was found. In the third process, silicone grease was used for glass joints and taps of the chamber to avoid mercury. The reduction was carried out at 1200~1300°C. (No. 11 to 17) The sample made by this procedure con-

Table I. The results of spectroscopic analysis.

Process	Sample		Impurities									Total	Reduction
	for electrical measurement	for spectroscopic analysis											
			C	Na	Mg	Al	Si	Ca	Ni	W	Pb

	20	f					6				6	12	
Fifth	21	g			0.4		2					2.4	1150~1200°C

tained some silicon according to spectroscopic analysis. (Table I) In the fourth process, ordinary grease for high vacuum was used in place of silicone grease, attempting to reduce silicon. The reduction temperature was about 1100°C. (No. 18 and 20) The sample made in this process was not so pure as those in the third, in spite of reducing the amount of silicon. (see Table I) The boron tribromide used in this process was the same bromide as that used in the third process which had been kept in a container of hard glass for about half a year after the third process was carried out. It seems probable that bromine liberated from tribromide had attacked glass walls and produced various bromide during this period. In view of this, the reduction of bromide was carried out in the fifth process, as soon as possible after the distillation. The process used was that of the fourth. The reduction temperature was 1150~1200°C. (No. 21) The sample obtained in this way was the purest as shown in the table. There was an optimum reduction temperature for getting a large block of boron. If the temperature was too high, local heating was apt to occur in the filament and it was broken before a block of boron had grown up sufficiently. If the temperature was too low the rate of reduction was too low for a block of sufficient size to be grown in a few days.

All the samples used for the measurement were obtained when tantalum ribbon was used as the filament. After removing the tantalum ribbon and grinding with carborundum and water, specimens up to $(5\sim10) \times (1.0\sim1.5) \times (0.3\sim0.6)$ mm³ were prepared for the measurement.

The spectroscopic analysis were carried out on the material which were taken from the same blocks as those used in preparing samples for the electrical measurements. As the quantitative spectroscopic analysis was difficult, only relative amount of impurities are determined, assuming it to be proportional to the density of spectral line divided by its arc intensity value. As copper electrode was used, the content of copper could not be

determined. The results are shown in Table I along with the reduction temperature. A sample produced in the third process was compared with commercial boron which contained 1.5 % carbon and 1 % other impurities, by a spectroscopic analysis using carbon electrode.* It is concluded that the impurity content of this sample may be about the same as the commercial boron. Samples obtained in the second and fifth process seem to be purest, about 99.5 %, and those in the third are most impure.

§ 3. Debye-Scherrer X-ray Patterns

Debye-Scherrer X-ray patterns obtained for various samples are shown in Fig. 1 together with that obtained by Laubengayer *et al*³⁾ on a tetragonal single crystal of boron (not ideal).

Fig. 1. Debye-Scherrer X-ray patterns, with that observed by Laubengayer *et al*, for reference.

They show that the crystal structure of our specimens except No. 20 is similar to that of the single crystal. The ideal structure of tetragonal single crystal of boron was reported by Hoard³⁾ to have a axis of 8.73 ± 0.02 Å and c axis of 5.03 ± 0.02 Å. Its unit cell contains four deformed isocahedra and four large holes, two of which are occupied by special atoms having only four first neighbours, interspread among the very compact isocahedral groups.

* For this spectroscopic analysis, we are indebted to Dr. Matsuo of Matsuda Research Laboratory, Tokyo-Shibaura Electric Co. Ltd.

The patterns shown in Fig. 1 indicate that No. 14 and No. 21 have the same structure although they may contain different amount of impurities, and that No. 14, 15 and 16 have different structures in spite of having nearly the same amount of impurities and that No. 21 shows a reflection from a plane of large spacing and its pattern resembles that of No. 1.

The pattern like that observed by Lagrenaudie⁶⁾ on a boron sample produced from boron tribromide was not observed.

§ 4. Electrical Conductivity

The electrical properties of the samples prepared in the first and second processes were reported previously.⁷⁾ In the previous

tween 120 and 1000°K. To assure good electrical contacts with the electrodes and probes, usual technique of sputtering of gold or platinum was used. The specimen was held in vacuum of about 10^{-3} mmHg during the measurements. It was verified on some of the typical samples that Ohm's law is satisfied in the range between 0.1 and 1.6 V/cm at room temperature and at about 700°K.

The results are shown in Fig. 2. Conductivities of all the samples increase exponentially with reciprocal of absolute temperature, showing that they have the usual characteristics of semiconductor. Absolute value of each curve may contain some error, because the shapes of some samples are irregular. If the conductivity in the range of straight line in Fig. 2, is expressed by the relation

$$\sigma = \sigma_0 \exp \left(-\frac{E}{2kT} \right) \quad (1)$$

where E , k , T and σ_0 are the activation energy, Boltzmann's constant, absolute temperature and some constant respectively. The value of E 's shown in the figure may be obtained for the points indicated on the curves. These values are not inconsistent with those obtained by Lagrenaudie⁶⁾ and others.¹⁾

All the samples seem to have intrinsic conductivity of about $10 \Omega^{-1} \text{ cm}^{-1}$ at 1000°K but their conductivity differ at lower temperatures from sample to sample, showing a structure sensitive characteristics. According to the usual interpretation of the behaviour of semiconducting characteristics, the higher conductivity should correspond to a lower amount of impurities.

However, this does not seem necessarily to be the case for our boron samples. For example, No. 21 and No. 14 have almost the same conductivity, although the former seems to contain much smaller amount of impurities. On the other hand, No. 14, 15 and 16 which may contain about the same amount of impurities, show considerably different behaviours in conductivity. It seems, therefore, necessary to look for some other causes than

Fig. 2. Electrical conductivity.

report, the results on two kinds of boron, the one showing low conductivity (No. 1) and the other showing high conductivity (No. 3, 4 and 5) at room temperature, were presented. In the present paper, the results on the samples showing intermediate conductivity were included as well as the main results previously reported.

Electrical conductivity was measured by direct current in the temperature range be-

the impurity content of the samples to explain the difference in conductivity at lower temperatures. In this respect, it may be worth noting that the samples showing the same Debye-Scherrer pattern, No. 14 and 21, have almost the same conductivity and those showing different patterns, No. 14, 15 and 16, have different conductivities. It is also probable that there are some correlation between the temperature of reduction and the conductivity, that the samples reduced at lower temperature in the process of preparation generally show lower conductivity. Those facts suggest that the conductivity of boron depends, unlike usual semiconductors, more on the structure of the crystal than on the impurity content.

§ 5. Thermoelectric Power

Thermoelectric power Q was measured in the temperature range between 150 and about 1000°K. In the measurement above room temperature, the sample was placed between two electrodes of copper each of which had an auxiliary heater to produce temperature difference across the sample. Temperatures at both ends of the sample were measured with an alumel-chromel thermocouples of 0.25 mm in diameter, which were welded to each electrode. The entire system was held in a quartz tube which was evacuated and heated electrically. The observation below room temperature was conventionally carried out with an apparatus, only one electrode of which had an auxiliary heater. The apparatus was covered with a glass tube and immersed in liquid air. The temperature was measured by copper-constantan thermocouple. The thermoelectric power was obtained from the gradient of the thermoelectromotive force versus temperature difference across the sample, because the thermoelectromotive force did not vanish when the temperature difference measured was zero, although the relation between the electromotive force and the difference was almost linear. This arose probably from the small difference in temperature between the point on the sample where the electrode was applied and the point at which the temperature was measured.

All the samples measured were p -type and the results are shown in Fig. 3. In Fig. 4 the thermoelectric power is plotted against

the logarithm of the absolute temperature, showing that there is approximately a linear relation expressed by

$$Q = Q_0 + \alpha \log T \tag{2}$$

where Q_0 and α are constants. It seems that the sample showing lower conductivity at room temperature has larger value of α .

Fig. 3. Product of the thermoelectric power and the absolute temperature.

Fig. 4. The thermoelectric power against the logarithm of the absolute temperature.

§ 6. Carrier Concentration and Mobility

Carrier concentration and mobility of the boron samples were analysed from the data of conductivity and thermoelectric power.

As the samples are all p -type, all the carriers were assumed to be holes in a single band. According to the expression used by Johnson and Lark-Horovitz,⁹⁾ the product of thermoelectric power and the absolute temperature is given by,

$$eTQ = L_2/L_1 - \zeta \quad (3)$$

where $L_j = \int_0^\infty \varepsilon^j l \frac{\partial f}{\partial \varepsilon} d\varepsilon$, ζ is the Fermi energy, f the Fermi distribution function, ε the energy of holes, l the mean free path of holes, taking $\varepsilon=0$ at the top of valence band. If we assume the mean free path is independent of energy (lattice scattering),

$$\begin{aligned} L_2/L_1 &= - \frac{2 \int_0^\infty \varepsilon f(\varepsilon, \zeta) d\varepsilon}{\int_0^\infty f(\varepsilon, \zeta) d\varepsilon} \\ &= 2kT \frac{F_{1/2}(\eta)}{F_0(\eta)} \end{aligned} \quad (4)$$

where $F_j(\eta) = \int_0^\infty \frac{x^j dx}{e^{x-\eta} + 1}$ and $\eta = \zeta/kT$. $F_1(\eta)/F_0(\eta)$ can be calculated by the expressions given by Stoner¹⁰⁾ when $\eta < 0$ or $\eta > 5$. For the region $0 < \eta < 5$ numerical calculation was carried out.* As L_2/L_1 was calculated as a function of ζ and T , the Fermi energy ζ was obtained as a function of temperature, substituting the experimental values of thermoelectric power in Eq. (3).

The concentration of holes was then calculated from

$$n_p(T) = 2 \int_0^\infty D(\varepsilon) f(\varepsilon, \zeta(T)) d\varepsilon$$

where $D(\varepsilon)$ is the level density. If it is assumed that the ε -space has spherical symmetry, $D(\varepsilon)$ will be given by,

$$D(\varepsilon) = \frac{1}{4\pi} \left(\frac{2m^*}{\hbar^2} \right)^{3/2} \varepsilon^{1/2}$$

where m^* is the effective mass. Thus we get

$$\begin{aligned} n_p(T) &= 2 \int_0^\infty \frac{1}{4\pi} \left(\frac{2m^*}{\hbar^2} \right)^{3/2} \varepsilon^{1/2} f(\varepsilon, \zeta) d\varepsilon \\ &= \frac{1}{3\pi} \left(\frac{2m_0}{\hbar^2} \right)^{3/2} \left(\frac{m^*}{m_0} \right)^{3/2} (kT)^{3/2} F_{1/2}(\eta) \end{aligned} \quad (5)$$

where m_0 is the mass of electron. $F_{1/2}(\eta)$ can be calculated in the same way as $F_1(\eta)/F_0(\eta)$. If we assume that m^* is equal to m_0 ,

* The result of our calculation is in good agreement with those of H. Weiss, Z. Naturforschg. 11a (1956) 13.

the value of $n_p(T)$ can be obtained from Eq. (5), using the known value of $\zeta(T)$ given above. Finally, the mobility of holes $\mu_p(T)$ was obtained from $\mu_p(T) = \sigma(T)/en_p(T)$ using the experimental value of conductivity $\sigma(T)$.

The mobility may be obtained from Seitz's theory¹¹⁾ of the mobility in homopolar crystal which gives

$$\mu_p = 6 \frac{e}{m^*} \frac{c^2 \hbar^4}{C^2 k T} \frac{M_0}{m^{*2}} n_0 \sqrt{\frac{\pi m^*}{8kT}}$$

where M_0 is atomic weight, c the sound velocity, n_0 the density of unit cell and the constant C can be approximated by

$$C(eV) = 1.7 \times 10^{-2} \Theta$$

where Θ is the Debye characteristic temperature. In evaluating this expression, the value of 1220°K, obtained from the observation on specific heat, was used for the Debye temperature. The sound velocity was interpolated as 1.4×10^6 cm/sec from a measurement of the threshold energy of various metals for sputtering.¹²⁾ The density of unit cell was obtained assuming that the crystal structure of our specimens agree with those reported by Hoard *et al.*⁸⁾ The result of the calculation gives $2.9 (m_0/m^*)^{1/2}$ cm²/volt-sec as the value of the mobility at 300°K. To equate the value of mobility just obtained to the value obtained from the analysis of experiment,

Fig. 5. The Fermi energy.

m^* must be taken equal to $150 m_0$ for the sample No. 16 at room temperature. Such a large effective mass may be unreasonable, and it was thought preferable to assume m^* equal to m_0 in the later analysis.

The results of the analysis are shown in three figures. Fig. 5 gives the temperature dependency of Fermi energy, Fig. 6 the carrier concentration and Fig. 7 the mobility. Below 500°K the Fermi energies of the specimens

are all positive, that is, they lie in the valence band at low temperature. The carrier concentration remain nearly constant from about 100 to 1000°K. The mobility varies exponentially with $1/T$. This dependence on $1/T$ is not so usual as a semiconductor.

The assumption made in the analysis may be too simple to interpret the properties of boron. From the temperature dependency of conductivity (Fig. 2), several acceptor levels may be assumed to exist, but, if such levels

Fig. 6. Carrier concentration.

Fig. 7. Mobility.

are present, TQ (Fig. 3) must be constant in some range of temperature. It was not the case, however, the energy of the acceptor level could not, therefore, be obtained from the thermoelectric power. The very simple model was chosen only for simplicity. The results of analysis, of course, depend on the assumption we have made, but the dependence of mobility on the temperature obtained, resembles those of NiO reported by F. J. Morin.¹³⁾

§ 7. Discussion

It was suggested above that the conductivity of boron may depend more on the structure of crystals than on the impurity contents. The first evidence which indicated this is the fact that sample No. 1 and No. 20, which have smaller conductivities (Fig. 2) compared to other samples have a line in the Debye-Scherrer photograph (Fig. 1) showing the existence of an extremely large spacing. The existence of this large spacing seems to show that the structure of these samples is monoclinic¹⁴⁾ whose axis are reported to be $a=10.0 \text{ \AA}$, $b=17.8 \text{ \AA}$, $c=8.8 \text{ \AA}$ and $\beta \approx 90^\circ$. Most of the other samples which lack the evidence of this large spacing is expected to belong to the tetragonal structure as already reported above.

In the case of tetragonal crystals, the ideal structure has four large holes in a unit cell, two of which are always occupied. It has also been reported¹⁵⁾ that the Fourier projection of electron density on (001) plane gave a definite evidence for the presence of occasional "extra" boron atoms in these vacant holes. It seems most probable that these holes can be filled with extra boron atoms to a varying degree for different specimens. If this is the case, it may result in the difference of various properties such as electrical conductivity, density, and the difference of the intensities of Debye-Scherrer rings. All the atomic position of ideal structure are given by Hoard⁸⁾ in terms of $D_{2d}^8-P\bar{4}n2$. Two of 50 atoms occupy the position 2(b) and 48 atoms the position 8(i). As the position 2(a) has the same symmetry properties as 2(b), it seems probable that the extra atoms may occupy the position 2(a) partially. An attempt was made to calculate the intensity of Debye-Scherrer patterns by assuming various degree of occupation, but consistent results could not be obtained yet.

The densities of samples were measured by floating method and the results are shown in Table II, along with the conductivity at room temperature. If the extra atoms occupy the position 2(a) partially, the value of the density should fall between 2.31 and 2.40. The observed densities of the samples No. 14, 15 and 16, however, exceed the upper limit of 2.40. As those samples are prepared by

the third process which gave the highest impurity content, this shows that the contribution of impurities must not be neglected in evaluating density, and therefore, it is not possible, in this case too, to set the relation between the degree of occupation and the density by straightforward calculation. As the position 2(a) and 2(b) have four nearest neighbours, it seems that some silicon atoms which were observed as impurities, may occupy these positions in place of boron atoms as they prefer to have four nearest neighbours. Nevertheless, there is some indication among No. 14, 15 and 16, that the sample having higher density shows higher conductivity.

Table II. The densities and the conductivities at room temperature.

Process	Sample	Density gr/cm ³	Conductivity at room temperature ohm ⁻¹ cm ⁻¹
Third	No. 14	2.510	1.5
	15	2.436	9.4×10^{-2}
	16	2.444	5.3×10^{-1}
Fourth	20	2.362	5.0×10^{-3}
Fifth	21	2.362	1.3

As the samples we have used were all polycrystalline, the grain boundary may give some influence on the observed conductivity. As preliminary measurement⁷⁾ of high frequency effective resistance in the range from 100 to 5×10^6 cycles at and above room temperature showed that the decrease of resistance at higher frequency was observed on the sample No. 1 but not on No. 5. Lagrenaudie¹⁶⁾ also observes a dispersion of resistance at low temperature. More detailed experiment are in progress.

Morita¹⁷⁾ observed the optical properties of boron film produced by the evaporation of our sample, in visible and near infrared. He observed that the absorption edge lie at about 1μ , corresponding to the activation energy of 1.2 eV. Lagrenaudie also observed the edge at about 1μ , on the optical transmission and photoconductivity experiment. This optical properties may be inconsistent with the constancy of carrier concentration over wide temperature range except when the concentration is very large.

Recently a report of Shaw, Hudson and Danielson¹⁸⁾ appeared on the electrical prop-

erties of the single crystal of boron. Their result on the electrical conductivity is in good agreement with ours which is obtained from the experiment on the polycrystalline specimens. This result suggests that the grain boundary of our specimens may not play a major role on the behaviour of conductivity. It is also reported that the mobility of electrons and holes is 0.7 and 0.9 cm²/volt-sec respectively and that the effective mass calculated exceeds ten times that of the free electron and the mean free path is between one and one hundred minimum interatomic distance. Qualitatively, the results may not be inconsistent with our results which suggest a small mobility and a large effective mass.

Change of Oxygen Concentration with Temperature of the Nickel and Cobalt Oxide Solid Solutions

By Tamio SAKATA

Research Laboratory, Ohkura Electric Company, Tokyo

and Kimiko SAKATA

Institute of Science and Technology, University of Tokyo

(Received February 28, 1958)

The oxide solid solution $\text{MeO} (=n^i \text{NiO} + m \text{CoO})$ having a rock salt type structure is obtained; its lattice parameter varies with cation composition according to Vegard's law. The deviation from stoichiometry in MeO thus produced was found to be less than $10^{-2}\%$ (in excess of oxygen). Taking this well defined divalent oxide, MeO as a reference, change of oxygen concentration was studied as functions of both temperature and cation composition, with special reference to the correlation between the nature of the defects in oxides introduced by reaction with oxygen in air and the various physical and chemical properties which they exhibit. It turned out that the whole reaction process is divided into five distinct stages when the temperature is raised from room to higher temperatures. At the first and the second stages, surface and subsurface reactions predominate. The third stage is characterized by incorporation of gaseous oxygen into the lattice. The first step of incorporation takes place without change of crystal structure, resulting in formation of the oxide phase characterized by (1) having smaller unit cell dimension, (2) having random distribution of trivalent as well as divalent cations among the lattice sites and (3) having low activation energy for current carriers (~ 0.02 eV). The second step is the spinel formation, resulted from the more ordered re-arrangement of these cations. As the result, the activation energy increases to ~ 0.1 eV. The fourth stage corresponds to transitional region in which the decomposition of the spinel into the rock salt type divalent oxide MeO occurs. The hysteresis is here appreciable in the reaction: oxide with spinel type structure $\rightleftharpoons \text{MeO}$. The reaction products at the fifth stage correspond to oxides with equilibrium *intrinsic defects* determined by the temperature and oxygen partial pressure of the atmosphere. Products of each reaction stage, without exception, proved to be *p*-type semiconductors.

§ 1. Introduction

The extensive studies of the semiconductive properties of oxides of iron group transition metals by C. Wagner and others^{1), 2)} led to

the conclusions that in the nearly stoichiometric divalent oxide MeO , the lattice always carries cation defects due to the excess of oxygen and localized positive holes produced

as the result of the increasing valency, the configuration of which may well be more specifically described as:

and that the positive hole conduction is accompanied by the exchange of the valence state of one cation with that of the neighbouring ones: $\text{Me}^{2+} + \text{Me}^{3+} \rightarrow \text{Me}^{3+} + \text{Me}^{2+}$. This concept has been clearly demonstrated in nickel oxide by the method of controlled valency³⁾, and in magnetite, Fe_3O_4 , by the application of principle of dilution³⁾. Moreover, a model has been proposed to explain the conduction in NiO and $\alpha\text{-Fe}_2\text{O}_3$, taking the above concept into account^{4),5)}.

On the other hand, there still remain some difficulties in the experimental approach to the unified interpretation in case of the oxides of transition metals because of its intrinsic tendency of changing its valence quite easily. Thus, the semiconductive properties of the oxide are changed radically by the heat treatment as the result of the formation of oxide phases with varied oxygen composition (so called berthollide). In this connection, the systematic studies how the change of oxygen composition takes place with temperature in an oxide are required for the through understanding of the semiconductive properties of the oxide. We may well abbreviate hereafter this reaction as oxide/oxygen reaction, because it is brought about by the reaction of the oxide with oxygen in the surrounding atmos-

phere.

We have studied this problem in cases of NiO, CoO and the oxide solid solution ($4\text{NiO} + 8\text{CoO}$), the results proving to be quite instructive, because the physical and chemical behaviours of the same type of oxides with different cations against the same reaction were successfully compared here⁶⁾. The present experiment was proposed, focusing attention on the correlation between the lattice defects of the oxides and various physical and chemical properties in order to extend the results of the foregoing studies of oxide/oxygen reaction throughout the whole range of the mixing ratio of NiO and CoO. Specifically, we will take, in the following, a divalent oxide phase MeO as a reference, and will discuss the stoichiometric deviation of the products of MeO/oxygen reaction from it. Informations about such deviations may be supplied from conductivity measurements, upon the basis of above mentioned conduction mechanism. In the present experiment, measurements of thermo electromotive force are also carried out in order to supplement the conductivity data.

§ 2. Preparation of Specimens

We have already established the procedure in obtaining the homogeneous oxide solid solution of nickel and cobalt, $\text{MeO} (=n\text{NiO} + m\text{CoO})$, from their carbonates⁶⁾. By the same method, series of the oxide solid solution are prepared with varying cation composition:

<i>n</i>	12	11	10	9	8	6	4	3	2	1	0
<i>m</i>	0	1	2	3	4	6	8	9	10	11	12
<i>h</i> *	0	8.34	16.7	25	33.2	50	66.8	75	83.3	91.7	100

* CoO percentage in divalent oxide, MeO.

The specimens are prepared from fine powder of these oxides, by mixing the material with lavender oil to a creamy consistency, spreading it in a film on a smooth mica plate, allowing the film to dry, cutting it into a desired size, pre-sintering it at 1000°C and finally being subjected to a heat treatment at 500°C during several hours. After the last treatment, a flake can be easily removed from the mica plate. The flake thus obtained is mounted upon free ends of four platinum

wires of the stem shown in Fig. 1-a, using the above mentioned creamy mixture as a cement. Then, the flake attached to the stem, is subjected to heat treatment again after being allowed to dry, being sintered at 1200°C in air during 1 hour and finally being quenched rapidly. Throughout these procedures, the flake of specimen is well sintered—well annealed platinum wires (0.5 mm in diameter) never prevent the shrinking of the flake to take place—, at the same time, the platinum

wires are completely buried in the specimen, assuring its intimate contacts with oxide flake. The flake is made small in size and weight, so as to satisfy the necessary condition for the present experiment that an equilibrium of the oxide/oxygen reaction is readily established at a temperature within an appreciably short time and also that the state in question is easily frozen in by rapid quenching.

Fig. 1a. Specimen mounting and stem.

L_1, L_2 platinum wires (0.5 mm in diameter) serve as leads for measurements of resistivity and thermo electromotive force.

L_1', L_2' platinum wires (0.3 mm in diameter) serve as auxiliary leads for measurements.

H_1, H_2 small platinum heaters for temperature gradient along specimen.

J_1, J_2 Pt-PtRh couples for measurements of specimen temperature and temperature difference.

Fig. 1b. Setup of specimen and whole apparatus for investigation of oxide/oxygen reaction.

The setup of the specimen as well as the whole apparatus is given in Figs. 1a and 1b. The Pt-PtRh thermo-couples J_1 and J_2 are welded directly to the lead wires L_1 and L_2 respectively, so that the junctions are completely buried in the specimen. The small platinum heaters H_1 and H_2 produce a temperature gradient along the specimen for the measurement of thermo electromotive force. The auxiliary leads L_1' and L_2' are applied to the specimen in order to measure its resistivity by a potentiometer. All the contacts, however, were so intimate that the simple bridge method is applicable without any appreciable error.

The measurement of resistivity is carried out continuously throughout the treatments, which serves to indicate how the reaction is proceeding and what kind of product is ob-

tained. Both measurements of the resistivity and thermo electromotive force can be carried out up to 1200°C under various surrounding atmospheres. The present report, however, concerns with the part of experiments carried out mainly in air, so in the following, if not specified, all experiments should be considered to be carried out in air.

§ 3. Oxide for Reference

We regard $\text{MeO} = n \text{NiO} + m \text{CoO}$, the divalent oxide, as stoichiometric oxide in the present system of the oxide solid solution and deal with the deviation from stoichiometry brought about through MeO/oxygen reaction. Nevertheless, the only one we can prepare is not such an ideal stoichiometric oxide but one with excess of oxygen deviating from stoichiometry, i.e., $\text{Me}_{1-\delta}\text{O}$ or more strictly $(\text{Me}_{1-3\delta}^{2+}\text{Me}_{2\delta}^{3+}\text{Hole}_{\delta})\text{O}^{2-}$. We must, therefore, specify the nature of the reference state of an oxide more definitely.

Fig. 2. Lattice parameter of oxides with rock salt type structure derived from the divalent oxide solid solution $\text{MeO} (=n \text{NiO} + m \text{CoO})$.
abscissa: $m/(n+m) \times 100$.

- (1) reference oxide satisfies Vegard's law.
- (2) products at the third stage reaction have a shrunk unit cell.
- (3) over shrunk oxide, coexisting with spinel type oxide.

As will be described in § 4, the specimen quenched after a heat treatment at 1200°C during 1 hour is identified with $\text{Me}_{1-\delta}\text{O}$, having a rock salt type structure irrespective of the previous history. δ cannot be determined analytically, but can be estimated to be less than 10^{-4} by comparing its resistivity with that of NiO with known amount of Li, i.e., $(\text{Ni}_{1-2\delta}^{2+}\text{Ni}_{\delta}^{3+}\text{Li}_{\delta}^{+})\text{O}^{2-}$. The cation composition in the oxide solid solution is accurate within 1 per cent. $\text{Me}_{1-\delta}\text{O}$ has a characteristic lattice parameter $a_{\text{Me}_{1-\delta}\text{O}}$ to each composition of com-

ponent oxides and is little affected by δ value so long as it remains within the order of magnitude mentioned above. It varies, however, with composition of component oxides satisfying Vegard's law:

$$a_{\text{Me}_{1-\delta}\text{O}} = \frac{n}{n+m} a_{\text{NiO}} + \frac{m}{n+m} a_{\text{CoO}},$$

where $a_{\text{NiO}} = 4.176 \text{ \AA}$ and $a_{\text{CoO}} = 4.262 \text{ \AA}$, as shown in Fig. 2. As the present experiment deals mainly with "large" variation in oxygen concentration and, furthermore, only the information about the direction in which oxide/oxygen reaction proceeds is important, the specification of the divalent oxides for reference just described will be quite sufficient.

§ 4. Procedure and Results of the Experiment

$\text{Me}_{1-\delta}\text{O}$ /oxygen reaction is studied as a function of the temperature, observing the change in resistivity R and thermo electromotive force Θ . Three different ways of heat treatment are carried out for each of 11 different oxide solid solutions mentioned in § 2. We shall illustrate the procedures and results obtained in three typical cases of the oxide solid solution $4\text{NiO}+8\text{NiO}$, CoO and NiO .

1) Oxide solid solution $4\text{NiO}+8\text{CoO}$.

Heating process The temperature is raised gradually from room temperature to 1200°C , the formation temperature of $\text{Me}_{1-\delta}\text{O}$. The reference oxide has a high resistivity more than at least 10^8 ohm cm at the room temperature, so that measurements cannot be made possible up to a certain temperature indicated as T_1 in Fig. 3. When the temperature is raised beyond T_1 , the resistivity is at first, still high, but measurable, and is order of 10^6 ohm cm , then it decreases gradually. Thus a stationary $\log R-1/T$ relation is not obtainable in this region of temperature. It depends, not only upon the way how the measurement is made, but also upon the previous history.

An essential difference appears in the temperature region above T_2 in Fig. 3. If we observe the resistivity by fixing the temperature at any point above T_2 , it decreases with time, and finally reaches a certain definite value within an accessible time. This fact indicates that a certain equilibrium exist in the reaction $\text{Me}_{1-\delta}\text{O}$ /oxygen above T_2 . Thus,

in reality, an definitely stationary $\log R-1/T$ (and $\Theta-1/T$) relation is obtainable, and it proves to be characteristic to the oxide solid solution. $\log R-1/T$ and $\Theta-1/T$ relations thus obtained are shown in Figs. 4 and 5, respectively.

Fig. 3. Oxide/oxygen reaction in the oxide solid solution $n\text{NiO}+m\text{CoO}$ proceeds with temperature. It can be divided into five temperature regions.

abscissa: $m/(n+m) \times 100$.

- 1: divalent oxide is metastable.
- 2: reaction proceeds at surface and subsurface of the oxide.
- 3: oxygen is incorporated into lattice.
 - (a) shrunked rock salt type oxide.
 - (b) spinel type oxide coexists with over shrunked rock salt type oxide.
 - (c) pure spinel oxide.
- 4: transition region for 3→5.
- 5: divalent oxide $\text{Me}_{1-\delta}\text{O}$ is stable, in which δ decreases with increasing temperature.

Sudden increases of resistivity and thermo electromotive force take place within a narrow temperature region from T_3 to T_4 , thereafter they decrease with increasing temperature. At this stage, the specimen returns back to its original divalent oxide phase, $\text{Me}_{1-\delta}\text{O}$.

The stationary $\log R-1/T$ and $\Theta-1/T$ relations shown in Figs. 4 and 5, respectively, are divided into two regions, namely, high temperature region and low temperature one, the discontinuity existing between T_3 and T_4 .

Cooling process The temperature is lowered gradually from 1200°C , the formation temperature of the reference oxide, to room temperature. The stationary $\log R-1/T$ and $\Theta-1/T$

relations, in this process, are shown also in Figs. 4 and 5, respectively.

Comparing two stationary $\log R-1/T$ (and $\theta-1/T$) relations of the heating and cooling

Fig. 4. Resistivity vs. temperature obtained in heating (solid line) and cooling (dotted line) process.

Reference oxides are:

- 1 oxide solid solution $4\text{NiO}+8\text{CoO}$
- 2 CoO
- 3 NiO

Fig. 5. Thermo e.m.f. vs. temperature obtained in heating (solid line) and cooling (dotted line) process.

Reference oxides are:

- 1 oxide solid solution $4\text{NiO}+8\text{CoO}$
- 2 CoO
- 3 NiO

processes, it is seen that the reaction is entirely reversible with respect to heating and cooling processes as far as the high temperature region is concerned. The sudden changes of resistivity and of thermo electromotive force are seen in both processes, but there is some difference in temperatures at which they occur.

Quenching The equilibrium products at various temperatures are quenched from corresponding temperatures, defects being frozen in. Thus, the change in crystal structure with progress of the reaction is inferred from the results of the X-ray analysis of the quenched specimens. Results show that products corresponding to the higher temperature region of the stationary $\log R-1/T$ or $\theta-1/T$ relations are identified with $\text{Me}_{1-\delta}\text{O}$, the reference state of the oxide itself, and, on the other hand, those obtained at the lower temperature region are, in the order of increasing temperature, as follows: (1) rock salt

Fig. 6. The characteristic relations of resistivity vs. temperature for the 3rd. stage reaction products.

- I, II: for $\text{Me}_{1-\delta}\text{O}$, shrunk rock salt type oxide.
- III: for mixed oxide, in which one with spinel type predominates over one with shrunk rock salt type structure (reference oxide is solid solution $4\text{NiO}+8\text{CoO}$).
- IV: for the cobalt spinel oxide Co_3O_4 (reference oxide is CoO).

type oxide $\text{Me}_{1-\delta}\text{O}$, (2) rather amorphous oxide, (3) rock salt type oxide with shrunk unit cell compared with (1), (4) mixture of spinel type and shrunk rock salt type structure. The relative amount of oxygen increases from (1) to (4). The discontinuities in resistivity and thermo electromotive force are considered to result from the reaction: $(4) \rightleftharpoons \text{Me}_{1-\delta}\text{O}$.

The $\log R-1/T$ and $\Theta-1/T$ relations for oxides (3) and (4) are measured in the temperature range between room and their formation temperatures. It is found out that these relations are independent of the direction of the temperature variation, indicating that these products are practically stable below their formation temperature. Some of the typical results are shown in Figs. 6 and 7 respectively.

Fig. 7. The characteristic thermo e.m.f. vs. temperature relations for the 3rd. stage reaction products.

- I, II: for $\text{Me}_{1-\delta}\text{O}$, shrunk rock salt type oxide.
- III: for mixed oxide, in which one with spinel type predominates over one with shrunk rock salt type structure (reference oxide is oxide solid solution $4\text{NiO}+8\text{CoO}$).
- IV: for the cobalt spinel oxide Co_3O_4 (reference oxide is CoO).

The curve III, the $\log R-1/T$ and $\Theta-1/T$ relations for the oxide (4) described above, coincides with one of the low temperature region of the stationary $\log R-1/T$ and $\Theta-1/T$ relations obtained in cooling process, respectively, so that we may conclude that even if the cooling was carried out very slowly, the reaction never proceeds reversibly at the temperature just below T_3 in Fig. 3. The product obtained in the slow cooling

process is the mixed oxide (4).

2) Pure cobalt oxide.

The general behaviours are much the same with those described in the case of oxide solid solution $\text{NiO}+2\text{CoO}$. Only difference is the existence of a pure oxide with spinel type structure Co_3O_4 . The $\log R-1/T$ and $\Theta-1/T$ curves for Co_3O_4 is shown in Figs. 6 and 7 respectively. The stationary $\log R-1/T$ and $\Theta-1/T$ relations for CoO/oxygen reaction obtained in the heating and the cooling process are shown in Figs. 4 and 5, respectively.

3) Pure nickel oxide.

In Ni-rich oxide solid solution, T_2 practically coincides with T_3 in Fig. 3. The reaction in narrow temperature region (T_3 to T_4) seems to correspond to the reaction: amorphous oxide $\rightleftharpoons$ reference oxide, $\text{Ni}_{1-\delta}\text{O}$.

§5. Oxide/Oxygen Reaction

It follows from the foregoing experimental results that the progress of the $\text{Me}_{1-\delta}\text{O}/\text{oxygen}$ reaction with increasing temperature can be divided into five distinct stages. Their temperature regions are shown in Fig. 3.

The first stage The divalent oxide shows no measurable change. We can tell nothing about this stage except that the resistivity is more than 10^8 ohm cm. Very likely, oxygen is adsorbed on the oxide surface.

The second stage No change in the crystal structure and the lattice parameter is detectable. The resistivity, however, decreases markedly to the order of 10^3 ohm cm. The reaction does not attain any definite equilibrium within finite period of time. The surface geometry and the initial δ value in the divalent oxide affects largely the reaction in this stage, so that no stationary resistivity and thermo electromotive force can be obtained, in the heating process. The reaction, moreover, seems to be fairly reversible. It is likely that the incorporation of oxygen in the reaction is taking place mainly at the oxide surface. The conductivity may principally due to the migration of charges through grain boundaries.

The third stage The interior of the oxide begins to take part in the reaction. An equilibrium state at a temperature, say T_a , is frozen in below this temperature. Therefore, $\log R-1/T$ and $\Theta-1/T$ relations which may considered to be characteristic of the reaction

product at T_a , are obtained in temperature region below its formation temperature, i.e. T_a . Some of such characteristic curves, are shown in Figs. 6 and 7 respectively. We may express the reaction product at this stage as $\text{Me}_{1-\varepsilon}\text{O}$, in order to distinguish it from a reference oxide, where ε measures a "large" deviation compared with δ . ε almost tends to the value corresponding to the composition in the oxide with spinel type structure. The crystal structure is still of rock salt type, but the lattice parameter decreases markedly with the progress of the reaction. The parallel relation between decrease of lattice parameter and increase in conductivity is much the same as is found in NiO substituted by known amount of Li atom, i.e., $(\text{Ni}_{1-2\delta}^{2+}\text{Ni}_{\delta}^{3+}\text{Li}_{\delta}^{+})\text{O}^{2-}$, where it is believed that the addition of Li^{+} into the lattice results the formation of Ni^{3+} at normal cation site. The unit cell contracts owing to the difference in ionic radius between Ni^{2+} and Ni^{3+} , while the resistivity decreases in proportion to the amount of Li^{+} incorporated into the lattice, or Ni^{3+} induced. In $\text{Me}_{1-\varepsilon}\text{O}$ the excess oxygen introduces cation vacancies and simultaneously cation sites trapping positive hole in the neighbourhood of these vacancies, the structure being

Therefore, number of trivalent cations is comparable with that of divalent cations. With increasing number of trivalent cations,

the interaction between defects becomes more appreciable and at last the rearrangement of cations will take place, resulting in the oxide with spinel type structure:

rock salt type oxide with shrinked unit cell
→oxide with spinel type structure.

The transformation seems, in some respects, to be cooperative. The oxide with *over* shrinked rock salt type structure, however, can still coexist with spinel structure except in case of Co-rich oxide solid solution. The lattice parameter of the oxide with shrinked rock salt type structure is shown in Fig. 2 for the comparison with that of reference oxide. The rather smooth change of the stationary $\log R-1/T$ and $\theta-1/T$ relations which are obtainable in the heating process, may be responsible for the existence of mixed oxide phase (oxide with spinel type and one with *over* shrinked rock salt type, the former becoming predominant with increasing temperature).

On the other hand, between the characteristic $\log R-1/T$ and $\theta-1/T$ relations for the oxide with shrinked rock salt type and those for the mixed oxide in which one with spinel type structure is predominant, there appears marked differences. Curves in Figs. 6 and 7 show the $\log R-1/T$ and $\theta-1/T$ relations for such products obtained in the case of oxide solid solution $4\text{NiO}+8\text{CoO}$ and for Co_3O_4 , the pure spinel type oxide, from which we can derive following results:

products	composition in solid solution from which products were derived	resistivity* (ohm cm)	ionization energy (eV)	thermo e.m.f.* (mV/°C)
oxide with shrinked rock salt type structure: $\text{Me}_{1-\varepsilon}\text{O}$	$(4\text{NiO}+8\text{CoO})$	$3 \cdot 10^0$ $8 \cdot 10^0$	0.02 0.02	0.03 0.03
mixed oxide in which one with spinel type is predominant over one with rock salt type structure: spinel + $\text{Me}_{1-\varepsilon}\text{O}$	$(4\text{NiO}+8\text{CoO})$	$7 \cdot 10^2$	0.1	0.09
pure spinel type oxide: Co_3O_4	CoO	$8 \cdot 10^4$	0.1	0.1

* at room temperature.

The $\log R-1/T$ relations in Fig. 6 for two products with shrinked rock salt type structure show the parallel displacement, indicating the difference in defect concentration in both cases, and at the same time the existence of

definite low ionization energy of the current carrier (~ 0.02 eV). These results are consistent with that obtained from $\theta-1/T$ relations in Fig. 7. On the other hand, the spinel rich oxide has a much more enhanced activa-

tion energy (~ 0.1 eV) and much higher resistivity. Comparing the $\log R-1/T$ and $\Theta-1/T$ relations for the spinel rich oxide derived from solid solution $4\text{NiO}+8\text{CoO}$ with those for the pure spinel type cobalt oxide, Co_3O_4 , it is seen that the activation energy is rather insensitive to the cation composition. This fact suggests a somewhat regular local arrangement of cations in the spinel structure: octahedral sites may be preferentially occupied by cobalt ions and the conduction takes place through them as is believed to be the case in the magnetic spinel, Fe_3O_4 .

This stage may be sub-divided into three temperature regions a, b and c as shown in Fig. 3, each of which corresponding mainly to following products:

- 3 (a) shranked rock salt type oxide $\text{Me}_{1-\delta}\text{O}$,
- 3 (b) mixed oxide of $\text{Me}_{1-\delta}\text{O}$ with the spinel type oxide, the latter becoming predominant with increasing temperature,
- 3 (c) the pure spinel oxide.

The fourth stage There is a critical temperature for the oxides with *over* shranked rock salt type and spinel type structure to be stable. Both of them, sustaining comparable number of trivalent and divalent cations, decompose into the divalent oxide with normal rock salt type structure, $\text{Me}_{1-\delta}\text{O}$, which is essentially the reference oxide itself. Surprisingly, when the decomposition takes place under low oxygen partial pressure, which is still high compared with dissociation pressure of corresponding MeO , the oxide is readily reduced to a metal or a metallic alloy. As stated already in § 4, the discontinuity of the stationary $\log R-1/T$ and $\Theta-1/T$ relations which are obtainable in the course of heating and cooling processes, appears as the result of this decomposition.

The fifth stage The reaction at this stage proceeds with increasing temperature towards the desorption of oxygen. $\text{Me}_{1-\delta}\text{O}$ approaches the nearer to the ideal stoichiometry the more higher the temperature is raised. δ remains always positive and is a definite function of temperature, oxygen partial pressure and cation composition. This stage may be regarded as the *intrinsic defective* state referring to the above condition.

§ 6. Conclusion

In higher temperature region than T_3 (cf.

Fig. 3), NiO and CoO form an homogeneous divalent oxide solid solution with rock salt type structure over whole range of component oxide composition. It has an inherent tendency to be a non-stoichiometric oxide with excess oxygen and may be expressed as $\text{Me}_{1-\delta}\text{O}$, in which δ never exceeds at least 10^{-4} and decreases with increasing temperature.

Provided the experimental conditions are suitably chosen, $\text{Me}_{1-\delta}\text{O}$ /oxygen reaction equilibrium can be attained in the bulk of the oxide within an accessible time in temperature region between T_2 and T_3 .

In the range of component oxide composition from 75% NiO to 100% NiO , general behaviour of $\text{Me}_{1-\delta}\text{O}$ /oxygen reaction is found to be *NiO-like*, that is, the rock salt type structure of $\text{Me}_{1-\delta}\text{O}$ remains stable in temperature region lower than T_3 .

On the other hand, *CoO-like* character may be taken to be a tendency to transform into the homogeneous oxide phase with spinel type structure Co_3O_4 through CoO /oxygen reaction taking place in temperature region lower than T_3 .

In the range of component oxide composition from 25% CoO to 100% CoO , behaviours of the oxide solid solution are such that *CoO-like* character is modified continuously by incorporation of NiO , or *vice versa*. The spinel formation is suppressed to some degree by incorporation of NiO , while the affinity with gaseous oxygen is promoted by incorporation of CoO . Thus the third oxide phase, $\text{Me}_{1-\delta}\text{O}$ appears, where $\varepsilon \gg \delta$.

The crystal form of $\text{Me}_{1-\delta}\text{O}$ is mainly affected by *NiO-like* character. On the other hand, oxygen content in it is already comparable with that corresponding to the spinel type oxide. Thus, in this phase, number of trivalent cation is comparable with that of divalent and these cations are randomly distributed among crystallographically equivalent cation sites in the rock salt type oxide. It is pointed out that the unit cell dimension, here, is appreciably smaller than in the divalent oxide, $\text{Me}_{1-\delta}\text{O}$. The spinel formation from this phase may be considered as the result of ordered rearrangement of these cations.

In the present oxide system, the temperature region in which the third stage reaction proceeds, i.e., the temperature region from

T_2 to T_3 is rather narrow, so that the oxide phase Me_{1-x}O never develops to bring about the oxide Me_2O_3 , in which all cations are in trivalent state. Throughout all of three oxide phase mentioned above, number of trivalent cation is always less than number of divalent cation, and p -type semiconduction is predominant. On the other hand, in cases of iron or manganese oxides, a temperature corresponding to T_3 might be much higher. Thus the oxides such as Fe_2O_3 or Mn_2O_3 are really stable. It is interesting to note that in such oxides n -type conduction is sometimes produced^{4),6)}. This difference which appears in Me_{1-x}O phase is due to difference in the relative stability of divalent cations of transition elements in Me_{1-x}O phase.

In case of transition elements, it must be noted that the reaction product depends largely upon the valence state of transition element in the reactant. Thus, for example, such oxides as Ni_2O_3 or Co_2O_3 never appear in the

present experiment, although they are sometimes cited in chemical literatures.

Paramagnetic Effect in Superconductors. Part I. Quasi-Paramagnetism and Resistance of Indium at the Superconducting Transition

Yoshio SHIBUYA

*The Research Institute for Iron, Steel and
Other Metals, Tohoku University, Sendai*

(Received January 8, 1958)

As a continuation of the previous investigation on the paramagnetic effect in tin we have investigated the same effect in indium. The minimum of current I_0 necessary for the occurrence of the paramagnetic effect has been represented by the same functions of the temperature T and the maximum of external magnetic field H_0 , beyond which we cannot observe the quasi-paramagnetism at that temperature, as in the case of tin i.e. $I_0 = \xi \gamma d (T_0 - T)$ and $H_0 = \xi (T_0 - T) - I_0 / \gamma d$. Here I_0 , ξ and T_0 are characteristic constants of the superconductor and have values 0.6 amp., 94.4 oersted/deg. and 3.422°K respectively for the case of indium: γ is 0.27 amp./mm. oe. The maximum of external magnetic field H_0 and the specimen diameter d are measured in oersted and in mm. respectively. These formulas are understood in a good approximation as those for the intersection of the plane $I = I_0 + \gamma d H$ with the transition surface in the $(I-H-T)$ space. In parallel with the measurement of the magnetic flux, plotted as a function of the current at constant temperature and external magnetic field, a measurement of the resistance of the same specimen has been performed. The results obtained are in good accordance with an expression derived in a modified form from the theory proposed by H. Meissner.

§ 1. Introduction

A superconductor through which an electric current flows in the presence of an external magnetic field shows a remarkable quasi-paramagnetism preceding the change to perfect diamagnetism, which is well-known now as the so-called paramagnetic effect in superconductors.¹⁾ In the previous papers²⁾ we reported the experimental results of the paramagnetic effect in tin. In these reports we confirmed that the paramagnetic effect was not an apparent but an intrinsic one observed, irrespective of the measuring procedure, and claimed that the minimum of current required for the occurrence of the paramagnetic effect should be determined in the $(I-H-T)$ space, instead of merely on the $(I-H)$ plane as formerly proposed, where I , H and T were the current supplied, the external magnetic field and the temperature respectively.

H. Meissner formulated a theory of the paramagnetic effect³⁾ at about the same time of the publication of the paper I, basing upon the idea⁴⁾ that in the intermediate state

the specimen current following a helical path so as to connect the oblong superconducting grains oriented along the resultant field H_t (the vector sum of external field H and current field H_I) produced a longitudinal flux greater than that due to the external field. According to H. Meissner, the maximum of quasi-paramagnetism, e.g. at constant external magnetic field and temperature, occurs when the resultant field H_t is equal to the critical field H_0 at that temperature. Our previous result (the paper II) did not, however, agree with this prediction. Afterward H. Meissner gave a detailed analysis on our experimental result (the paper II) and claimed that our result substantiated rather than invalidated his theory.⁵⁾

In order to confirm this point we performed measurements on the paramagnetic effect in solid circular indium cylinders. Further the resistance measurement was thought quite important for the understanding of the nature of the paramagnetic effect. Nevertheless it seemed that the simultaneous measurement of the resistance and the mag-

netic flux was hitherto very scanty except those of W. Meissner and R. Doll⁶⁾ and of A. Sellmaier⁷⁾. No quantitative analysis of the experimental result was, however, given in these investigations. Basing upon H. Meissner's theory, we have derived an expression for the resistance as a function of current at constant magnetic field and temperature. In order to compare this result with the experiment we performed the resistance measurement in parallel with the magnetic flux measurement.

In course of the present investigation it came to our notice that J. C. Thompson who obtained the same expression as ours for the resistance as a function of current at constant field and temperature, obtained, moreover, an analytical expression for the apparent permeability as a function of current at constant field and temperature.⁸⁾ Our result of magnetic measurement was compared with

the expression for the apparent permeability derived by J. C. Thompson.

Special care was taken in the determination of the temperature within the specimen throughout the present investigation.

§ 2. Experimental Details

The experimental apparatus used in this investigation is for the most part the same as used previously²⁾ except two pairs of large Helmholtz coils of square-type located perpendicularly to each other in place of the Helmholtz coils previously used and a thin walled, slotted copper tube used as the return current lead in place of the cylindrical copper mesh. The experimental apparatus is shown schematically in Fig. 1. A circular indium cylinder S and circular copper cylinders L_1 and L_2 of about the same diameter as that of S , soldered together with Wood's metal at the upper and the lower end of S , are placed in a uniform, external, longitudinal, magnetic field, and an externally supplied electric current flows down or up through them.

The magnetization of the specimens was measured with the use of a ballistic-type galvanometer which had a period of 13 sec. We employed mainly the so-to-speak dynamic method* of holding T constant throughout, taking H as a parameter and I as a variable which was changed in small steps: at each step the galvanometer deflection was measured when H was reversed. A search coil C_1 was fixed around the center of the specimen, and a compensating coil C_2 connected in opposition to C_1 was fixed in a uniform magnetic field, around a copper lead at a position sufficiently far from the specimen. The difference in the magnetic flux through two coils C_1 and C_2 induced a current in the ballistic-type galvanometer circuit, when the external magnetic field H was reversed. Two coils C_1 and C_2 have nearly the same structure. We confirmed also the intrinsic nature of the paramagnetic effect in indium

Fig. 1. Schematic diagram of the experimental apparatus. The outer Dewar vessel for containing liquid nitrogen and two pairs of large Helmholtz coils of square-type for nullifying the earth magnetic field are not shown.

* We are indebted to H. Meissner who recommended us this dynamic procedure in place of the dynamic one, previously adopted, of holding T constant throughout, taking I as a parameter, and reversing H which was taken as a variable and changed in small steps. The latter procedure might yield some inaccuracy in the measurement in small magnetic field.

by the static method of measurement reported previously.

The thin-walled, slotted copper tube T surrounding the specimen concentrically is used as the return current lead in order to nullify the magnetic field around the specimen due to the return current. The P.V.F. wire-wound solenoid system C_3 is the same as used previously. The earth magnetic field was cancelled with two pairs of large Helmholtz coils of square-type located perpendicularly to each other (one horizontally, the other vertically) which were not shown in Fig. 1 for spatial reasons. A small heater F is placed in the bottom of the helium column. The manostat previously reported²⁾ was used to fix the helium vapour pressure to within $0.2 \text{ mm } H_g$. The helium vapour pressure was measured with a mercury manometer. The temperature within the specimen was determined together by vapour pressure thermometry using the 1948 Mond Laboratory Tables and by taking the liquid helium column head into consideration. The determination of the liquid helium column head was performed as follows. Observing the liquid helium levels at the beginning and at the end of the measurement at a given temperature, we determined the mean liquid helium

level during the measurement at that temperature and defined the mean liquid helium column head by the distance of the mean liquid helium level from the specimen-centre. The lowering of the liquid level during one run of measurements at a given temperature was, generally speaking, considerable and sometimes amounted to about 10 cm, when the level was high i.e. it lay near the liquid helium Dewar cap A in Fig. 1, but it became 3~4 cm when the level lay far below the cap A . The helium vapour pressure above the liquid helium and the liquid helium column head thus determined served to determine the true temperature within the specimen.

The indium specimens were prepared from Johnson-Matthey spectroscopically pure indium ($>99.99\% I_n$). They were cast in vacuo in glass tubes and then drawn to the required diameter. After cutting the specimen to about 80 mm long, the specimen was sealed in a evacuated glass tube and annealed at 100°C for several hours. Although the melting point of indium was relatively low (about 156°C) and the room temperature annealing would be sufficient for indium, the annealing process above mentioned was performed by way of precaution. The specimen No. 1 was 2.38 mm in diameter and about 80 mm in

length, and No. 2 was 1.63 mm in diameter and about 75 mm in length. Both specimens showed the same critical temperature 3.422 °K.

The resistance measurement was performed only with the specimen No. 2 by the use of a Diesselhorst compensation apparatus which ensured to measure such a small potential difference as 10^{-8} V. The galvanometer used for the resistance measurement had a voltage sensitivity of 3×10^{-8} V. Two BS# 38 enamelled wires soldered with Wood's metal to the specimen No. 2 near its both ends were used as the potential probes. The potentiometer circuit for measuring the resistance is shown in Fig. 2.

The parallel measurement of the magnetic flux and the resistance was carried out in such a way as follows. After measuring the potential drop between two potential probes for a certain value of I at constant values of H and T , we observed the ballistic deflection of the galvanometer caused by the reversal of H . Then I was somewhat increased while H and T were kept constant, and the same procedure was repeated. This procedure started with $I=0$ and ended with such a large current as 15 amp. The current I was increased by about 1 amp. except near the current I^* where the maximum of quasi-paramagnetism occurred. The current increase was made in smaller steps near I^* .

The method employed for finding the critical field H_c consisted in raising the field steadily and watching for signs from the search coil that flux was entering the specimen as the superconducting phase collapsed. This method was sometimes supplemented by the method of determining H_c from the magnetization curve of the specimen obtained by reversing H . We observed supercooling of some degree in both specimens.

§ 3. Experimental Results

1. The determination, in the ($I-H-T$) space, of the minimum of current I_0 required for the occurrence of the paramagnetic effect.

In the magnetic flux measurement for this purpose we employed the dynamic method described above. Typical examples of results obtained with the specimens Nos. 1 and 2 are shown in Figs. 3 and 4 respectively. a/b

shown in the inset of Fig. 3 or Fig. 4 gives the apparent permeability μ , which is a function of I only, provided H and T are constant. μ^* which designated the maximum of μ for

Fig. 3. Ballistic deflections of the galvanometer for No. 1 specimen as a function of current I for the specified values of magnetic field H , when H was reversed. a/b shown in the inset defines the apparent permeability μ .

fixed values of H and T and plotted against I^* where μ^* occurred, and the extrapolation to the abscissa where $\mu^*=1$ defined the minimum of current I_0 at that temperature. I_0 changed with temperature and there was a one-to-one correspondence between I_0 and T . Figs. 5 and 6 show these extrapolations at

Fig. 5. μ^* for No. 1 specimen as a function of current I^* at the specified temperatures.

Fig. 6. μ^* for No. 2 specimen as a function of current I^* at the specified temperatures.

the specified temperatures for the specimens Nos. 1 and 2 respectively. From Figs. 5 and 6 we obtained the I_0 - T relations for two specimens. In a similar way we plotted μ^* against H and obtained H_0 , the maximum of magnetic field over which we could not observe the quasi-paramagnetism at a given temperature, by the extrapolation of μ^* to

Fig. 7. μ^* for No. 1 specimen as a function of external magnetic field H at the specified temperatures.

Fig. 8. μ^* for No. 2 specimen as a function of external magnetic field H at the specified temperatures.

Fig. 9. I_0 - T relations for the specimens Nos. 1 and 2.

the abscissa (Figs. 7 and 8). There was also a one-to-one correspondence between H_0 and T . Thus we obtained the H_0 - T relations.

Further we obtained the I_0-H_0 relations for two specimens from Figs. 5, 6, 7 and 8. The I_0-T , the H_0-T and the I_0-H_0 relations thus obtained for two specimens are shown as straight lines at least in the measured region in Figs. 9, 10 and 11 respectively.

Fig. 10. H_0-T relations for two specimens.

Fig. 11. I_0-H_0 relations for two specimens.

Just as in the case of tin, it was ascertained that the formula for the minimum of current required for the appearance of the paramagnetic effect was represented graphically by a straight line (the critical line) in the $(I-H-T)$ space, the orthogonal projections on the $(I-T)$, the $(H-T)$ and the $(I-H)$ plane of which are the straight lines shown in Figs. 9, 10 and 11 respectively.

The $(I-T)$ projections having inclinations, proportional to the specimen diameter d , to the T -axis point to the transition temperature

T_0 . The $(H-T)$ projections are approximately parallel to each other and T_0-T_g is inversely proportional to d , where T_g is the intersection of the projection with the T -axis (Fig. 12). The $(I-H)$ projections have inclinations, proportional to d , to the H -axis but intersect with the I -axis at a definite value of current I_0 , irrespective of the specimen-diameter. Thus the critical lines terminate at the point (I_0, T_0) on the $(I-T)$ plane.

Fig. 12. Proportionality of T_0-T_g to the reciprocal of specimen diameter, $1/d$. The straight line for tin was drawn by using data obtained previously (the paper II).

In a similar way to the case of tin we obtained as the formulas for the $(I-T)$, the $(H-T)$ and the $(I-H)$ projection which satisfied those relations described above the following three equations (1), (2) and (3) respectively.

$$I_0 = \xi \gamma d (T_0 - T), \quad (1)$$

$$H_0 = \xi (T_0 - T) - I_0 / \gamma d, \quad (2)$$

$$I_0 = I_g + \gamma d H_0. \quad (3)$$

Here ξ , T_0 and I_0 are the characteristic constants of the superconductor. The value of γ which was believed formerly to be also a characteristic constant of the superconductor was found to scatter widely according to the recent measurement.⁹⁾ This may be mainly due to the fact that μ^* in Figs. 7 or 8 is a slowly varying function of H . It cannot be decided at the present stage of investigation whether γ is a characteristic constant of the superconductor, a constant originated merely from the circular nature of the specimen cross-section or a quantity depending upon the condition of the specimen surface. The numerical values of ξ , T_0 , I_0 and γ for two specimens are tabulated in Table I. Averaging the values for two specimens, we decided that $\xi = 94.4$ oersteds/deg., $T_0 = 3.422^\circ\text{K}$, $I_0 = 0.6$ amp. and $\gamma = 0.27$ amp./mm. oerst. for indium. Of three equations (1), (2) and (3)

Table I. Numerical values of constants which appear in the formulas for the minimum of current I_0 for indium cylinders.

$$I_0=\xi\gamma d(T_c-T),$$
$$H_0=\xi(T_c-T)-I_0/\gamma d,$$
$$I_0=I_g+\gamma dH_0.$$

γ (amp./mm. oerst.)	0.26	0.28	0.27
T_c ($^{\circ}$ K)	3.422	3.422	3.422
$[T_g$ ($^{\circ}$ K)]	3.412	3.408	

Fig. 13. Critical lines (lines of current minimum) for two specimens in the $(I-H-T)$ space. The $(I-H)$ projections (1)' and (2)' of the critical lines are represented well by Eq. (3) in the text which is analogous to the equation obtained by Meissner *et al* i.e. $I_0=I_g+\gamma dH$.

only arbitrary two equations are independent and the critical line in the $(I-H-T)$ space is represented by the simultaneous equations of the two. Fig. 13 shows schematically the critical lines for two specimens in the $(I-H-T)$ space. The quasi-paramagnetism can be observed only in the region of larger I and smaller H at each temperature than those given by the critical line. Eq. (3) coincides formally with formula $I_0=I_g+\gamma dH$, obtained by Meissner *et al*. T_g , which does not appear explicitly in the above equations is given by $T_c-I_0/\xi\gamma d$.

It should be emphasized that such a somewhat systematic structure in the apparent permeability-curve as reported in the previous report (Fig. 16 in the paper II.) could

not be observed throughout this investigation. The existence of such a structure in the μ -curve as found previously seems now to us to be apparent. Furthermore we could not obtain in this investigation such closed contours as found in the previous report (Fig. 17 in the paper II.). These results formerly obtained might be spurious and be attributed to the experimental procedure formerly adopted.

Although the extension of the I_0-T relation to the absolute zero of temperature would not be permissible, it seems, in a similar way to the case of tin, from this extension that there is a lower limit of specimen diameter, d_0 for the appearance of the paramagnetic effect. This limit can be deduced from the equation $I_g=\xi\gamma d_0T_c$. For the case of indium, d_0 becomes 6.9×10^{-3} mm.

2. The verification of the theory which predicts that the apparent permeability-maximum μ^* at a given temperature occurs at the point where the resultant magnetic field $H_t=[(H^2+H_t^*)^{1/2}]$ equals the critical field H_c at that temperature.

As the previous report II suffered criticism in regard to this problem⁵⁾, we tried to confirm the prediction in this investigation. In Fig. 14 the resultant field

$$H_t=[(H^2+H_t^*)^{1/2}=(H^2+(4I^*/d)^2)^{1/2}]$$

at the surface of the specimen No. 2 for several temperatures, obtained at the point where μ^* occurred were compared with the critical field H_c . As can be seen in Fig. 14, most of measured points lie below the threshold curve $H_c=136(T_c-T)$ i.e.

$$H_t=[H^2+(4I^*/d)^2]^{1/2}<H_c(T).$$

Denoting provisionally H_t for the maximum of quasi-paramagnetism at a fixed temperature by $H_c^*(I^*,T)$ (the effective critical field),

$$H_c^*(I^*,T)<H_c(T).$$

However, we found the general trend that H_c^* at a fixed temperature approached H_c with the decrease of current I^* , and H_c^* at the point (I_0, H_0) lay nearly on the H_c -curve. This situation can be seen more clearly in Fig. 15, where the orthogonal projections, on the $(I-H)$ plane, of the intersections (the Silsbee's lines), for several temperatures, of

the planes $T=\text{const.}$ with the transition surface $[H^2+(4I/d)^2]^{1/2}=H_c(T)$ are shown toge-

Fig. 14. Comparison of the resultant magnetic field H_c at the specimen surface (the vector sum of external field H and current field H_I^*) with the critical magnetic field H_c .

Fig. 15. Orthogonal projections, on the $(I-H)$ plane, of the intersections (the Silsbee's lines), for the specified temperatures, of the planes $T=\text{const.}$ with the transition surface $[H^2+(4I/d)^2]^{1/2}=H_c(T)$, and the μ^* -lines for the corresponding temperatures.

ther with the μ^* -lines for the corresponding temperatures. It can be said that H_c^* at the point (I_0, H_0) coincides nearly with H_c in accordance with the theory proposed by H. Meissner. This point will be touched again in the following.

3. Comparison of the resistance measurement at the superconducting transition with the theoretical prediction.

The ratio of electric resistance at 4.2°K of the specimen No. 2 to that at 290°K was 1.7×10^{-4} . The result of resistance measurement for $H=2.66$ Oe. at 3.301°K are shown in Fig. 16 (lower figure) where the resistance

Fig. 16. Relative resistance R/R_n (lower figure) and μ (upper figure) as a function of current I for constant temperature and magnetic field.

is plotted as the relative resistance R/R_n against the current I . R_n , the resistance of the specimen in the normal state at that temperature which was measured in an external magnetic field strong enough to destroy superconductivity, was 2.1×10^{-7} ohms in this case. The solid curve represents the relative resistance as a function of the current at constant magnetic field and temperature, which was derived from a calculation based upon H. Meissner's theory (Appendix):

$$R/R_n=1/2[1+\sqrt{1-(I/I^*)^2}],$$

where I^* represents the current where the

maximum of quasi-paramagnetism occurs. This expression is quite the same as that obtained by F. London¹⁰⁾ for the case of zero magnetic field. In accordance with the result that the perfect diamagnetism did not change abruptly to the maximum of quasi-paramagnetism at I^* but changed in the certain range of current to the maximum of quasi-paramagnetism at I^* , the relative resistance did not appear abruptly at I^* where according to the theory we should expect it to be $1/2$, but left the abscissa at about the same current where the perfect diamagnetism began to be destroyed (see the upper figure in Fig. 16). It can be seen, however, that the agreement between theory and experiment is fairly good.

As described in the introduction J. C. Thompson who obtained the same expression as ours for the electric resistance as a function of current and found also a fair agreement between theory and experiment, obtained furthermore an expression for μ at constant values of H and T as a function of I i.e.

$$\mu = 1 + (\mu^* - I)[2(I/I^*)^2 - 1 - 2(I/I^*)\sqrt{(I/I^*)^2 - 1}],$$

and found that the experiment showed a good agreement with the theory in this case also⁸⁾. Our result of magnetic measurement performed in parallel with the resistance measurement above described is shown also in Fig. 16 (upper figure) in which μ was plotted against I . The solid curve represents the expression obtained by J. C. Thompson. The experiment agrees also fairly with the theory.

§ 4. Discussion and Conclusion

Although the same formulas for the minimum of current required for the appearance of the paramagnetic effect as obtained in the previous reports which dealt with tin specimens have been obtained in the present investigation with indium specimens, it has become adequate to consider from the present investigation that some of conclusions in the previous report (the paper II) was apparent. We have not been able to draw out from the present investigation some of the previous conclusions (i) that the closed contour lines for μ could be obtained on the ($I-H$) planes

at relatively higher temperatures near T_0 , and (ii) that a somewhat systematic structure in the μ -curve as a function of H could be obtained also at relatively higher temperatures near T_0 .

As once thought of by us²⁾, suggested also by J. T. Thompson* and pointed out by H. Meissner⁶⁾, the critical line (I_0 -line) determined in the ($I-H-T$) space can be understood as the intersection of the plane $I = I_0 + \gamma dH$ with the transition surface $H_0^2 = H^2 + (4I/d)^2$. We obtain the following equations for the intersection.

$$I_0 = \frac{I_0 + \gamma \sqrt{(1+16\gamma^2)d^2 H_0^2 - 16I_0^2}}{(1+16\gamma^2)},$$

$$H_0 = \frac{-16\gamma(I_0/d) + \sqrt{(1+16\gamma^2)H_0^2 - 16(I_0/d)^2}}{(1+16\gamma^2)}.$$

Although these equations are not such linear equations as Eqs. (1) and (2) but quadratic ones, they can be approximated by the following linear equations respectively, provided $H_0 \gg 4I_0/d$.

$$I_0 = \frac{\xi' \gamma d(T_0 - T)}{(1+16\gamma^2)^{1/2}} + \frac{I_0}{(1+16\gamma^2)},$$

$$H_0 = \frac{\xi'(T_0 - T)}{(1+16\gamma^2)^{1/2}} - \frac{16\gamma I_0}{(1+16\gamma^2)d},$$

since $H_0 = \xi'(T_0 - T)$. ξ should be understood as $\xi'/(1+16\gamma^2)^{1/2}$, which is 95.5 oerst./deg. for $\xi' = 136$ oerst./deg. and $\gamma \sim 0.25$ amp./mm. oe. as compared with $\xi = 94.4$ oerst./deg. (see Table I). Then we have

$$I_0 = \xi \gamma d(T_0 - T) + I_0/2, \quad (4)$$

$$H_0 = \xi(T_0 - T) - I_0/\gamma d \times 0.5. \quad (5)$$

Eq. (4) differs from Eq. (1) by the second constant term, which is only 0.3 amp. in the present case. Eq. (5) differs from Eq. (2) by a factor $1/2$ in the second term. When allowance has been made for the difficulty of the quantitative measurement inherent in such a investigation as on the paramagnetic effect, it should be approved that the agreements between Eq. (1) and (4) and between Eq. (2) and (5) are good.

The result that the perfect diamagnetism and the zero resistance at constant values of H and T began to be destroyed at about the same current slightly smaller than I^* cannot be explained with the theory. This unexplained result may be due to other causes e.g. the end effect of the specimen.

* Private communication.

The result that the paramagnetic effect vanishes abruptly at I_0 seems quite curious. What comes across the mind in this regard is that the line $I_0 = I_0 + rdH_0$, though obtained as a straight line in the measured range, may not be a straight line near T_0 but the one, shown in trial with a dotted line in Fig. 10, so curved as to lead the paramagnetic effect to appear at T_0 and to be observed continuously from T_0 down to lower temperatures. Such a speculation, however, would diminish in some measure the mystery of I_0 . At the present stage of investigation we have no theoretical reason why the I_0-H_0 line should thus become curved. Alternatively the mysterious constant I_0 may be connected with the boundary effect between normal and superconducting regions.¹¹⁾ If this is the case, the fact that the paramagnetic effect vanishes abruptly at I_0 may be not so curious as it seems. It may be, however, meaningless to continue such a speculation further without establishing a concrete theory.

As seen in Fig. 16, the specimen shows a small resistance of $R = 1/2 R_n$ at that current where μ^* occurs. If the heating due to the current causes the temperature of the specimen to be slightly higher than that of the liquid bath, we shall understand in some degree the discrepancy between H_c and H_c^* . If this is the case, the theory of the paramagnetic effect proposed by H. Meissner will be a fairly satisfactory one, except its drawback that it cannot explain the mysterious constant I_0 . Although we cannot give an exact estimate of the heating of the specimen due to the current, it seems, however, unlikely that such small resistance of the specimen as 1×10^{-7} ohms, through which the current of 5~10 amp. flows, causes a noticeable change in the temperature of the specimen. At any rate an essentially new concept seems necessary for the explanation of the mysterious constant I_0 .

The author would like to express his hearty thanks to Professor T. Fukuroi for his helpful suggestions and encouragements and to Mr. T. Aizawa for his sincere assistance. Thanks are also due to Professor H. Meissner, the Jones Hopkins University for kind

suggestions and valuable discussions and to Dr. J. C. Thompson, the University of Texas for his helpful discussions. The present work was supported partly by the Grand in Aid for Fundamental Scientific Research from the Ministry of Education.

Appendix

As described in the text, the maximum of apparent permeability occurs for given external magnetic field H and temperature T at I^* where the resultant magnetic field H_t at the surface of the specimen is less than the critical field H_c :

$$H_t = [H^2 + (I^*/\pi d)^2]^{1/2} \\ = H_c^*(I^*, T) < H_c(T),$$

where we used the rationalized mks-unit system in order to reconcile the unit system with that which was adopted by H. Meissner. As the current is increased above I^* , the apparent permeability does not drop at once from its maximum value to the normal state value but decreases slowly toward it.

Fig. A1. Cylindrical specimen in the stage $I > I^*$ for constant temperature and magnetic field, where I^* is the current at which the paramagnetic maximum occurs. C is the intermediate core of radius R through which the current I_1 flows and S is the normal conducting sheath through which the current I_2 flows.

It seems reasonable to assume, following F. London and H. Meissner, that the specimen in this stage consists of an intermediate core C of radius R , through which the current I_1 flows, surrounded by a normal conducting sheath S through which the current I_2 flows (see Fig. A1). The radius of the intermediate core R is determined by the condition that the resultant field at R is equal to H_c^* :

$$I^*/\pi d = I_1/2\pi R. \quad (1)$$

Regarding our H_o^* as H_o in H. Meissner's theory, from his theory [Equation (17)]³⁾ we have

$$R = I^*/\pi d \sigma_n E, \quad (2)$$

where E is the electric field and σ_n is the normal state conductivity.

Combining (1) and (2), we get

$$I_1 = 2I^*/\pi d^2 \sigma_n E.$$

The current I_2 , which passes through the normal conducting sheath, S , is given by

$$\begin{aligned} I_2 &= \int_R^{a/2} 2\sigma_n E \pi r dr \\ &= \sigma_n E \pi (d/2)^2 - I^{*2}/\pi d^2 \sigma_n E. \end{aligned}$$

The sum of the current I_1 and I_2 must be equal to the total current I . Then

$$\begin{aligned} I &= I_1 + I_2 = \sigma_n E \pi (d/2)^2 + I^{*2}/\pi d^2 \sigma_n E \\ &= E/\Omega_n + \Omega_n I^{*2}/4E, \end{aligned}$$

where

$$\Omega_n = [\pi (d/2)^2 \sigma_n]^{-1}$$

is the normal resistance per unit length R_n/l , R_n and l being the normal resistance and the length of the specimen respectively.

Solving the above equation with respect to E , we get

$$E = 1/2 \cdot I \Omega_n [1 + \sqrt{1 - (I^*/I)^2}]$$

or

$$\Omega = (\Omega_n/2) [1 + \sqrt{1 - (I^*/I)^2}],$$

where

$$\Omega = E/I.$$

Then we have for the resistance $R = \Omega l$

$$R = (R_n/2) [1 + \sqrt{1 - (I^*/I)^2}].$$

Paramagnetic Effect in Superconductors. Part II.

Quasi-Paramagnetism in Non-Circular Cylindrical Tin Specimens

By Yoshio SHIBUYA

*The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai*

(Received January 8, 1958)

Using circular cylindrical samples, we have shown in previous reports, that the minimum of current I_0 required for the appearance of the paramagnetic effect is composed of two terms I_g and γdH_0 and that I_g is independent of the sample size. In this paper, using the several kinds of non-circular cylindrical samples (rectangular, semi-circular, triangular, hollow circular, and three other forms which may show no paramagnetic effect), we have studied the same effect.

In the former four samples, the value of I_g has proved to be the same as in the case of circular cylinders. In the latter three samples (sandwich-type, cylinder and hollow cylinder with a longitudinal wedge-shaped slot) no paramagnetic effect has been found.

§ 1. Introduction

The formula $I_0 = I_g + \gamma dH^{1)}$ hitherto proposed for the minimum current requirement for the appearance of the paramagnetic effect in circular cylindrical superconductors has been shown, in the previous report,^{2),3)} to be one for the orthogonal projection on the $(I-H)$ plane, of the critical line in the $(I-H-T)$ space, where I , H and T represent the current, the external magnetic field and the temperature respectively. The characteristic quantity d , the diameter of the specimen, which specifies the cross-section of the specimen appears only in the second term of the above formula. As I_g , the so-called mysterious constant in the paramagnetic effect, is independent of d in circular cylindrical samples, we are inclined to suppose that it should be the same in cylindrical superconductors of non-circular cross-section, if the paramagnetic effect should be observed in them. It may be some aids to the clarification of the origin of the mysterious constant I_g to ascertain whether non-circular cylinders, if the paramagnetic effect occurs in them, give the same I_g as the circular cylinders. This is the reason why we undertook an experiment with non-circular cylindrical superconductors. We observed the paramagnetic effect in a rectangular, a semi-circular, and a regular, triangular cylindrical tin specimen.

The critical line representing the minimum of current in the $(I-H-T)$ space was determined after the same procedure as in the case of circular cylinders. It is represented by the simultaneous equations:

$$\begin{aligned} I_0 &= \xi \beta (T_c - T), \\ H_0 &= \xi (T_c - T) - I_g / \beta. \end{aligned}$$

From these two equations the $I-H$ relation i.e. $I_0 = I_g + \beta H_0$ could be derived as in the former case. Although β was different from specimen to specimen according to the shape of their cross-sections, I_g proved to be the same, irrespective of the shape of cross-section i.e. I_g was 1.2 amp. for tin.

Although it seems not adequate to deal here with the experiment with a hollow circular cylinder, a description of additional measurements performed with it is given. The result was in agreement with that reported already by W. Meissner *et al.*⁴⁾

Furthermore we performed an experiment with non-circular tin cylinders having reentrant cross-sections without observing the paramagnetic effect in them. We retraced also the experiment of W. Meissner and R. Doll⁵⁾ with a tin specimen of sandwich-type consisted of two semi-circular cylinders which were insulated from each other by a mica foil and in accordance with their result we observed no paramagnetic effect in it.

§ 2. Experimental Details

As the experimental apparatus and procedure are almost the same as appeared in the previous reports^{3),7)} here we do not repeat them. Most of the magnetic measurements were performed by the dynamic method and some by the static method.

All the tin specimens except the rectangular cylindrical one were prepared from Johnson-Matthey spectroscopically pure tin. The rectangular cylindrical tin specimen was prepared from Kahlbaum pure tin. The specimen was machined to the size of 5 mm in breadth, 1 mm in thickness and 80 mm in length. A tin rod of 6 mm in diameter was cut longitudinally right in two with a cutter of 0.5 mm in thickness, one of which was used as the semi-circular cylindrical specimen whose length was 80 mm. Therefore, strictly speaking, the specimen was not semi-circular. The tin specimen of sandwich-type was constructed from a pair of semi-circular cylinders thus prepared and an insulating mica foil. The regular triangular cylindrical tin specimen was prepared by machining a tin rod to the size of 5 mm in an edge of the regular triangle and 70 mm in length. The hollow cylindrical specimen was machined so as to have the outer diameter of 5 mm, the inner diameter of 2 mm, and the length of 70 mm.

Fig. 1. Cross-sections of tin cylinders showing no paramagnetic effect. The length is in the unit of mm.

In three kinds of non-circular tin cylinders we could not observe the paramagnetic effect. One was prepared in such a way that a circular cylinder of 5 mm in diameter and 70 mm in length was cut away to the cylinder axis longitudinally with a cutter having the angle of 30° [see Fig. 1 (a)]. The other was prepared from a hollow cylinder of 5 mm in

outer diameter, 2 mm in inner diameter and 70 mm in length by cutting it longitudinally and perpendicularly to its surface with a cutter of 1 mm thick at one side of the wall. Its cross-section is shown in Fig. 1 (b). The third was the specimen of sandwich-type afore-mentioned.

The annealing procedures of all the specimens were quite the same i.e. the specimens were sealed in evacuated glass tubes separately and were annealed at 190°C for two hours.

All these specimens were soldered with Wood's metal at their upper ends to copper cylinders of the same cross-section and length as theirs respectively.

§ 3. Experimental Results

1. Non-circular cylinder showing the paramagnetic effect.

(a) Rectangular cylinder.

A typical result obtained by the dynamic method is shown in Fig. 2, in which the ballistic deflection of the galvanometer was plotted as a function of current I for a given field H at 3.691°K . According to the similar procedure to that adopted in the previous report the apparent permeability μ was defined. μ^* which corresponded to the maximum of quasi-paramagnetism for constant values of

Fig. 2. Ballistic deflections of the galvanometer for the rectangular tin cylinder as a function of current I for the specified values of magnetic field H , when H was reversed.

magnetic field and temperature was plotted as a function of the current I^* , where μ^* occurred, in Fig. 3 (a). It can be seen that in this case also there exists the minimum of current I_0 for the occurrence of the paramagnetic effect. In the same way the maxi-

mum of external magnetic field H_0 at that temperature was determined (Fig. 3 (b)). I_0 and H_0 thus determined at several temperatures gave the I_0-T , the H_0-T , and the I_0-H_0 relation shown in Fig. 4 (a), (b) and (c) respectively. These three relations are

Fig. 3. (a) μ^* for the rectangular tin cylinder as a function of current I^* at the specified temperatures. (b) μ^* for the same as a function of external magnetic field H at the specified temperatures.

Fig. 4. (a) I_0-T relation, (b) H_0-T relation, and (c) I_0-H_0 relation for the rectangular tin cylinder.

represented by three equations as follows:

$$I_0 = \xi \beta (T_0 - T), \tag{1}$$
$$H_0 = \xi (T_0 - T) - I_0 / \beta, \tag{2}$$
$$I_0 = I_g + \beta H_0, \tag{3}$$

The critical line (the line for the minimum of current I_0) is represented in the ($I-H-T$) space by the simultaneous equations of arbitrary two equations of the above three. These equations are quite similar to those obtained in the case of circular cylinders except rd replaced by β . The mysterious constant I_g exists also in the present case and its numerical value is quite the same as in circular cylinders, i.e. $I_g=1.2$ amp. Other constants are $T_0=3.724^\circ\text{K}$, $\xi=62.0$ oerst./deg. and $\beta=1.61$ amp./oerst. Similarly to the case of circular cylinders the critical line terminates at the point (I_g, T_g) on the ($I-T$) plane, where T_g , which does not appear explicitly in above equations, is equal to $T_0-I_g/\xi\beta$ and its value is 3.712°K in this case.

(b) Semi-circular cylinder.

One example of the ballistic deflections of the galvanometer plotted against I is shown in Fig. 5 which was obtained for specified values of H at 3.672°K . It seems, at first sight, curious that whereas the ballistic deflec-

tions caused by reversing H in the superconducting state should be proportional to H , the figure does not show such a proportionality. This is due to the procedure that we changed

Fig. 5. Ballistic deflections of the galvanometer for the semi-circular tin cylinder as a function of current I for the specified values of magnetic field H , when H was reversed.

Fig. 6. (a) I_0-T relation, (b) H_0-T relation and (c) I_0-H_0 relation for the semi-circular tin cylinder.

the shunt-resistance of the galvanometer with the magnetic field in order to plot the ballistic deflections for the magnetic field from 0.66 Oe. to 3.32 Oe. in a limited space. This procedure does not, however, affect the determination of the apparent permeability μ . Determining I_0 and H_0 for several temperatures, we obtained the I_0-T , the H_0-T , and the I_0-H_0 relation shown in Fig. 6 (a), (b) and (c) respectively. These relations are represented also by above three equations. In this case also the mysterious constant I_0 exists and its value is again 1.2 amp. Other constants appearing in the equations are $T_0=3.732^\circ\text{K}$, $\xi=85.5$ oerst./deg. and $\beta=1.44$ amp./oerst. T_0 is 3.722°K .

(c) *Regular triangular tin cylinder.*
The ballistic deflection curves obtained at 3.694°K by the dynamic method are shown in Fig. 7. The circumstances are quite similar to those in former two cases. The $(I-H)$, the $(H-T)$ and the $(I-H)$ projection of the critical line in the $(I-H-T)$ space are shown in Fig. 8 (a), (b) and (c) respectively. These projections are also represented well by the above three equations (1), (2) and (3). We obtained $I_0=1.2$ amp. in this case also. The values of T_0 , ξ and β are 3.734°K , 81.9 oerst./

deg. and 1.08 amp./oerst. respectively. T_0 is 3.720°K .

Fig. 7. Ballistic deflections of the galvanometer for the regular triangular tin cylinder as a function of current I for the specified values of magnetic field H , when H was reversed.

Fig. 8. (a) I_0-T relation, (b) H_0-T relation and (c) I_0-H_0 relation for the regular triangular tin cylinder. The critical field H_0 is represented by $H_0=\xi'(T_0-T)$, where $\xi'=150.5$ oerst./deg. and $T_0=3.734^\circ\text{K}$.

2. Hollow circular cylinder.

We observed the quasi-paramagnetism in this specimen both with a search coil surrounding the specimen and with a search coil placed into the hole. One of the results obtained by the dynamic method at 3.662°K is shown in Fig. 9. It can be seen that the

Fig. 9. (a) Ballistic deflections of the galvanometer for the hollow tin cylinder obtained with the outer search coil as a function of current I for $H=2.66$ oersteds and $T=3.662^\circ\text{K}$, when H was reversed. (b) The same obtained with the inner search coil.

Fig. 10. Ballistic deflections of the galvanometer for the hollow tin cylinder as a function of current I for $H=1.33$ oersteds and $T=3.689^\circ\text{K}$ obtained by the static method.

flux increase occurred not only in the body of the specimen but also in the hole.

The result obtained by the static method is shown in Fig. 10 which ensures that the paramagnetic effect is not a transient, apparent phenomenon accompanying the change in time of any one of I , H or T . The critical line for the minimum of current required for the appearance of the paramagnetic effect was determined from the results obtained with the outer search coil by the dynamic method. It is represented in the $(I-H-T)$ space by the same equations as in circular tin or indium cylinders, which need not be repeated here. We did not ascertain the current minimum requirement with the inner search coil placed in the hole. We observed a hysteresis in the magnetization curve with $I=0$ in this specimen which was a characteristic of hollow cylinders. The hysteresis is shown in Fig. 11 obtained by the static

Fig. 11. Hysteresis in the magnetization curve for the hollow tin cylinder obtained by the static method.

method at 3.667°K. The magnetic field was increased from 0 to 13.30 oerst. by small steps, and vice versa; at each step a moving search coil connected to the galvanometer was dropped and the ballistic deflection was measured.

3. Non-circular cylinders showing no paramagnetic effect.

(a) Cylinder having a longitudinal, wedge-shaped slot (Fig. 1 (a)).

It may be justified both from Fig. 12 obtained by the dynamic method and from Fig. 13 by the static method to conclude that the quasi-paramagnetism cannot be observed in this specimen. This specimen showed

hysteresis in the magnetization curve with $I=0$, as shown in Fig. 14 which was obtained by the static method, in spite of the fact that the specimen was a singly-connected body.

Fig. 12. Ballistic deflections of the galvanometer for the tin cylinder having a wedge-shaped longitudinal slot as a function of magnetic field H for the specified values of current I at 3.655°K , when H was reversed.

Fig. 13. Ballistic deflections of the galvanometer for the tin cylinder having a wedge-shaped longitudinal slot as a function of current I for $H=1.99$ Oe. and $T=3.655^{\circ}\text{K}$ obtained by the static method.

In Fig. 14 the ballistic deflections were plotted as a function of the magnetic field which varied from zero to 18.61 oerst. by small steps without returning back, and vice versa.

(b) *Hollow cylinder having a longitudinal slot at one side of its thickness* (see its cross-section in Fig. 1 (b)).

The ballistic deflection *vs.* current curve at 3.676°K for a fixed value of H which was reversed is shown in Fig. 15. We could not observe the quasi-paramagnetism in this specimen.

Fig. 14. Hysteresis in the magnetization curve for the tin cylinder having a wedge-shaped longitudinal slot obtained by the static method.

Fig. 15. Ballistic deflections for the hollow tin cylinder having a longitudinal slot as a function of current I for $H=1.33$ Oe. and $T=3.676^{\circ}\text{K}$, when H was reversed.

(c) *Sandwich-type cylinder.*

The results of dynamic measurement and of static measurement are shown in Figs. 16 and 17 respectively. In this case also we found no paramagnetic effect.

§ 4: Conclusions

The results obtained with non-circular tin cylinders showing the paramagnetic effect as seen in § 3.1. are tabulated in Table I. As the experimental results cannot be compared with

Fig. 16. Ballistic deflections for the tin cylinder of sandwich-type as a function of magnetic field H for the specified values of current I at 3.700°K , when H was reversed.

Fig. 17. Ballistic deflections for the tin cylinder of sandwich-type as a function of current I for $H=1.99$ Oe. and $T=3.694^{\circ}\text{K}$ obtained by the static method.

Table I. Numerical values of constants which appear in the formulas for the minimum of current I_0 for non-circular tin cylinders showing the paramagnetic effect.

$$I_0 = \xi \beta (T_0 - T),$$

$$H_0 = \xi (T_0 - T) - I_0 / \beta,$$

$$I_0 = I_g + \beta H_0.$$

	■ Sn (Kahlbaum)	◐ Sn (J. M.)	▲ Sn (J. M.)
I_g (amp.)	1.2	1.2	1.2
ξ (oerst./deg.)	62.0	85.5	81.9
β (amp./oerst.)	1.61	1.44	1.08
T_0 ($^{\circ}\text{K}$)	3.724	3.732	3.734
$[T_0$ ($^{\circ}\text{K}$)]	3.712	3.722	3.720

the theory in contradiction to the case of circular cylinders, because the analytical expression for the magnetic field distribution around such specimens cannot be easily obtained, the critical field H_c was determined only for the triangular cylinder, which was represented by $H_c = \xi'(T_0 - T)$ where $\xi' = 150$ oerst./deg. and $T_0 = 3.734^{\circ}\text{K}$.

The shapes of specimen cross-section dealt with in this paper were not, of course, geometrically accurate ones, because their edges were more or less rounded off. The fact that the paramagnetic effect can be observed in such specimens can be explained qualitatively with the idea⁽⁴⁾ on which the theory of H. Meissner⁽⁵⁾ bases. In such specimens also the resultant magnetic field of the external field and the field produced by the specimen current shows a helical path, irregular as it is, and the current flowing so as to connect the oblong superconducting grains which remain in the intermediate state along the resultant field produces a longitudinal flux greater than that due to the external field.

On the other hand in such specimens showing no paramagnetic effect as dealt with in § 3.3. the paramagnetic effect may not be observed owing to the possibility that the helical path for the current cannot be completed.

β corresponds to γd in the formula obtained for circular cylinders where γ having the dimension amp./mm. oerst. is more or less constant i.e. nearly 0.25 in both cases of tin and indium and d is the specimen diameter in mm. β seems to depend on the cross-section of the specimen. It is not, however, clear from the present investigation in what way β depends on the cross-section of the specimen. Similar arguments can be said in regard to ξ . The difference of T_0 between the rectangular and the semi-circular or the triangular cylinder should be ascribed to the difference of their sources.

The mysterious constant I_g which appeared in the formulas for the minimum of current I_0 in the $(I-H-T)$ space for circular cylinders was 1.2 amp. for tin. The fact that I_g exists also in non-circular cylinders and its value is also 1.2 amp., irrespective of the cross-section of the specimen, may throw a light on the explanation for I_g .

The discrepancies between our experiment reported in the previous paper⁽³⁾ which dealt

with circular tin cylinders and the theory of H. Meissner⁵⁾ could not be removed completely by our recent results on circular indium cylinders⁷⁾. However, the facts that our recent results showed a qualitative agreement with the theory and that the paramagnetic effect observed in some specimens of non-circular cylinders can be explained qualitatively with the idea due to W. Meissner *et al*⁴⁾ seem to substantiate to some extent the theory of H. Meissner on the paramagnetic effect⁵⁾. Nevertheless the explanation for the origin of the mysterious constant I_0 seems to be sought in a new direction.

Acknowledgement

The author would like to express his hearty thanks to Professor T. Fukuroi for his helpful suggestions and encouragements, to Mr. S. Tanuma for his discussions and to Mr. T.

Aizawa for his sincere assistance. The author is also indebted to Professor H. Meissner, the Johns Hopkins University for his simulating correspondence. The present work was supported partly by the Grant in Aid for Fundamental Scientific Research from the Ministry of Education.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 13, No. 7, JULY, 1958

The Effect of Tension on the Magnetostriction of Iron Single Crystals

By Hideo TAKAKI and Jun-ichi HAYASHI

Faculty of Science, Kyoto University

(Received January 27, 1958)

Under various tensions the magnetostriction of iron single crystals was measured at room temperature by means of strain gauge technique. Two magnetostriction constants λ_{100} and λ_{111} were found to be independent of tension. Formerly one of the authors observed a tension-dependent magnetostriction constant by using a mechano-optical lever, which was found to be due to the overlooking of the fact that the long rod specimen is not uniformly magnetized over the whole length on account of its demagnetizing field. It was found that the magnetostriction of the rod specimen must be measured only in its uniformly magnetized portion. The mean values of magnetostriction constants were:

$$\lambda_{100} = 19.2 \times 10^{-6}, \quad \lambda_{111} = -22.6 \times 10^{-6}.$$

§ 1. Introduction

In the previous work, one of the authors¹⁾ observed the effect of tension below the elastic limit on the magnetization and the magnetostriction of the long rod single crystals of iron. In this case we observed that a sharp corner of the descending hysteresis curves of magnetization, which was called 'remanence',

shifted by the application of tension to a little higher magnetic field side, the amount of the shift being dependent both on tension and on the crystal orientation of the rod axis of the specimen. The remanent magnetization, however, was insensitive to the application of tension, thus satisfying Kaya's law²⁾. In other words, the distribution of magnetic domains

at the remanence point is determined uniquely by the crystal orientation of the rod axis. Therefore, taking the remanence and the saturation magnetization as two standard states, the magnetostriction constants were calculated from the descending hysteresis curves of magnetostriction of some single crystals which were observed by means of mechano-optical lever. It was concluded from this experiment that the λ_{100} decreases with increasing tension and falls to about half the value under the tension of 1.0 kg/mm^2 , while the λ_{111} remained unchanged.

Recently one of the authors and Tsuji²⁾ observed the magnetostriction of the long rod single crystals of 3.2 percent silicon steel by using strain gauge technique, and compared the result with previous one obtained by the mechano-optical method. These two methods often gave a remarkable different result, which was thought to be due to the fact that the specimen is not to be uniformly magnetized over the whole length on account of the demagnetizing field, especially in lower magnetic field. The magnetization of the rod specimen has the maximum value at its centre and decreases gradually to the end of the specimen. Accordingly the magnetostriction can not be uniform over the whole length of the specimen, either. Since the magnetization measured by the ballistic method corresponds to that in the central portion of the specimen, the magnetostriction should also be observed in the same portion of the specimen. This requirement was not satisfied by the previous mechano-optical method of observing the change of a length over the greater part of the rod specimen, but it could easily be attained by the strain gauge technique.

Since an applied tension is below the elastic limit and the anisotropy energy is large in case of iron, tension may not affect the rotation of magnetic domains in low as well as

high field. The magnetization of all magnetic domains, therefore, are oriented along any of the easy directions of magnetization below the remanence point, but their distribution may be affected considerably by tension as well as by magnetic field. But since the distribution may be affected considerably by tension as well as by magnetic field. But since the distribution of magnetic domains at the remanence point is to be uniquely determined it should be, and actually is, independent of external tension. So we can take the remanence point as one of the standard states for the calculation of the magnetostriction constants even in the case of measurement under the application of tension. According to the above consideration we have made the measurement by using strain gauge and calculated magnetostriction constants and their dependence on tension.

§2. Experiment

The specimens used were four single crystals of the cylindrical rod of about 2 mm in diameter and 20–30 cm in length, prepared by the strain anneal method from vacuum melted electrolytic iron. Three in them were the

Fig. 1. Stereographic projection of the orientation of the specimens.

Table I.

Specimen number	Direction cosines			Length mm	Diameter mm	Demagnetizing factor	Remanent magnetization	Nearest orientation
	l	m	n

same as used in the previous measurement by the mechano-optical lever. The crystallographic directions and dimensions of these specimens are shown in Table I and Fig. 1. The strain gauge used was that of type K-12-1 manufactured by Kyowa Musen Kenkyusho Co.. Its gauge factor is 2.00 ± 0.03 and its effective length is 23 mm. Two equal strain gauges, an active gauge and a dummy gauge were used, the former being fixed at the mid-position of the specimen by Duco cement, and the latter on a brass tube in order to avoid the temperature fluctuation. By using two additional gauges in two branches, a bridge circuit was constructed as shown in Fig. 2. After clamping the both

Fig. 2. Experimental apparatus and scheme of electric circuits.

s; specimen to be measured, b; brass tube bearing the dummy gauge, c; magnetizing coil, t; cotton cord, w; weight for loading tension.

ends of the specimen by the chucks for loading, the specimen was placed in the brass tube which was attached by the dummy gauge, then the whole system was inserted into the magnetizing coil which was kept at constant temperature by circulating water. The apparatus is also shown in Fig. 2. All measurements were carried out at room temperature. The change of length was read by the deflection of a mirror of galvanometer. The strain sensitivity was estimated to be 4×10^{-7} per 1 mm deflection of the scale at a distance of 2 m. We could attained more higher sensitivity, but the above value was found to correspond to a good dumping of the galvano-

meter. After demagnetizing the specimen in alternating field and then loading a tension on it, the hysteresis curves of magnetostriction were measured. The yield strength of the specimen was estimated from the stress-strain curves reported by Paxton and Churchman⁴⁾ for the single crystals of Armco iron which were prepared and treated in almost all the same way as ours. According to their result, the yield strength of the iron single crystals is about 3 kg/mm² (as tensile stress) nearly independent of the crystal orientation, and no upper yield point appears. As the purity of our specimens is believed to be higher

than that of Armco iron, the yield point may be lower. Consequently, we limited the tension within 0.6 kg/mm^2 , in which range the material may be regarded as nearly elastic during the experiment. According to the Becker's consideration⁵⁾, the internal stress should be induced by magnetostriction and given by $\lambda_{100}E$ (E is the Young's modulus),

Fig. 5. Descending hysteresis curves of magnetostriction of specimen No. 2, near $[210]$, under various tensions. The signs of measured points are the same as in Fig. 3.

Fig. 6. Descending hysteresis curves of magnetostriction of specimen No. 67, near $[411]$, under various tensions. The signs of measured points are the same as in Fig. 3.

which is evaluated for iron to be about 0.5 kg/mm^2 . This value is comparable to the higher values of applied tension. Magnetostriction under 0.8 kg/mm^2 was also observed, but in this case the specimen showed a little tendency to creep and no satisfactory result for calculating the magnetostriction constants was obtained. Descending hysteresis curves of magnetostriction under various tensions are shown in Fig. 3 to Fig. 6.

§ 3. Discussion and Calculation of Magnetostriction Constants

Magnetization curves of each specimen has a sharp corner at remanence point, where the magnetization remained unchanged under various tensions. Magnetization curves of three specimens out of the four were shown in the previous paper¹⁾, and the last one No. 67 is similar to them in its behaviour. Comparing the present result with the former one, we found that the behaviour of magnetostriction curves is somewhat different from each other. As already mentioned by Takaki and Tsuji³⁾, below the remanence point magnetostriction curves obtained by the two methods are considerably different from each other for the specimen except one with $[111]$ orientation, an example of which is shown in Fig. 7. The above discrepancy between the

Fig. 7. Comparison of the descending hysteresis curves of magnetostriction obtained by two measuring methods, specimen No. 61, $[110]$.

— obtained with strain gauge.
 - - - - - obtained with optical lever.
 a, a' under no tension.
 b, b' under 0.64 kg/mm^2 .

two magnetostriction curves may be explained by the fact that the magnetostriction is not uniform over the whole length of the specimen but its value is variable below the remanence. For the specimen of nearly $[111]$ direction, however, the two methods gave nearly the same descending hysteresis curves of magnetostriction, and below the remanence this specimen has the uniform and constant magnetostriction though it has not been uniformly magnetized (Fig. 6). This is because

that the magnetic domains are oriented along any of the easy directions of magnetization, which are directed symmetrically around the rod axis, and the magnetostriction has the same value in any portion of the specimen. From Fig. 3 to Fig. 6, magnetostriction varies considerably with tension below the remanence point, but does not depend on tension between saturation and remanence as shown in Table II and Fig. 8. This result is quite different from

Table II. Dfference of Magnetostriction between Saturation and Remanence under Various Tensions.

Specimen number	$-(\frac{\delta l}{l})_{\text{sat-rem}} \times 10^6$ under tension			
	0 kg/mm ²	0.15 kg/mm ²	0.35 kg/mm ²	0.64 kg/mm ²
61	17.7	18.2	17.2	18.0
105	21.6	19.9	20.6	21.3
2	5.2	4.7 ₅	4.5 ₅	5.2
67	-1.3	-1.0	-1.2	-1.1

Fig. 8. Difference of magnetostriction between saturation and remanence of four specimens.

the previous result¹⁾, which must be considered to be incorrect. The specimen with the orientation near [100] was also measured but gave no satisfactory result which was probably caused by the fact that this single crystal specimen has a curved form at initially prepared state and stretched by tension. But this specimen has only small effect on determining magnetostriction constants because the coefficients of λ_{100} and λ_{111} have small values in this orientation as shown in equation (1). Anyhow, it may be safely concluded that the magnetostriction constants do not vary with tension. This is further confirmed by the

calculation of the magnetostriction constants for various tensions. The method of calculation is the same as in the previous report, that is, the difference of length between the state of saturation magnetization and remanence is expressed by the following relation,

$$\begin{aligned} \left(\frac{\delta l}{l}\right)_{\text{sat-rem}} &= \lambda_{100} \left\{ \frac{3}{2} \left(1 - \frac{l^3 + m^3 + n^3}{l + m + n} \right) \right. \\ &\quad \left. - 3(l^2m^2 + m^2n^2 + n^2l^2) \right\} \\ &\quad - 3\lambda_{111}(l^2m^2 + m^2n^2 + n^2l^2), \end{aligned} \tag{1}$$

where l , m and n are the direction cosines of the measured orientation referred to the cubic crystal axes. Using the equation (1) two magnetostriction constants λ_{100} and λ_{111} were calculated by the least square method. λ_{111} is also determined by the other method. Namely magnetostriction for [110] specimen can be expressed at near to its saturation by the following formula,

$$\begin{aligned} \left(\frac{\delta l}{l}\right) &= \frac{3}{4} \lambda_{100} + \frac{3}{4} \lambda_{111} \left(2 \frac{I^2}{I_s^2} - 1 \right) \\ &\quad \text{(above remanence),} \end{aligned} \tag{2}$$

that is, the gradient of $(\delta l/l)$ versus I^2/I_s^2 curve gives the value of λ_{111} . Our specimen No. 61 deviates about 2° from [110] direction, but this deviation has only negligible effect on the calculated λ_{111} . The calculated magnetostriction constants are shown in Table III and

Table III. Magnetostriction Constants of Iron Single Crystals under Various Tensions.

Tension kg/mm ²	$\lambda_{100} \times 10^6$	$\lambda_{111} \times 10^6$	$\lambda_{111} \times 10^6$ calculated from [110] specimen.
0	19.3±1.0	-22.9±0.8	-22.9
0.16	19.7±1.3	-21.7±1.1	-22.7
0.35	19.4±0.6	-21.8±0.6	-21.4
0.64	18.4±1.1	-23.0±1.0	-24.3
Mean	19.2	-22.6	

Fig. 9 in comparison with the previous result. Their rather large probable error may come from the lack of the number of the specimens, but the two constants were independent of tension. The mean values of the magnetostriction constants over various tensions are: $\lambda_{100}=19.2 \times 10^{-6}$ and $\lambda_{111}=-22.6 \times 10^{-6}$. Although the values of λ_{111} obtained by the two measuring

methods are both independent of tension, yet the one obtained with strain gauge is larger than the one with mechano-optical lever. This difference may have the other origin. When we compare the mechano-optical method with the strain gauge method for the same portion of the same specimen, we get always greater value with the latter. Strain gauge being calibrated by a known strain, so we must suppose that the mechano-optical method contains some error probably caused by the multiplying factor of the mechano-optical lever. Therefore we believe that the present result obtained by using strain gauge is more reliable.

Fig. 9. Magnetostriction constants of iron versus tension.

- — ○ Our results with strain gauge.
- — ● Our results calculated from curves of specimen No. 61.
- × — — — × Takaki's former results with mechano-optical lever.

In the above discussion we have assumed that the state of saturation and remanence are the two standard states*, but the process from saturation to remanence may somewhat vary with tension. From the experimental results, the specimens $[110]$ and $[111]$ remain nearly unchanged under any tension, but the specimens having the orientation deviated from the principal axes take somewhat dif-

ferent values under varying tension. In the state of saturation and remanence the distribution of magnetic domains is uniquely determined, but this is not necessary the case on the way between the two states.

The main factors to determine the domain distribution are the magnetic anisotropy energy and the energy by external field. The energy by external tension is smaller than the above two energies, but when external tension is applied, it may affect the behaviour of magnetostriction in the process from saturation to remanence. For the specimen with the orientation of the principal axes, the distribution of magnetic domains is uniquely determined in the whole process between saturation and remanence. Generally speaking, magnetostriction below the remanence point decreases with increasing tension. In this case the magnetic anisotropy energy and the energy by external field become smaller and the energies from internal stress, surface free poles and other origins become comparable to the energy by external tension. Thus the condition of setting and fixing strain gauge become an important factor, so that the discussion about the domain distribution is insignificant below the remanence point. For example,

Fig. 10. Descending hysteresis curves of magnetostriction observed on the various lateral surfaces of specimen No. 61, near $[110]$.

the magnetostriction of the specimen No. 61 of $[110]$ direction was observed with strain gauge fixed on the various lateral surfaces of the cylindrical specimen in the central portion (Fig. 10). Two strain gauges on symmetrical position give the different results, which mean that the condition determining the domain distribution is very delicate and complex. Lee⁶⁾

* The demagnetized state is often taken as the standard state, but it is incorrect because the distribution of magnetic domains is not uniquely determined in such a state.

discussed the effect of the surface closure domains in relation with the specimen size, but, for our specimen size this effect is concealed in the experimental error.

We wish to thank Mr. Y. Nakamura and Mr. T. Tsuji for their valuable assistance throughout the work. The expenses of this research were partly defrayed by the Scientific Research Expenditure of the Ministry of Education.

Electronmicroscopic Observation of Coloured and Bleached Alkali-Halide Crystals

By Tadatōsi HIBI and Kazuo ISHIKAWA

*Research Institute for Scientific Measurements,
Tōhoku University, Sendai, Japan*

(Received June 18, 1957)

Alkali-halide crystals coloured with X-ray irradiation were observed electronmicroscopically using replica techniques. Crystals bleached by keeping them in air and by thermal treatment were also observed. Growth of crystallites was seen not only on the irradiated front face, but also on the side face and on the newly cleaved section. An interesting growth of crystallites was observed all over the front face with the progress in colouration. It was also seen on the side face that the growth of crystallites similar to that on the front face occurred in accordance with the degree of colouration. At the inner part of coloured crystal, growth of crystallites was observed only along the steps or in the neighbouring part. By the process quite reverse to the crystal growth in colouration, crystallites grown during colouration disappeared in the process of bleaching. Results obtained were discussed.

§ 1. Introduction

With application of replica techniques, we found that small crystallites appeared on the surface of AgBr crystal in photographic emulsion after optical colouration while observing the print-out effect. This process was considered to be due to atomic or ionic diffusion to the surface from the inner part¹⁾. It was also found that the crystal MgO changed its shape with colouration due to the heating to high temperature²⁾. From these phenomena crystal growth on the surface of alkali-halide crystal coloured with X-ray irradiation was expected. To confirm this, the present experiment was performed. While this experi-

ment was in progress, several studies^{3,4)} were published on the surface change of the alkali-halide crystals by X-ray irradiation, in connection with the decrease in the density of alkali-halide crystals by colouration. These results will be discussed in comparison with our experimental results.

§ 2. Specimen and Experimental Method

In this experiment, transparent natural crystals of NaCl and KBr were used. The small crystals of 5×3×3 mm cleaved in air from a single block of the crystal were used as coloured specimens on one hand and standard specimens on the other, respectively. Speci-

mens were always used without any pre-treatment such as water-polishing or annealing. The front-, the side- and the cleavage-face after colouration by X-rays were examined and compared with the standard un-irradiated specimens. Each face to be examined is shown schematically in Fig. 1, where the incident

Fig. 1. Faces which was examined with the electronmicroscope.

beam of X-rays hits normally the front-face. Specimens were all irradiated at room temperature in dark with X-rays of 40 KV, 5 mA from Fe target. The distance between the specimen and the target was about 4 cm. Aluminum foil of 0.02 mm thick was used as a window of X-ray tube. Chromium oblique replicas reinforced by carbon were used for the electronmicroscopic observation. In making oblique replicas, evaporation angle, measured from the crystal surface, was about $\tan^{-1}(1/3)$ for both the front and the side faces and about $\tan^{-1}(1/6)$ for the cleavage face. It took about 1 hour for replication. Coloured crystals were exposed to room light only during this time interval. Much care was paid to the shadowing for the determination of the orientations of crystallites grown on the surface, as shown in Fig. 2. We could also distinguish, the parts locating closed to

Fig. 2. Direction of evaporation in making oblique replicas. Arrows show the direction of evaporation. (a) front face: $\theta \approx \tan^{-1}(1/3)$, (b) side face: $\theta \approx \tan^{-1}(1/3)$, (c) cleavage face: $\theta \approx \tan^{-1}(1/6)$.

detached from the front face, from the direction of the shadows.

§ 3. Experimental Results

First, two NaCl crystals, one of which was kept in the desiccator and another in air for 14 days, were compared. We could hardly find any difference between them, and so it can be said that humidity in air has no pronounced effect*.

Under a comparatively uniform condition of irradiation, the change of the front face of NaCl crystals with duration of X-ray irradiation was next observed. Fig. 3 (a) shows the electron micrograph of the surface of NaCl crystal without any X-ray irradiation, while (b), (c), (d), (e) and (f) show the electron

images of the front face of crystals irradiated by X-rays for 10, 15, 30 minutes and 1 and 3.5 hours, respectively. The surface of the standard un-irradiated crystal is almost smooth and even in the special case it has only low steps as seen in (a). After the X-ray irradiation for a short time, fine crystallites having circular contour shown in (b) appear first here and there. It is known from (b) that crystallites are easy to appear along the steps. By further irradiation, crystallites grow to leaf-like pattern (c), and then the distinct parallelepipedal crystallites appear (d). Judging from the direction of shadows, the [100] direction of the crystallites is predominantly parallel to the cube edge of the base crystal and parallel to the diagonal of the base crystal. By still further irradiation, however, large circular crystal patterns appear. (e) shows a small portion of such a circular pattern. Crystallites still grow and distribute

* This experiment was made during the season of low humidity, but in the season of high humidity we should pay attention to the effect of humidity⁶⁾.

all over the front face. After irradiation for a sufficiently long period, very large crystallites are formed and the substrate becomes completely smooth (f). It should be noted

that a very peculiar behaviour of the crystal growth appears with the increase of X-ray colouration and the surface change from (e) to (f) is very similar to the behaviour of ag-

Fig. 5. Electron images of the cleavage face of NaCl crystal coloured by X-ray irradiation for 4 hours: (a) the place nearest to the front face, (b), (c) the places farther away from the front face.

Fig. 6. The change of the front face of NaCl crystals by natural bleaching: (a) immediately after (b) 13 days after, and (c), (d) 33 days after the colouration by X-ray irradiation for 3 hours.

Fig. 7. Electron images of the side face of NaCl crystal bleached for 33 days after the colouration by X-rays for 3 hours: (a) the place nearest to the front face, (b), (c) the distant places farther from the front face.

Fig. 8. The change of the front face of NaCl crystals by thermal bleaching: (a) the surface of uncoloured standard specimen after thermal treatment: (b) the front face immediately after colouration by X-ray irradiation for 3.5 hours, (c), (d) the front faces immediately after thermal bleaching.

Fig. 9. The change of the front face of KBr crystals by X-ray irradiation: (a) 0, (b) 20 minutes, (c) 3, (d) 4 hours.

Fig. 11. Electron images of the cleavage face of KBr crystal coloured by X-ray irradiation for 3.5 hours: (a) the place nearest to the front face, (b), (c) the distant places farther away from the front face.

Fig. 10. Electron images of the side face of KBr crystal coloured by X-ray irradiation for 3.5 hours: (a) the place nearest to the front face, (b), (c), (d) the distant places in this order from the front face.

gregation of deposited thin film.

Fig. 4 shows the electron micrographs of the side face of NaCl crystal coloured by X-ray irradiation for 4 hours: (a) shows the image of the place nearest to the front face while (b) and (c) show those of the distant places from the front face. In (a) large

crystallites are seen, while crystallites are small in (b) and a few steps only appear on the smooth plane in the deeper place (c). Therefore, it is found that the behaviour of crystal growth on the side face also changes with colouration degree. In the case of (a), it should be noted that the [100] direction of the

crystallites is approximately parallel to the edge of the base crystal.

For the observation of inner parts of coloured NaCl crystals, the section newly cleaved parallel to the side face of the crystal coloured by X-ray irradiation for 4 hours was examined. Fig. 5 shows the result obtained: (a) shows the image of the place nearest to the front face irradiated by X-rays, and (b) and (c) show those of the places farther away from the front face respectively. In (a), large crystallites are seen only along the steps or in the neighbouring place. While small crystallites are observed along steps in (b) and only a few steps are seen on the smooth plane in (c). It is noted that in (a) and (b) steps bend remarkably, while in (c) almost straight steps are only observed.

The bleaching behaviour was next examined by keeping the coloured crystals in the air for a long time. In Fig. 6,⁴ (a), (b) and (c) show this effect on the front faces of crystals which were photographed immediately after, 13 days and 33 days after the colouration by X-ray irradiation for 3 hours, respectively. (b) shows a part of a large circular crystal pattern and this is very similar to the pattern in Fig. 3 (e) which was observed in the process of crystal growth by X-ray irradiation. In this figure, (d) shows the image which was taken from the crystal bleached for 33 days after the colouration, and the crystallites in (d) are very similar to those in Fig. 3 (c). It is seen from these that the crystallites on the front face of NaCl crystal disappear on bleaching. Moreover, it might be conceivable from (b) and (d) that crystallites grown during colouration disappear during bleaching by the process quite reverse to crystal growth in colouration.

Fig. 7 shows the side face of NaCl crystal, which was bleached for 33 days after the colouration. (a) shows the image of the place nearest to the front face, while (b) and (c) show those of the distant places farther from the front face. It is interesting to note that the crystallites on the side face does not disappear completely after 33 days, notwithstanding almost complete disappearance of the crystallites on the front face. The crystallites in (c) are very similar to those in Fig. 3 (c).

It was found from the observation of the part of section near the front face of NaCl crystals bleached for 33 days after the colouration

that crystallites still remained but steps became lower or nearly disappeared.

Fig. 8 shows the results obtained by thermal bleaching. After heating for 10 minutes at 300°C, specimens were slowly cooled to room temperature in 1 hour. (a) shows the image after the thermal treatment in the case of uncoloured standard specimen. Any change is hardly observed by thermal treatment. (b) shows the image of the front face immediately after the colouration by X-ray irradiation for 3.5 hours, while (c) and (d) show those of the front face immediately after the thermal bleaching. In (b) a pronounced crystal growth is seen, while in (c) crystallites are very small. Therefore, it is concluded that the front face becomes smooth also by the thermal bleaching. Stratified laminar crystallites as shown in (d), the lamellae of which are supposed to be formed in the earliest stage of crystal growth during colouration, were rarely observed on the front face of thermally bleached NaCl crystal.

KBr crystals were next observed electron-microscopically. Fig. 9 (a) shows the electron micrograph of the surface of KBr crystal without any X-ray irradiation. A step and the smooth plane are only seen. In this figure (b), (c) and (d) show the electron images of the front face of crystals coloured by X-ray irradiation for 20 minutes and 3 and 4 hours respectively. Rod-like and point-like patterns appear on the front face by X-ray irradiation for a short time. (b) shows the image of the place on the front face where the both kinds of crystal pattern appeared at the same time. After X-ray irradiation for 3 hours, a pattern very similar to deposited thin film was obtained all over the front face as shown in (c). By further irradiation, crystallites grow into larger ones and the substrate becomes smooth as in (d). Surface change from (c) to (d) is very similar to the behaviour of aggregation of deposited thin film as well as in the case of NaCl crystals. Fig. 10 shows the images of the side face of KBr crystal coloured by X-rays for 3.5 hours: (a) shows the pattern nearest to the front face, while (b), (c) and (d) show the patterns in the distant places in this order from the front face. In (a) and (b) many crystallites are seen and the substrate is not smooth, while in (c) and (d) leaf-like patterns such as in Fig. 3 (c) and small crystallites

are only observed on the almost smooth surface. This phenomenon is similar to the case of NaCl crystals. Fig. 11 shows the electron images of the cleavage face of KBr crystal coloured by X-ray irradiation for 3.5 hours. In this figure, (a) shows the image of the place nearest to the front face, and (b) and (c) show those in the distant places from the front face respectively. In this case, observation was made along the same one step. In (a), a large crystallite is seen only along the step and most parts of the section are smooth. The size of crystallites along the step becomes smaller with the distance from the front face as seen in (b). At a farther distance only a few steps appear on the smooth surface as in (c). It is to be noted that in (a) the step bends remarkably, while in (b) and (c) it is almost straight. These results are consistent with those of NaCl crystals.

The effect of thermal bleaching was also examined in the case of KBr crystals. It was observed that crystallites grown during colouration did not disappear completely by heating for 10 minutes at 300°C, although their complete disappearance may be expected by further treatment.

§ 4. Discussion of Results Obtained

It is clear from the present results that in the case of colouration of alkali-halide crystals by X-ray irradiation, crystal growth appears on the front face. The maximum height of crystallites was about 2500–3500 Å. Recently Leider⁴⁾ found by electron diffraction that crystallites larger than several hundred Å appeared on the front face of NaCl crystal with X-ray irradiation. On the other hand, Smith, Leivo and Smoluchowski³⁾ found by multiple-beam interferometry that steps having the height of about 180–1400 Å only appeared on the front face of KCl crystal of X-ray irradiation. Leider's result agrees with our experiment. It has been found in electronmicroscopic observation of KCl crystal coloured in the vapour of potassium that the straight or wound steps appeared first, and then crystallites appeared on the surface with further colouration⁶⁾. Therefore, it may be due to the sufficiently pure and well annealed KCl crystals that steps only were observed in the examination with multiple-beam interferometry in the case of Smith and others. Saka-

guchi and Suita⁷⁾ also obtained the value of about 3000–4000 Å as the increase in thickness of alkali-halide crystals at the saturated colouration due to X-ray irradiation, from the measurement by electric micrometer. This value agrees with the maximum height of crystallites obtained in our experiment. Expansion of alkali-halide crystals due to X-ray irradiation of weak intensities was also observed by Lin⁸⁾. The value of maximum relative linear expansion of 10^{-6} obtained by him does not conflict with our result. It is, therefore, considered as atomic or ionic diffusion to front face from inner part of crystal that crystallites grow on the front face by X-rays. It may be reasonably understood from this mechanism that time lag occurs on the expansion of alkali-halide crystals due to X-ray irradiation of weak intensities⁸⁾.

Crystal growth on the front face was observed as very peculiar behaviours in the course of colouration degree. In the case of appearance of the distinct parallelepipedal crystallites, the [100] direction of the crystallites is, in general, parallel to the cube edge of the base crystal and parallel to the diagonal of the base crystal, though Leider⁴⁾ did not confirm accurately this fact. This phenomenon is considered to be physically reasonable. In earlier stage of colouration, crystallites are easy to appear along the steps as shown in Fig. 3 (b). This phenomenon shows that ions or atoms are easy to diffuse to the surface from the inner part of crystal through steps or micro steps. In a later stage, however, a surface change is very similar to the behaviour of aggregation of deposited thin film in both cases of NaCl and KBr, and also pronounced steps could not be observed in both cases though there may be micro steps which is unresolvable in our experiment. In this stage, therefore, surface migration seems to be an important factor in the crystal growth on the surface. It should be also noted that patterns such as Fig. 3 (e) and Fig. 9 (c) perhaps show the colloidal state.

On the front face, crystal growth will appear not only along the steps, but also on the smooth area. On one hand, from the observations on cleaved faces, it appears that crystal growth mainly happens along the steps. To explain this it may be considered that ions aggregate to the mechanical imperfections—

cracks or slips (perhaps dislocations)—leaving vacancies behind. This mechanism seems to be very similar to that of the internal latent image formation⁹⁾ in the photographic emulsion. It was also found that at the parts farther inside from the front face, crystal growth becomes less marked with difficulty of penetration of X-rays, and steps more straight. The winding of steps is considered to be connected with crystal growth, because the winding of steps is most pronounced at the part nearest to the front face.

Decrease in the density of alkali-halide crystals by X-ray irradiation, discussed by several investigators^{7,8,10)}, may be explained from our experimental results which suggest that crystallites appear not only on the surface, but also vacancies are created inside the crystal, though Smith and others³⁾ attached great importance only to the internal mechanism. The surface structure appeared in earlier stage of X-ray irradiation may be explained on the standpoint of dislocation as a result of the climb of dislocation which occurs when the exciting radiation causes the dislocations to yield vacancies. This will explain some of the structure originated in the depth of the crystal where the radiation penetrates¹¹⁾. However, crystal growth in later stage of X-ray irradiation cannot be discussed here as climb of dislocations, because it is not yet clear whether surface migration connects with climb motion of dislocation or not.

It is very interesting that crystallites grown during colouration disappear in the course of bleaching, by the process quite reverse to crystal growth in colouration. If the coloured state is considered to be the excited one and the bleached state the normal one, it may be physically reasonable that in the bleaching process ionic diffusion occurs to the inner part of crystal to fill up the vacancies created by X-ray irradiation.

The delay of disappearance of crystallites on the side face grown by X-ray irradiation, as compared with that on the front face, may be due to the difference of degree of crystal growth. It has not yet been made clear from the observation whether crystallites appeared at the surface and the inner part of alkali-halide crystal are alkali crystal or alkali-halide one. However, both kinds of crystallites seem to appear perhaps at different stages of colour-

ation.

Finally the relation between crystal growth and colouration is to be discussed. Positive or negative ions removed from the lattice points produce the crystallites and colouration of crystal occurs from many vacancies which are left in the crystal behind. It is reasonably understood that colouration is most pronounced at the part nearest to the front face and it becomes less marked at the part farther inside from the front face. This mechanism does not conflict with the considerations hitherto accepted. From the results in our experiment, it seems that there is not only the interaction between colour centers and dislocations as reported by Amelinckx¹²⁾ but crystal growth is closely connected with them excepting surface migration stage. So, electronmicroscopic observation of crystal growth or steps will be very important in learning the behaviours of ions in alkali-halide crystals, though hardly any such observation has hitherto been made. However, some obscurities may remain on the above-mentioned phenomena and interpretations. To make these clear, several studies are being carried out under simpler conditions.

In conclusion, we wish to express our thanks to Prof. Y. Uchida, Kyōto University, Prof. M. Ueta and Dr. T. Suzuki, Tōhoku University for their kind interest. The authors would like to express their thanks to Prof. F. Seitz and Prof. J. S. Koehler, University of Illinois for their kind comments on this work.

A Note on Thermodynamics of the Harmonic Oscillator with Radiation Damping

By Nobuhiko SAITÔ

Department of Applied Physics, Waseda University, Tokyo

and Jun-ichi HORI

Department of Physics, Hokkaido University, Sapporo

(Received March 15, 1958)

Previously one of the authors showed that the system with positive real impedance can be described within the framework of irreversible thermodynamics. In this paper we first remark that the impedance of the system which is describable by irreversible thermodynamics should necessarily be positive real. This conclusion is immediately drawn from the theorem of network synthesis that a system with non-positive-real impedance cannot be constructed from elementary RLC circuit. That a system is constructed from RLC circuit is the necessary and sufficient condition for the system to be described by irreversible thermodynamics. Then we examine some statistical properties of the harmonic oscillator with radiation damping, a typical example of the system with non-positive real impedance, which will help us to apprehend the above conclusion somewhat more intuitively. The main point is that in the presence of radiation damping, we cannot set up the Fokker-Planck equation for the fluctuation without having recourse to an approximation. The result of this approximation is however at variance with the requirement of the rigorous irreversible-thermodynamical description.

§ 1. Introduction

In a recent paper¹⁾, which in the following will be referred to as I, one of the authors showed that the system whose impedance is of the form

$$Z(i\omega) = z^{-1}/(i\omega) + z^0 + (i\omega)z^1 + \sum_{j=1}^{n+1} c_j/(i\omega - p_j) \quad (1.1)$$

(the so-called positive real impedance in the network theory) can be described within the framework of irreversible thermodynamics. The problem whether the physical system whose impedance are not positive real can or cannot be described by irreversible thermodynamics, was however remained open. In I it was shown that the irreversible change (including fluctuation) of the system whose impedance is positive real can be described by a system of (say r) Langevin equations of the second order, if we introduce $r-1$ appropriate inner variables, in addition to the variable x under consideration. In other words, such a system eventually reduces to a many-dimensional irreversible-thermodynamical system as treated in § 2 of I. The problem mentioned above amounts to inquiring whether

the system with non-positive-real impedance can or cannot be reduced to such a many-dimensional system. It is not self-evident that we can exclude the possibility of such a reduction, inasmuch as we have not examined the possibility of, e.g., taking the derivatives of the variable under consideration as inner variables, which seems to be natural in the case of the system with non-positive-real impedance, as will be seen below. The answer to this question is readily given by combining the well known theorem in the network theory that a network with non-positive-real impedance cannot be constructed from elementary RLC circuits (which means that such a system cannot be described macroscopically by a set of differential equations of the second order tractable by irreversible thermodynamics), together with the argument of Saitô²⁾, extending his formulation of the ordinary irreversible thermodynamics to a system described by a set of differential equations of the second order. This extension is easily carried out starting from his original treatment by making use of the technique of Ostrogradsky, as was pointed out by Saitô and Namiki³⁾,

In effect consider a set of differential equations of the second order

$$\sum_j (m_{ij}\ddot{x}_j + r_{ij}\dot{x}_j + s_{ij}x_j) = 0, \quad (1.2)$$

where the coefficients m_{ij} , r_{ij} and s_{ij} respectively form positive definite matrices. The fluctuating force $p_i(t)$ to be introduced into the right-hand sides of these equations have the statistical properties

$$\begin{aligned} \langle p_i(t) \rangle &= 0, \\ \mathcal{P}_{ij}(\omega) &= (2/\pi)kTr_{ij}, \end{aligned} \quad (1.3)$$

according to the fluctuation-dissipation theorem, where $\mathcal{P}_{ij}(\omega)$ is the spectral density, and hence

$$\langle p_i(t)p_j(t+\tau) \rangle = 2kTr_{ij}\delta(\tau). \quad (1.4)$$

These properties and further assumption that the distribution function of the fluctuating forces is normal are necessary and sufficient for the system to be described irreversible-thermodynamically. A system with non-positive-real impedance cannot be described, as was mentioned above, by a set of differential equations of the form (1.2), and consequently it cannot be described in the framework of irreversible thermodynamics.

This is all that we want to conclude. We should like, however, to present a more detailed discussions on the harmonic oscillator with radiation damping, a typical system with non-positive-real impedance, in order to elucidate the nature of such a system.

We first examine in §2 the many-dimensional irreversible-thermodynamical system treated in §2 of I, in more detail, showing that the rank of the matrix of the quadratic form of dissipation function should be equal to that of the matrix whose elements are the coefficients of the diffusion terms of the Fokker-Planck equation describing this system. This means that the variables which contribute independently to the macroscopic entropy production or energy dissipation should necessarily contribute also to the diffusion terms of the Fokker-Planck equation. This is a natural consequence since the fundamental idea of irreversible thermodynamics is that each mechanism of energy dissipation is accompanied with a microscopic fluctuation, which should appear as a diffusion in the space in which the process under consideration becomes Markovian.

In §3 we take up the harmonic oscillator

with radiation damping, and show that we cannot obtain its Fokker-Planck equation without having recourse to an approximation, and if this approximation is admitted, the resulting Fokker-Planck equation has only one diffusion term, despite the fact that there are two mechanisms of, and hence two variables which contribute to, the energy dissipation. According to the above-mentioned characteristic property of the irreversible-thermodynamical system, this will mean that the harmonic oscillator with radiation damping cannot be reduced to a many-dimensional irreversible-thermodynamical system.

§2. A Characteristic Property of Irreversible-Thermodynamical System.

Let us consider a many-dimensional irreversible-thermodynamic system which is described by (I, 2.36), and assume that the matrix $\{L_{ij}\}$ is singular, i.e., its rank R is smaller than r . Since $\{L_{ij}\}$ is symmetric, it can be diagonalized by an orthogonal transformation*

$$C_k^i x^k = y^i, \quad (2.1)$$

as

$$G_i^k L_{kl} G_j^l = D_i \delta_{ij}, \quad (2.2)$$

where $r-R$ D_i 's are zero. We can let $D_i = 0$, $i = R+1, \dots, r$, without loss of generality. By this transformation, (I, 2.16) and the entropy production become

$$Ts'_{ij}y^j + \sum_{j=1}^R D_j \dot{y}^j + Tm'_{ij}\dot{y}^j = p_i'(t), \quad (2.3)$$

and

$$4\dot{S} = \sum_{j=1}^R (1/T) D_j (\dot{x}^j)^2, \quad (2.4)$$

respectively, where $s'_{ij} = G_i^k s_{kl} G_j^l$ and $m'_{ij} = G_i^k m_{kl} G_j^l$. (2.3) and (2.4) indicate that there are only R variables which contribute to the energy dissipation.

If we derive the Fokker-Planck equation corresponding to (2.3), we see that the rank of the matrix whose elements are the coefficients of its diffusion terms is equal to R , provided that the matrices $\{s'_{ij}\}$ and $\{m'_{ij}\}$ are non-singular (this assumption bring about no loss of generality³⁾). The Fokker-Planck equation is none other than the diffusion equation for a Markov process in a $2r$ -dimensional phase space V with the coordinates

* We use here the summation convention for the sum from 1 to r .

$\{y'_i, \dot{y}'_i\}$, $i=1, 2, \dots, r$. Now the above result shows that in the present case the process is completely causal and exhibits no fluctuation in a certain $2r-R$ -dimensional subspace of V . Viewed from the angle of fluctuation, therefore, this is nothing but an R -dimensional process. Let us express this fact by saying that the process is stochastically only R -dimensional. In other words, there are only R independent mechanisms of diffusion; that is, those variables which independently contribute to the energy dissipation all contribute to the diffusion, whilst the variables other than these make no contribution.

As was already mentioned in the introductory section, this is a natural result in accordance with the fundamental idea of irreversible thermodynamics.

§ 3. Fokker-Planck Equation for the Harmonic Oscillator with Radiation Damping.

Saitô and Namiki⁴⁾ gave a general method of obtaining the Fokker-Planck equation corresponding to a given Langevin equation by throwing the theory of Brownian motion into the formalism of the quantum mechanics. In this section we try to derive after their method the Fokker-Planck equation for the harmonic oscillator with radiation damping.

The stochastic property of the fluctuating force to be introduced into the Langevin equation can easily be derived from the fluctuation-dissipation theorem. There seems to be no doubt about the validity of this theorem since it yields a correct results for the energy distribution of the radiation field which is in equilibrium with the oscillator⁵⁾. As is well known, such an oscillator is described macroscopically by the differential equation of the third order

$$\alpha\ddot{x} + m\ddot{x} + r\dot{x} + sx = 0, \quad (3.1)$$

at least approximately, where $\alpha = -(2/3)e^2c^{-3}$ (e : the electric charge of the oscillator; c : the velocity of light) and $s = m\omega_0^2$ (ω_0 : natural frequency of the oscillator). The impedance of the system is

$$Z(i\omega) = s/(i\omega) + r + m(i\omega) + \alpha(i\omega)^2, \quad (3.2)$$

and the fluctuation of the system is described by the Langevin equation

$$\alpha\ddot{x} + m\ddot{x} + r\dot{x} + sx = p(t), \quad (3.3)$$

which is obtained from (3.1) by adding the term of the fluctuating force $p(t)$. The spectral density of $p(t)$ is given by

$$\mathcal{P}(\omega) = (2/\pi)kT \operatorname{Re} Z(i\omega) = (2/\pi)kT(r - \alpha\omega^2),$$

according to the fluctuation-dissipation theorem. This indicates that the term $\alpha\ddot{x}$ in (3.3) which represents the radiation damping and the term $r\dot{x}$ which corresponds to the ordinary viscous damping contribute independently to the energy dissipation, that is, that there are two independent variables which contribute to the energy dissipation. It is, therefore, reasonable to take x and $\dot{x}$ as such variables.

The correlation function of $p(t)$ is given by

$$\langle p(t)p(t+\tau) \rangle = 2T[r\delta(\tau) + \alpha\delta''(\tau)], \quad (3.5)$$

as can easily be seen from (3.4). It is to be noted that this contains a very singular term $\delta''(\tau)$. As was mentioned in § 1, a system with radiation damping has a non-positive-real impedance and hence cannot be describable by irreversible thermodynamics. This fact manifests itself in the right-hand side of (3.5) which contains a term proportional to $\delta''(t)$. However in order to cast the formalism into the framework of the irreversible thermodynamics, it is necessary to assume that the fluctuating force to be introduced into the right-hand side of (3.1) has a correlation function expressed by a δ -function. Thus we put

$$\langle p(t)p(t+\tau) \rangle = \gamma\delta(\tau), \quad (3.6)$$

instead of (3.5), where γ is a constant which is determined below. Physically speaking the functions δ and δ'' are only the idealized abstraction and should really be regarded as the functions such as, for example, those shown in Fig. 1 and Fig. 2, respectively with small correlation times τ_0 and τ' . The correlation time τ' is somewhat larger than τ_0 . The irreversible thermodynamics is valid only when we neglect the behavior of the system within τ_0 , looking only upon the coarse-grained phenomenon. The assumption (3.6) does not mean that the term $\delta''(t)$ can be neglected but it is an approximation to the whole right-hand side of (3.5) including the term $\delta''(t)$. The physical meaning of this approximation will be made clear in what follows.

In this connection it is noted that the values at different times of a stochastic variable with correlation function represented simply by a δ -function are completely independent, while

those of δ'' -type correlation function are not independent at contiguous times as is seen in Fig. 2.

Fig. 1.

Fig. 2.

As the Lagrangian we should take $\mathcal{L} = (1/2)\{\alpha\ddot{x} + m\dot{x} + r\dot{x} + sx\}^2$. Putting $\dot{x} = u$ and $\ddot{x} = w$ and regarding x , u and w as independent variables, we therefore obtain as the modified Lagrangian⁴⁾

$$\mathcal{L}' = (1/2)(\alpha w + mw + ru + sx)^2 + p_1(\dot{x} - u) + p_2(\dot{u} - w). \quad (3.7)$$

The momenta and the corresponding differential operators are

$$\pi = \frac{\partial \mathcal{L}'}{\partial w} = \alpha(\alpha w + mw + ru + sx),$$

$$p_1 = \frac{\partial \mathcal{L}'}{\partial \dot{x}} = p_1, \quad p_2 = \frac{\partial \mathcal{L}'}{\partial \dot{u}} = p_2, \quad (3.8)$$

and

$$p_1 \rightarrow -\gamma \partial / \partial x, \quad p_2 \rightarrow -\gamma \partial / \partial u, \quad \pi \rightarrow -\gamma \partial / \partial w, \quad (3.9)$$

respectively, where the coefficient γ is to be determined below. The Hamiltonian then is

$$\mathcal{H} = \dot{w}\pi + \dot{x}p_1 + \dot{u}p_2 - \mathcal{L}'$$

$$= up_1 + wp_2 + (\pi/2\alpha)(\pi/\alpha - 2mw - 2ru - 2sx). \quad (3.10)$$

Thus the Fokker-Planck equation for the distribution function $W(x, u, w, t)$ is given immediately by

$$\gamma \partial W / \partial t = \mathcal{H} W = -ru(\partial W / \partial x) - rw(\partial W / \partial u)$$

$$+ (\gamma/2\alpha)(\partial / \partial w)[(\gamma/\alpha)(\partial W / \partial w)$$

$$+ 2(mw + ru + sx)W] \quad (3.11)$$

It is not always necessary to solve this equation in order to obtain various average quantities. We have for example the equilibrium value of $\langle u^2 \rangle$, by letting $t \rightarrow \infty$

$$(m/2)\langle u^2 \rangle_\infty = r/4(r - \alpha/m).$$

Since this must be equal to $(1/2)kT$, r is determined to be

$$r = 2kT\alpha(1 - \alpha/mr). \quad (3.12)$$

The Fokker-Planck equation obtained above contains only *one* diffusion term: In the present case there are *two* variables contributing to energy dissipation, whereas the process looks stochastically like only one-dimensional, contrary to the requirement of rigorous thermodynamical description mentioned in § 2. In the coarse observation, which smoothes out the behavior within τ' , the radiation damping does not accompany its own fluctuation, but only modify indirectly the magnitude of the fluctuation accompanying the ordinary viscous damping, according to Eq. (3.12).

It is a difficult problem to handle consistently the term $\delta''(\tau)$. We shall not however worry about it since it is evident from the argument given in § 1 that even if we could take into account the effect of this term rigorously, we cannot at any rate obtain the Fokker-Planck equation which has a full significance from the point of view of the irreversible thermodynamics. We think that

the peculiar property of the radiation damping mentioned above suggests the reason why the radiation damping cannot be treated by irreversible thermodynamics.

However in order to incorporate, consistently, the formalism of radiation damping into the framework of the irreversible thermodynamics, we put the first term of the differential equation of radiation damping (3.1) $\alpha\ddot{x}$ equal to $-\omega_0^2\alpha\dot{x}$, where ω_0 is the natural frequency given by $\omega_0^2=s/m$, as is usually done in simple calculation⁷⁾ assuming that the frequency of the motion is hardly affected by the radiation damping. Then the process can effectively be described by a differential equation of the second order with the coefficient of the damping term $r-s\alpha/m$. In this approximation, therefore, our system can be treated in the framework of irreversible thermodynamics. The approximation $\alpha\ddot{x}\approx-\omega_0^2\alpha\dot{x}$ will however be valid only for a narrow neighborhood of the particular frequency ω_0 , and indeed the spectral density of the system in this approximation $(2/\pi)kT(r-s\alpha/m)$ is nothing but the equation (3.4) at the frequency $\omega=\omega_0$.

It is however interesting to note that the coefficient of the diffusion term $r-s\alpha/m$ just coincides with value of r obtained above ((3.12)), and it should also be noted that the δ -function approximation (3.6) with $r=2kT(r-s\alpha/m)$ given by (3.6) for the correlation function of the fluctuating force is strictly valid for the approximation $\alpha\ddot{x}\approx-\omega_0^2\alpha\dot{x}$. Our treatment in deriving Eq. (3-11) is, we surmise, a little better approximation than that of $\alpha\ddot{x}\approx-\omega_0^2\alpha\dot{x}$.

§ 4. Conclusions

We have shown above that the impedance of irreversible-thermodynamical system should necessarily be positive real. That the fluctuation of any system with positive real im-

pedance can be described by a system of Langevin equations of the second order means that we can regard the system described by a Langevin equation of the second order as the *fundamental* irreversible thermodynamical system, and every irreversible-thermodynamical system can be represented by a suitable combination of these fundamental systems. This conclusion corresponds to the well known fact in the network theory that every passive network can be constructed of elementary RLC circuits (which corresponds to our fundamental system). Our conclusion represents a generalization of the result of the network theory in the sense that the fluctuation has now been taken into account. It may be said that any system which can be represented macroscopically by a model of passive network can be described by the irreversible thermodynamics.

We can also say from the above result that the irreversible thermodynamics is valid only for the irreversible phenomenon which is described as an ordinary viscous damping proportional to the "velocity" $\dot{x}$. This corroborates the point of view of Cox⁶⁾ concerning the nature of irreversible thermodynamics.

This work is supported in part by a Grant in Aid from the Ministry of Education.

Gel Formation of Aqueous Solution of Polyvinyl Alcohol Irradiated by Gamma Rays from Cobalt-60

Akibumi DANNO*

Faculty of Engineering, University of Tokyo, Tokyo

(Received March 6, 1958)

Experiments were carried out on the irradiation of aqueous solution of polyvinyl alcohol by gamma rays. For sufficient dose of radiation, the polymer molecules in the solution interlinked with each other and formed an insoluble gel. The change in degree of polymerization of the polymer with the absorbed dose, and the minimum dose R_g , required to produce a gel, were measured as a function of concentration of polyvinyl alcohol. In dilute solutions below the critical concentration, gel formation did not occur even for prolonged irradiation. Some considerations are given on the phenomena.

§ 1. Introduction

A number of works have been done on the radiation effects of water¹⁾ and aqueous solutions of low molecular organic substances²⁾, but only a few reports have appeared on high polymer solutions. Examples are radiation-induced-polymerization of aqueous solution of acrylonitrile³⁾ and the gel formation of aqueous solution of polyvinyl pyrrolidone⁴⁾. In both of these reports, it was suggested that the radicals formed in water play an important role in the polymerization of acrylonitrile or the gel formation of polyvinyl pyrrolidone. Such a phenomenon is frequently observed for the radiation-induced-decomposition of aqueous solution of low molecular weight substances⁵⁾. Charlesby, in his work on the gel formation of polyvinyl pyrrolidone solution, reported that the minimum dose, R_g , required to produce gel varies as the concentration of the solute is changed. The value of R_g was minimum at a certain concentration and increased as the concentration is increased or decreased and below a certain concentration gel formation did not occur even for a prolonged irradiation.

No detailed study on the radiation effect of polyvinyl alcohol has appeared hitherto. In particular, the only article concerning its water solution is that of Charlesby in which it is simply stated that polyvinyl alcohol behaves in the same manner as polyvinyl pyr-

rolidone**. Polyvinyl alcohol is a polymer which belongs to the so-called degradation type polymer⁷⁾, but it is shown in the present experiment that it can be interlinked when irradiated in water.

§ 2. Experiments

The polyvinyl alcohol in the form of powder was used in this experiment. It was carefully fractionated to get uniform distribution of molecular weight and washed with methanol to eliminate residual sodium acetate. The amount of residual sodium acetate was estimated to be less than 0.06–0.08% in weight. Three samples differing in molecular weight were used. The degrees of polymerization, i.e. the degree of polymerization derived from the molecular weight divided by the monomer weight, of the samples were 1050, 1740 and 2680, respectively. They were dissolved in distilled water and solutions of concentration 1/16, 1/8, 1/4, ..., 4, 6, 8 and 12 gr/100 cc were prepared. The solution was filled in a test tube of 170 mm in length and 12 mm in diameter, leaving the air of about 5 mm above the surface of solution, closed with a cork and sealed with paraffin wax.

** In the course of the preparation of the present manuscript, following paper on the irradiation of aqueous solution of polyvinyl alcohol has appeared. In this letter, Berkowitch, Charlesby and Desreux studied the behaviour in the concentration range below 3% and they observed the formation of microgel⁸⁾.

* Present address; Japan Atomic Energy Research Institute, Tokyo.

Irradiation was carried out with a cylindrical cobalt-60 of approximately 120 curies. The source cylinder was constructed with 20 rods of cobalt-60 and each rod was of 170mm in length and 3 mm in diameter. These rods were arranged at equidistance on a circle of 64 mm in diameter to form a cylinder. To extend, along the axis, the uniform part of the field at both ends, two pairs of 20 rods of cobalt-60 of 20 mm in length and 3 mm in diameter were arranged at both ends.

The dose rate at the center of the cylinder, measured with the ferrous-ferric dosimeter, was 7.5×10^4 r/hr. The distribution of the field intensity in the cylinder and also outside of it was determined relatively to that of the center by the use of glass dosimeter.

②: Outer Chamber

Co: Cobalt-60 rod

Fig. 1. Schematic diagram of Co-60 Source.

Fig. 1 shows the schematic diagram of the cobalt-60 source. Irradiation was carried out in the central chamber and also in the outer chamber, which is divided into six sub-chambers. The central irradiation chamber is 200 mm in height and 52 mm in diameter.

§ 3. Results of the Experiment

Aqueous solution of polyvinyl alcohol of various concentration, described above, was irradiated at about 5°C by gamma rays from cobalt-60. Fig. 2 shows, as an example, the degree of polymerization, P_r , of the polymer in the irradiated solution as obtained from the viscosity measurements. The initial degree of polymerization of this polymer was 1740.

Fig. 2. Change of degree of polymerization, P_r , of polyvinyl alcohol in aqueous solution.

Figures attached to each curve give the number of grams of the polymer dissolved in 100 cc of water.

For any concentration, P_r decreases at first as the absorbed dose increases but increases, in general, after passing a minimum value. For a further increase of the dose, P_r passes a maximum and decreases again, when the concentration is below a certain critical value. Above the critical concentration, P_r continues to rise rapidly showing that gelation occurred. The critical concentration varies as the initial degree of polymerization of the polymer changes. For the sample of initial degree of polymerization 1740, the critical concentration was approximately 0.36 gr/100 cc.

In the solution above the critical concentration, insoluble gel is formed. Fig. 3 shows

- ① unirradiated sample
 ② irradiated with 1.6×10^6 rads
 ③ " 3.3×10^6 rads
 ④ " 4.9×10^6 rads
 ⑤ " 13.3×10^6 rads

Fig. 3. Photograph of various phases of gel formation.

$P_0 = 1740$
 concentration 4 g/100 cc
 dose rate 7.5×10^4 r/hr

Fig. 4. Dependence of degree of polymerization of polymer on Min. Dose for Gel Formation, R_g .

various phases of gel formation. The solution as a whole turns to gel at first and the gel formed is similar to the fragile gelatine solution. On receiving further radiation the gel shrinks, giving off some water. The water given off increases with increasing dose. It does not contain dissolved polyvinyl alcohol.

The gel of polyvinyl alcohol solution formed on receiving sufficient irradiation exhibits rubber like elasticity and often contains a number of bubbles. This rubber like substance is not dissolved even when boiled in hot water of 150°C in an autoclave for one hour. It also retains its original shape through boiling in 0.1 N HCl solution or in 0.1 N NaOH solution at 100°C for three hours. When the gel is dried up, it shrinks remarkably to become a hard pale yellow substance but swells back to the original form when immersed in water.

Minimum dose R_g required for gel formation depends both on the degree of polymerization and the concentration of the polymer. Fig. 4 shows the relation between the minimum dose R_g and the concentration, C , defined as grams per 100 cc. As the degree of polymerization increases, the critical concentration increases, and at the same time the minimum point of the curve shifts to higher concentration. The curve, without much changing its shape moved upward, thus increasing the minimum dose R_g at the same concentration with decrease of the degree of polymerization.

§ 5. Discussion

It is known that degradation process rather than cross-linking occurs predominantly in polyvinyl alcohol irradiated by ionizing radiation. When it is irradiated in the coexistence of water, however, the cross-linking type of reaction occurs and gel is formed as is stated above. Importance of the role of water in gel formation of polyvinyl alcohol is also seen from an experiment on the irradiation

of films of polyvinyl alcohol swelled in water. In this experiment the yield of gel portion increased with the increase of the extent of swelling⁸⁾. Present experiment indicates that the amount of water needed to make gel per one monomer of polyvinyl alcohol is rather large but, at the same time, too much water prevents gel formation as is seen from the existent of the critical concentration.

It would be natural to suppose that the energy absorbed by water from the radiation is transferred to molecules to cause some chemical reactions. If we write the total number of monomer units and the molecules of polyvinyl alcohol in the solution of 100 cc as N and M , respectively, the mass of monomer unit as w , and the degree of polymerization of the polyvinyl alcohol as P , then the concentration of the solution, C , and the number of molecules, M , is

$$C=wN, \quad M=N/P \tag{1}$$

It may be assumed, as a first approximation, that gel formation occurs at an absorbed dose of R_g which is needed to link each polymer molecules in one gram of the solution once on the average. For dilute solution, R_g may be taken as proportional to the total number of molecules, M . If the energy to make one cross-linking is represented by σ , then

$$R_g=K\sigma M \tag{2}$$

where K is a constant which varies with the life time of the active species of dissociated water, the interaction between these species and polymer molecules, the life time of polymer radicals produced by the reaction of active species with the polymer molecules, and the recombination probability of these species and the polymer radicals. In other words, K is a function of temperature and the distribution of molecules in the solution.

From equation (1) and (2) we get

$$R_g=K\sigma C/wP \tag{3}$$

The minimum dose R_g is, thus, expected to be proportional to C and inversely proportional to P . Fig. 5 shows the relation, obtained experimentally, between the product $R_g \times P$ and the concentration C . Above the critical concentration, a linear relation exists between $R_g \times P$ and C . Results obtained for three different degrees of polymerization i.e.

1050, 1740 and 2680, all lie on the same straight line, which is expressed by

$$\begin{aligned} R_g \times P &= 5.1 \times 10^8 + 1.37 \times 10^8 C \\ &= 1.37(3.7 + C) \times 10^8 \end{aligned} \tag{4}$$

Fig. 5. Relation between $R_g \times P_0$ and concentration.

The line does not pass through the origin, but intersects with the ordinate. This fact may be interpreted as showing that some pre-irradiation is necessary to bring the solution to the state where equation (3) can be applied. The empirical formula (4) may be written in the form

$$R_g - R_0 = K\sigma C/wP \tag{5}$$

The slope of the experimental curve, $1.37 \times 10^8/P$ rad, is the dose absorbed by the solution which causes the interlinkage of all the molecules contained in one gram of the solution. Since the mass of the monomer (CH_2CHOH) is 7.36×10^{-23} gr, and the concentration C represents the grams of solute in 100 cc of water, the number of molecules in the unit mass of the solution is 1.36×10^{20} (C/P). By definition, one rad of absorbed dose liberates 6.2×10^{13} eV per gram of the substance irradiated. Therefore, the energy per one linkage absorbed from the solution may be estimated as 62 eV.

In the dilute solution below the critical concentration, the distance between polymer molecules in the solution becomes so large that the chance of linking which will be

caused by the collision of polymer radicals decreases to such an extent that the macro-gel will not be formed.

The critical concentration may correspond to the distribution of molecules at which neighboring molecules just interact. In this respect, following consideration may be of some interest. If all the molecules of polyvinyl alcohol are assumed to have the same degree of polymerization, P , and to have segmental configuration, then the square mean end to end distance of the polymer molecule is given by $l(P/n)^{1/2}$, where l is the length of the segment and n the number of monomer units in one segment. Since the mass of the monomer is 7.36×10^{-23} gr, and the critical concentration C_r represents the grams of solute in 100 cc of water, the number of molecules in the unit mass of the solution is $1.36 \times (C_r/P) \times 10^{20}$.

If we divide the solution into cubes of equal volume and allow one molecule to exist in each cube then the length of the side of cube, a , is given by

$$a = (7.36 \times 10^{-21} \cdot P/C_r)^{1/3}, \quad (6)$$

For the case of $P=1740$, C_r is 0.36 gr/100 cc and we have

$$\left. \begin{aligned} l(P/n)^{1/2} &= 43l(n)^{-1/2} \\ a &= 3.3 \times 10^{-6} \text{ cm} \end{aligned} \right\} \quad (7)$$

The length of the segment l can be taken to be equal to $1.54 \times 10^{-8} \times 2n$ cm, where 1.54×10^{-8} cm is the length of the C—C bond and n is a number usually smaller than 10. Therefore,

$$\begin{aligned} l(P/n)^{1/2} &= 43 \times 1.54 \times 10^{-8} \times 2n^{1/2} \\ &= 1.32 \times 10^{-6} n^{1/2} \end{aligned} \quad (8)$$

If, at the critical concentration, the length of the cube a is supposed to be equal to the square mean end to end distance of the polymers, i.e. $l(P/n)^{1/2} = a$, the value of n should be taken equal to 6 which is a reasonable value.

In the dilute solution below the critical concentration, the relation between the dose and the degree of polymerization is represented by curves with a minimum and a maximum as shown in Fig. 2. These results may be interpreted by considering that both degradation and cross-linking are taking place⁹. A theoretical treatment of this phenomena will be published by Saito elsewhere.

Above the critical concentration, a detailed

discussion was given by Charlesby⁴. Gel formation was explained by him by postulating indirect action and the effect of end-linking. His argument was carried out on the aqueous solution of polyvinyl pyrrolidone, but it may also be applied to polyvinyl alcohol, as it does not rest upon any special chemical character of the polymers. Of course, the mere existence of the critical concentration and of the minimum of the minimum dose required for gel formation at a certain concentration can be explained by a simple probability calculation assuming that the energy absorbed by water is used for the gel formation if the effects of both cross-linking and degradation or even only of cross-linking is assumed to take place⁴. Extensive treatment of the mechanism is not, however, possible from the knowledge obtained from our experiment alone, and will not be concerned here.

§ 5. Conclusion

Polyvinyl alcohol which belongs to the so-called degradation type polymer can be cross-linked when irradiated in the presence of water. The mechanism underlying its process, however, can not be made clear without a more detailed physical experiments such as on the temperature effect* and also the chemical experiments are carried out. Especially, the interaction of H^+ , OH^- , H , OH , H_2O_2 , HO_2 etc. which are the products of irradiation of water, with the molecules of polyvinyl alcohol would be an important and an interesting problem which deserves detailed investigation.

§ 6. Acknowledgment

The author wishes to express his sincere thanks to Dr. K. Shinohara of the Scientific Research Institute, Dr. A. Amemiya of the Faculty of Engineering, University of Tokyo and Dr. A. Harashima of Tokyo Institute of Technology for their constant encouragement and also to Dr. M. Tomonari of the Kurashiki Rayon Company for kindly preparing the samples of polyvinyl alcohol. He also wishes to thank the Tokyo Polymer Irradiation Group for their helps in the experiment.

* Minimum dose required for the gel formation changes considerably when the temperature is changed.

The Paramagnetic Resonance Absorption of Some Free Radicals in Sulfuric Acid Solution

By Yasaburo YOKOZAWA

Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received November 12, 1957)

The paramagnetic resonance absorptions in sulfuric acid solutions of some organic compounds, bianthrone, perylene and thio-compounds were observed at 9 kMc/sec under the range of room temperature to the liquid air temperature. One of these samples and the free radical of D.P.P.H. were attached to the different parts of the resonance cavity and their absorptions were separated through the difference of the static magnetic field in each position. The absorption intensities of the sample and the free radical were compared with each other and the number of unpaired electrons was calculated. In bianthrone the number was independent on temperature, while in perylene and thio-compounds it decreased with decreasing temperature. The activation energies of perylene and thio-compounds calculated from their temperature dependencies were respectively 1.7 kcal mol⁻¹ and 5.8 kcal mol⁻¹. On the activation energies and the absorption intensities, some considerations were made.

§ 1. Introduction

There have been many papers on paramagnetic resonance absorptions of powders or liquid solutions of organic free radicals. The detection of the paramagnetic resonance absorption was attempted on such aromatic compounds as anthanthrone, benzanthrone, pyranthrone, perylene, violanthrone and violanthrene. However the absorptions were not detected except those of powder of violanthrone and violanthrene¹⁾ and the sulfuric acid solutions of perylene²⁾, violanthrone and violan-

throne. Of these substances we interested in perylene which had resonance absorption only in sulfuric acid solution. The paramagnetic resonance absorptions of bianthrone³⁾ and thio-compounds⁴⁾ in sulfuric acid were already reported. So the work was attempted to measure the temperature dependencies of absorption intensities of these substances.

The homogeneity of magnetic field of the electromagnet available in this work was too poor to resolve the hyperfine structures of paramagnetic absorption of free radicals. Only

the absorption area was thus studied at several temperatures. The inhomogeneity of magnetic field smoothened the hyperfine structures of absorption line and the sensitivity of the apparatus was reduced. However the smoothened resonance curve facilitated the measurement of absorption area.

Few papers have reported the temperature dependency of absorption area but it seems to be important in order to understand the nature of absorption of free radicals.

§ 2. Experimental Procedure

Measurements were made at a frequency of about 9 kMc/sec in the range of room temperature to the liquid nitrogen temperature. The method of magnetic modulation was used and to eliminate the crystal detection noise, two ways were employed. The first way was a superheterodyne detection system similar to the one by Schneider and England⁵⁾. The reflected power from the resonance cavity was balanced using a magic tee to a level at which a superheterodyne receiver could be used. A slide screw tuner in the arm opposite to the cavity arm of the magic tee was adjusted to select the absorption signal in the detection arm correctly. In this way an absorption curve was observed by a C.R.O. and the absorption intensity was easily measured. When the cavity was cooled, beside the retuning of the cavity, the adjustment of the slide screw tuner was necessary not to include the dispersion signal. As it was very troublesome, the transmission cavity was employed as the second way. In this way only the retuning of the cavity was necessary in the cooling process, but as the level of transmitted power was not low the superheterodyne detection was not available. As usual, to a small absorption, the derivatives of absorption curves were recorded using a narrow band amplifier followed by a lock-in amplifier. The modulation frequency was 240 c/s and the time constant of recording system was about 3 sec and the time necessary to sweep a full curve had order of 3 to 5 minutes.

As sulfuric acid is dispersive in a microwave range and the Q of the cavity is greatly reduced, only a small amount of sample was available. A simple consideration shows that in the transmission cavity the optimum amount of sample is obtained when the Q

loaded with the sample is $8/9$ of the loaded Q without the sample⁶⁾. The amount of sulfuric acid solution used in this work was selected not to decrease the Q remarkably and the amount of sample soluble into this solvent had the order of a few mg. The solution was closed in a polyethylene envelope and attached to the bottom of the cavity.

The 2.1 cm gap of the available electromagnet necessitated some device for the resonance cavity used at a low temperature as shown in Fig. 1. Both an input and an

Fig. 1. The resonance cavity used in low temperatures, where A represents a liquid air vessel, B , an insulator coat of asbestos, C, C' , copper constantan thermocouples, D, D' , thermal insulating wave-guides and S, S' samples.

output waveguide feed were thermally insulated by bakelite waveguides, inside walls of which were plated by aluminium foils. Cooling was performed by the use of liquid nitrogen in the vessel attached to the cavity. Two samples were attached to the bottom and the ceiling of the cavity respectively and their temperatures were measured by two different copper constantan thermocouples. Though cooling was inherently inefficient, a constant temperature was obtained for a sufficiently long time to measure resonance absorptions.

The resonance absorption of α -diphenyl- β -picryl-hydrazyl (designated as D.P.P.H.) placed separately in the portion where the sample occupied had several peaks. From the spacings of these peaks, the inhomogeneity of the magnetic field was estimated about 3 oersteds at a field strength of 3000 oersteds. Though the shape of the absorption curve is thus deformed, the area of absorption is not influenced by the inhomogeneity, because each unit volume of sample contributes the equal area to the absorption intensity. By the inhomogeneity the hyperfine structure was not resolved and the sensitivity of apparatus was reduced, but the line shapes were simplified and the measurement of absorption area became facilitated by the lack of hyperfine structure.

§ 3. The Measurement of Susceptibility by Paramagnetic Resonance Absorptions

If the line width of paramagnetic resonance absorption is narrow, the next relation is easily obtained from Kramers' equation

$$\chi(0) = a \frac{A}{g}, \quad (1)$$

where $\chi(0)$ is static magnetic susceptibility, g , g -factor, A , the area of magnetic resonance absorption and a , a proportional constant. Thus the static susceptibility is calculated from an absorption intensity. This method is superior to other methods when paramagnetic components are hidden in the diamagnetic part of molecules.

To obtain the absolute value of magnetic susceptibility, the areas of absorptions of both a sample to be tested and a standard sample with known susceptibility attached to the same cavity were compared. As a standard sample, D.P.P.H. or other free radical such as

Wurster's blue was used and it was attached to the bottom (ceiling) of the cavity with the sample to the ceiling (bottom). The setting of the cavity was adjusted so as to separate the absorptions of two substances through the difference of magnetic fields at their positions in order to compare their intensities. To ascertain the correctness of this procedure, two samples with equal amount of free radical of Wurster's blue, were attached to the

Fig. 2. Paramagnetic resonance absorptions of two samples with equal amount of Wurster's blue which are separated through the difference of the static magnetic fields in each position. In the right figure, one absorption line is broadened due to the inhomogeneity of static magnetic field, the absorption area remaining unchanged.

Fig. 3. Paramagnetic resonance absorptions of Wurster's blue and bianthrone in sulfuric acid at different temperatures.

cavity as described above and their absorption intensities were compared. Fig. 2 shows the results in different settings of the cavity. Both absorptions have equal areas in spite of the deformation of absorption curve. Moreover, it was ascertained that the same mole number of D.P.P.H. and Wurster's blue had same absorption area and correctness of this procedure was thus established.

§ 4. Results and Discussion

(a) Bianthrone

Photographs of the absorption of the sulfuric acid solution of bianthrone observed on a C.R.O. detected by a superheterodyne system are shown in Fig. 3. In this case, Wurster's blue was used as a standard free radical.

As magnetic susceptibility χ is expressed as

follows;

$$\chi = \frac{g^2 \beta^2 N S(S+1)}{3kT}, \quad (2)$$

where N is the number of paramagnetic centers and other notations have their usual meanings, the ratio of the resonance absorption intensity of samples to that of Wurster's blue at the same temperature, $\chi/\chi_{w.b.}$, is proportional to the numbers of unpaired electrons of sample, when the temperature of Wurster's blue is above 190°K⁷⁾ in which this free radical obeys the Curie's law. Though the temperatures of the samples and the free radical were different, the absorption intensity of the free radical at the sample temperature was calculated.

The ratio $\chi/\chi_{w.b.}$ was independent on temperature and the number of unpaired electrons did not change.

Heated bianthrone shows also the paramagnetic resonance absorption⁸⁾. The products of heated material and the solution in sulfuric acid have probably the similar structures.

(b) Perylene

The absorptions of perylene detected by a derivative curve at different temperatures are shown in Fig. 4. D.P.P.H. was used as a standard free radical obeying Curie's law down to a very low temperature⁹⁾. The ratio of susceptibility of the sample to that of D.P.P.H. $\chi/\chi_{D.P.P.H.}$ decreased with decrease-

Fig. 4. Paramagnetic resonance absorptions of D.P.P.H. and perylene in sulfuric acid at a room temperature and in the low temperatures.

Fig. 5. The relation between the ratio of susceptibility of perylene in sulfuric acid to that of D.P.P.H. and temperatures. As for straight lines A and B, see the paper.

ing temperature and the relation between the logarism of the ratio and the inverse of absolute temperature is shown in Fig. 5. Nearly straight line with a bend at 180°K was obtained. This absorption may be considered to consist of two parts, A and B. The part A that is dependent on temperature may be assumed to be caused by an excited state and from the slope of the straight line A the activation energy ΔE is obtained as

$$\Delta E=1.70\text{ kcal mol}^{-1}.$$

(3)

As an excited state which has a resonance absorption, a triplet state may be considered.

Under the assumption that ΔE is equal to the energy difference between the ground singlet and excited triplet states, the populations of these two states N_1 and N_2 can be connected with each other by the following equation;

$$N_2/N_1=3\exp(-\Delta E/kT).$$

(4)

From this relation N_2 is calculated using Eq. (3) and using Eq. (2), the magnetic susceptibility of the sulfuric acid solution of perylene is obtained. The results are shown in Table I. The susceptibility of the part B was neglected, for it had the order of 10% of

Table I. Ratios of molar magnetic susceptibility of sample to that of D.P.P.H. at a room temperature

Samples	Structure formula	ΔE (kcal/mol)	$\chi/\chi_{\text{D.P.P.H.}}$ (observed)	$\chi/\chi_{\text{D.P.P.H.}}$ (calculated)
Perylene		1.7	0.32 ± 0.06	0.40
Thiophenol		5.8	—	2×10^{-4}
Diphenylsulfide		"	0.06 ± 0.01	"
Thianthrene		"	0.05 ± 0.01	"

the whole value at room temperature and was not important in the next rough estimation. Magnetic susceptibility is also measured by the absorption intensity. The total error consisted mainly 15% in measuring of line widths and a certain degree in measuring the amount of samples. The calculated and observed values are fairly in agreement.

As the cause of the existence of contribution of the triplet state to magnetic susceptibility, next reasons may be considered:

- (a) In sulfuric acid, the structure of perylene is deformed so that the energy of the triplet state lowers,
- (b) Positive ions of perylene are formed in sulfuric acid so that an appreciable population of the triplet state at room temperature is yielded.

According to the private communication. from Dr. Niira, there are two fourfold degenerate states in perylene when it is con-

sidered as a system of π electrons. The energy levels are shown in Fig. 6 together with those of naphthalene, where W is energy, α , a Coulomb integral and β , a resonance integral between neighbouring carbon atoms¹⁰⁾. From this result, it is clear that the energy

Fig. 6. The energy levels of π electrons in naphthalene and perylene. W : energy, α : Coulomb integral, β : resonance integral

necessary to excite the ground state to the triplet state is large and the condition of (a) is very unlike even in the sulfuric acid solution as was already stated by Weissman *et al.*¹¹⁾ In order that (b) is correct, four positively charged ions, in which π electrons fill up to the lower fourfold degenerate level, must be considered. As the degeneracies of this level are removed by the interaction of next neighbour of carbon atoms, an excited triplet state exists near the ground singlet state. However, there are some questions about the appearance of four charged ions. Four charged ions may be not always necessary for the population of the triplet state at room temperature. The energy levels of positive ion may be different from Fig. 6 especially in sulfuric acid, and the possibility of existence of triplet state of divalent ion near the ground state may be admitted. Divalent positive ion of perylene in sulfuric acid may be the cause of resonance absorption.

There is no other evidence of triplet state near the ground state. As the optical transition from a triplet to a singlet state is forbidden, the triplet state is detected only as a weak phosphorescence, which will be hidden in the strong vibrational spectra of molecules and perhaps it will hardly be observed.

Weissmann *et al.*¹¹⁾⁽¹²⁾ reported the paramagnetic resonance absorptions of anthracene, tetracene and perylene in sulfuric acid solution and stated that singly charged positive ions were responsible for a part of resonance absorption. In the present work, the resonance absorption of anthracene in sulfuric acid solution was also detected but it was so small that its temperature dependency could not be measured.

Recently MacLean *et al.*¹³⁾ stated that the paramagnetism in sulfuric acid was due to oxidation products of the aromatics. As reported previously²⁾, the precipitates obtained by throwing the sulfuric acid solution into ice water showed a resonance absorption. It was very weak in the precipitate obtained from fresh sulfuric acid solution and became stronger in that obtained from old solution. This fact shows the existence of some chemical reaction in the sulfuric acid.

It seems that there is no decisive reason to determine which opinion is correct. On the

nature of perylene in sulfuric acid, further experiments are desired.

(c) Thio-compounds

In the case of the sulfuric acid solution of thiophenol, two absorptions were obtained as stated by Wertz and Vivo⁴⁾ but the hyperfine structures of each line were not resolved due to the inhomogeneity of magnetic field. The sulfuric acid solution of diphenylsulfide and thianthrene was observed to have only one absorption line on the contrary to the results by Wertz and Vivo⁴⁾. The appearance of two lines may depend on the condition of solving the sample into sulfuric acid. Even in the case of thiophenol, there was frequently the case that only one absorption line appeared. The results of the temperature dependency of thiophenol were previously reported¹⁴⁾.

Fig. 7. The relation between the ratio of susceptibility of thio-compounds in sulfuric acid to that of D.P.P.H. and temperatures.

Fig. 7 shows the results obtained in diphenylsulfide and thianthrene with the results of one absorption line of thiophenol. The activation energies of thio-compounds were common and it was equal to

$$4E = 5.80 \text{ kcal mole}^{-1}. \quad (5)$$

The comparison of observed and calculated values of susceptibility is given in Table I. As thiophenol is liquid at room temperature, its amount was not measured and the comparison was not made. Contrary to the case

of perylene, even the orders of both values are not in agreement*.

This compounds may be in the dissociation equilibrium with free radicals in sulfuric acid solution. The temperature dependency of absorption intensity may be caused by the change of a dissociation constant. Their common value of activation energy shows the fact that the absorptions are caused by the same origin in these substances.

In conclusion some discussion must be done about the line widths. The unchange of line width is partly caused by the inhomogeneity of magnetic field. In the case of perylene, the line width was fairly narrow and showed the existence of exchange narrowing, whereas the diluted perylene in sulfuric acid solution was reported to have the hyperfine structures¹¹⁾¹²⁾ and fairly wide overall line width. Consequently, broadening of the resonance absorption in the process of decrease of temperature will be expected on account of the decrease of exchange narrowing with the decrease of unpaired electrons. In the case of thio-compounds the line width may be caused by the superposition of hyperfine structures, so the change of line width will not be observed.

The author wishes to express his sincere thanks to Dr. K. Niira, Tokyo Institute of Technology, for his helpful discussion. He is also grateful to Messrs. I. Miyashita and I. Tatsuzaki for their assistance throughout the work. This work was supported in part by a Grant in Aid from the Ministry of Education.

* The statement in our previous paper¹⁴⁾ should be corrected that the resonance absorption of thio-phenol was due to a triplet states.

Moving Striations in Arc Discharge

By HIROSI YOSHIMOTO, MITUO SATO and YASUHIRO NAKAO

Department of Physics, Faculty of Science, Okayama University

(Received February 7, 1957)

In the same manner as in glow discharge, the moving striations are observed in arc discharge. From the patterns of light oscillation, a light intensity wave travelling towards the cathode is obtained. The phenomenon of the moving striations is one manifestation of the light intensity wave which occurs due to an interaction between the following two waves, a space charge wave travelling towards the cathode and an electron density wave. The former changes the electron emission of the cathode, and this produces the latter. The stationary striations observed in the positive column also seem to be one aspect of the light intensity wave.

§ 1. Introduction

In arc discharge as well as in glow discharge, oscillations are usually observed in tube voltage, current and light intensity. Hitherto many experimental data^{1)~4)} have been reported concerning the striations in positive column of rare gas and mercury vapour discharge. These informations, however, are insufficient to give a theoretical explanation for striations. In particular, no relationship has been discovered between moving and stationary striations. In 1951, Donahue and Dieke⁵⁾ reported the oscillatory phenomena in direct current glow discharge comprehensively.

One of the present writers has previously reported the oscillatory phenomena of arc in hot-cathode discharge tube like fluorescent lamp^{6),7)}. In his reports the mechanisms of electrical oscillations have been discussed, but the moving striations accompanied by these oscillations have not been mentioned. The oscillations were not the so-called "Plasma Oscillation," and the frequencies were below 2000 cycle/sec. The circumstances of these oscillations mentioned in his reports may be summarized as follows.

The electrical oscillations are due to the periodical variation of the anode fall accompanied with sudden ionizations and are very much influenced by thermoionic emissivity of cathode, Hg vapour pressure, arc current, etc.. These oscillations can be easily controlled by ion-supply into the anode fall.

From these results we can say that, if there should happen periodical ionizations in front of the anode, the change of the space charge at the anode fall inevitably propagate towards

cathode. In this view point we may expect that some sorts of moving striation appear in the positive column and the space charge wave modulates the thermoionic emission or the discharge current. We have already reported the phenomenon of moving striation several times^{8)~10)}. In this paper we report collectively the experimental results of moving striation obtained hitherto. The discharge tube used is the same as ordinary fluorescent lamp, except that it has no fluorescent film on the inner surface of the tube wall. The cathode is self-heated by the discharge current itself, so that its thermoionic emissivity will change with current. This point is the special feature of this arc discharge which differs from the case of glow discharge.

§ 2. Experimental Apparatus and Technique

The experimental technique is almost the same as that of Donahue and Dieke. The experimental arrangement is shown in Fig. 1.

Fig. 1.

Discharge tube mounted horizontally has the same cathode as that of 20 watt fluorescent lamp and is filled with 4 mm Ar gas and Hg vapour. The arc discharge is maintained by a regulated rectifier power-supply in series with a variable resistance R . Photo-tube is movable horizontally almost in contact with the discharge tube. Light is admitted to the photo-tube through narrow slits. The electric circuit of photo-tube is shielded from the induction of electrical oscillations. Output currents from the photo-tube circuit flow through a resistance at the input terminals of an oscillograph, and the driven sweep of the oscillograph is triggered by the voltage oscillations. The light output about a selected point in the arc discharge is given by the pattern on the cathode ray tube screen as a function of time. Thus the moving striations can be easily observed by plotting the phase of the light intensity depending on the observation point of the arc discharge. The discharge voltage can be studied as a function of time, external resistance and ambient temperature merely by bringing leads directly from the electrodes to the oscillograph. The cathode filament can be externally heated by making current to flow through it by a suitable d.c. source, if it is needed to change the thermoionic emissivity of cathode.

§ 3. Modes of Moving Striations

Oscillations in the tube voltage, the current and the light intensity were observed for the current over the range 0.02–0.4 amp. Oscillations are unstable at a certain range of the current which is shifted to the smaller or larger value according to the increase or decrease of ambient temperature, as shown later. When the discharge is stable, regular oscillations are always observed and the positive column appears quite homogeneous or shows the appearance of stationary striations. The light intensity oscillations have always the same frequencies as that of the voltage oscillations. This shows that these two oscillations are different manifestations of the same phenomenon, as Donahue and Dieke have already pointed out. The light at any point of observation has two components, an a.c. one and a d.c. one. For the simplicity of the measurement, we observed the a.c. component.

Fig. 2 shows an example of the light intensity oscillations at different points in the tube. In this figure the zero of time is the moment at which the current takes its minimum value. The phase of the maxima of the light intensity oscillations retards and the amplitude of oscillation changes with the increasing distance

Fig. 2.

from the anode. This indicates that the maxima of light intensity oscillation travel from the anode towards the cathode. We shall call each of the maxima of the light intensity observed in the oscillation pattern a "striation" hereafter. Its movement over the whole length of the tube is shown in Fig. 3, where the abscissa is the distance of the observation point from the anode and the ordinate the time when a striation passes this point. This figure shows that there exist three different modes according to the current ranges. Mode (a): For the current 0.1–0.4 amp the moving

striation is observed only in the range 0–2 cm in front of the anode, but nowhere in the positive column. Mode (b): For the current 0.08–0.1 amp the moving striation is observed also in the cathode-side region of the positive column as well as in front of the anode. Mode (c): For the current below 0.08 amp

Fig. 3.

Fig. 4.

the moving striation is observed over the whole positive column. In this case the plot of striation is represented by curve segments discontinuous just at the moments of the current minimum, each segment, therefore, being always within one period. This discontinuity is, however, no characteristic property of the moving striation for the current below 0.08 amp, because for this current range

we can get rather continuous curve by changing the experimental conditions, i.e. external resistance, ambient temperature, etc..

Next, the variation of the amplitude of the light oscillation versus the distance from the anode is shown in Fig. 4, where the modes (a), (b) and (c) correspond to the modes (a), (b) and (c) in Fig. 3 respectively. The curves in (a), (b) and (c) embody the visual appearances of discharge, as it is the case for mode (c). Generally, in the region where the moving striations are observed, the points at which the amplitude of light oscillation takes its maximum or minimum value correspond nearly to the brightest or darkest points in the tube respectively. From Figs. 3 and 4 it is obvious that the phase of the striation at the brightest points coincides just with that of the current maximum. These facts show that in this case the stationary striations may be understood to be one manifestation of moving striations.

Now we mention some essential features of light oscillation. When we keep our eyes on the phase of minimum of the light oscillation in Fig. 2, we notice that there are two types of patterns of oscillation as follows. The one has a character that, though the maximum of oscillation retards, the minimum doesn't and its phase coincides always with that of the current minimum as shown in Fig. 2(a). The moving striations of modes (a) and (b) in Fig. 3 belong to this type. The other has a character that both the maximum and the minimum retard as shown in Fig. 2(b). The moving striations of mode (c) in Fig. 3 belong to this type. On the other hand, we can notice that the patterns of oscillation have one or two maxima within one period of current oscillation according to the observation point. When the curve of the movement of striation is discontinuous as for mode (c) in Fig. 3, the patterns of oscillation have always two maxima at the neighborhood of the discontinuity of the curve. If the movement of striation is represented by a continuous curve throughout the positive column, the patterns of oscillation will have only one maximum within one period at every point of observation.

We can get the instantaneous distribution of the variations of the light intensity throughout the positive column by measuring the

Fig. 5.

instantaneous deviations from the zero-level of light oscillation at different points of the tube. Fig. 5 shows a number of example of this distribution curve which were measured at different moments within one period of the oscillation. From these examples it is obvious that in the positive column there exists a travelling wave with a constant wave length towards the cathode. Both the amplitude and the shape of this wave are repeated periodically throughout the positive column. This means

that in the positive column there is no singularity to be regarded as the cause of the stationary striations. This travelling wave, however, changes its amplitude, shape and velocity as it moves along the tube. Fig. 6 shows the changes of amplitude, zero-level and current with time. The zero-level of this wave (broken line in Fig. 5) oscillates periodically up and down with time in such a way that at the maximum or minimum current the displacement of the zero-level is maximum in the positive or negative side respectively and moreover the shape of this curve is similar to the current wave form (compare (b) with (c) in Fig. 6).

Fig. 6.

Fig. 7.

From the curves in Fig. 5, we can trace the movement of the travelling wave as shown by curve (a) in Fig. 7. This curve is continuous and quite different from that of the moving striation (see Fig. 3 (c)). It is noticeable that the points marked with (o) at which this curve crosses with the horizontal lines

corresponding to the moments of the current minimum in Fig. 7 lie on the straight line (b). Since the gradient of the curve in Fig. 7 represents the velocity, the curve (a) shows that the velocity of this travelling wave changes oscillatorily about the constant value obtained from the straight line (b). This constant value is just equal to the product of the wave length and the frequency of oscillation. From the view point of the wave modulation, it is obvious that there exists a travelling wave with constant velocity and this wave must be modulated by a sort of wave in our present case. We can, therefore, say that the travelling light intensity wave shown in Fig. 5 appears due to an interaction of two waves. In order to make clear these circumstances, we must answer, moreover, to the next question, what is the wave modulating the travelling wave with constant velocity. About this problem we shall mention in detail later.

We can thus summarize these experimental results as follows. The time dependent part of the light intensity is composed of two components. One component is represented by a wave which depends on time only and whose wave form is similar to that of current (see Fig. 6(b)), and the other by a travelling wave which moves towards the cathode changing its amplitude and velocity periodically (see Fig. 5). We may expect that these two components should appear naturally as a result of interaction of two waves as already mentioned. On the other hand, the time independent part of the light intensity depends on the observation point. The distribution of this part coincides just with the visual appearance of the positive column and must be also given by the interaction of two waves.

§4. Velocity of Moving Striation

The velocity of the moving striation is apparently different from that of the travelling light intensity wave and varies as the striation moves along the tube. For the sake of convenience, we now consider the velocity calculated from the straight line (b) in Fig. 7 instead of that of the moving striation for the current over the range 0.02–0.08 amp. Table I shows these velocities for different value of current. The velocities for the current larger than 0.08 amp, however, are rough mean

values of the moving striations observed only in front of the anode, because for these values of current the straight lines mentioned in the former case can't be obtained. We see that the velocity of the travelling wave or the moving striation increases with current.

Table I

Current (amp)	Voltage (volt)	Frequency (cycle/sec)	Velocity (m/sec)
0.03	42.0	431	29.00

Table II

Current (amp)	Velocity (m/sec)			
	13°C.	20°C.	25°C.	30°C.
0.025	36.95	32.12	32.30	26.96
0.040	42.95	34.30	34.06	27.77

Series Resistance: 150Ω. Gap between Electrodes: 48 cm.

This velocity is very sensitively influenced by the external conditions, i.e. ambient temperature, external resistance, etc.. Table II shows some examples of the dependence of the velocity on ambient temperature. We see that the increase of ambient temperature causes to decrease the velocity of the travelling wave.

The drift velocity of positive ion is equal to the product of its mobility and the field intensity. From the equation given by Compton and Langmuir, we obtain in our experimental conditions

$$\text{mobility of Hg ion} = 24.6 \text{ m/sec/volt/cm.}$$

Since in our discharge tube the potential gradient in the positive column is about 1 volt/cm, the drift velocity of Hg ion is about 24 m/sec. From that the velocity of the ob-

served travelling wave is comparable with this drift velocity, it follows that the travelling wave might be a propagating density wave of positive ions.

§ 5. Characteristics of Frequency and Current Oscillation

It has been already mentioned that the light oscillations are always accompanied by current oscillations. The curve I in Fig. 8 shows the dependence of the frequency on the arc current. The frequency increases with the current in this case. It is noteworthy that the frequency changes suddenly at the current 0.1 amp. Corresponding to this, the visual appearance of discharge changes remarkably in such a way that for the current below the discontinuous point it is of the form such as stationary striations and for the current above the point it is of the form such as uniform positive column.

Fig. 8.

Next, expecting the enhancement of the electron emission, we have heated the cathode filament by d.c. 0.15 amp. Then the arc voltage apparently dropped a few volts. As shown by the broken curve in Fig. 8, for the current below the discontinuous point the frequency increases, while for the current above this point it decreases. The frequency change is about 30 cycle/sec. The ambient temperature which determines the Hg vapour density in the tube has great influence on the frequency as well as on the character of discharge. The decrease of the ambient temperature shifts the discontinuous point towards the larger current region and diminishes the

frequency remarkably.

The wave form of the current is shown in Fig. 9. There is the portion of the sudden increase of current. This sudden increment and the amplitude of current increase with effective current. The ratio of the time when the current becomes maximum after the moment of its minimum to the period of the current oscillation decreases with the increasing current as shown in Fig. 10.

Fig. 9.

Fig. 10.

§ 6. Mechanism of Light Intensity Wave

We have already mentioned that, whenever the moving striations are observed in the discharge, there exists a light intensity wave in the positive column. In this section we consider the mechanism which produces this light intensity wave.

The oscillatory phenomena of discharge are considered to be necessary for the occurrence of the moving striations. In this sense, the causes of the current (or voltage) oscillation must be those of the light intensity wave. About the causes one of the writers has previously reported a theory⁷⁾. Thus, we can say as follows, if his theory may be adopted here.

(1) In front of the anode there occur sudden ionizations periodically, and then a great deal of positive ions which are too much to

sustain the arc are created at each ionization. These positive ions will be immediately neutralized by the electrons coming from the cathode side and there appears a true plasma, so far as the supply of the electrons is just sufficient to neutralize the positive ions. On the contrary to this, if the supply of electrons is insufficient for neutralization, the positive ions remaining to be neutralized will move towards the cathode as a positive space charge. This may be considered as the origin of the space charge wave travelling towards the cathode.

Whether the supply of electrons is sufficient or not will presumably depend on the thermionic emissivity of the cathode. Thus we can say these circumstances as follows.

(2) If at the instant of every ionization the cathode is able to emit immediately electrons necessary to neutralize completely the positive ions created at the anode, the space charge wave will not occur. In this case the neutralization must be performed instantaneously at the moment of ionization.

(3) If the cathode is unable to emit sufficient electrons for the neutralization, the space charge wave will appear and the moving striations also will be observed. Here, we must pay attention to the manners of neutralization. If it takes much time for the complete neutralization, during this period a space charge wave will appear and damp away gradually with time.

(4) The space charge wave accompanies necessarily an electric field intensity wave.

(5) Since the light intensity is proportional to the drift velocity of electron determined by the electric field, the electric field intensity wave should accompany a light intensity wave.

(6) The positive space charge wave arrives at the cathode and modulates the electron emission. According to this modulation, the electron density throughout the tube will change nearly instantaneously.

(7) By this change of the electron density the amplitude of the light intensity wave will be modulated, because the light intensity is proportional to the electron density.

From these fundamental processes, we can deduce further that the light intensity wave occurs as such a manifestation of the interaction between the electric field intensity wave

and the electron density wave, as it is embodied by

$$L \propto \bar{Q} v n = \bar{Q} k E n,$$

where L is the light intensity, $\bar{Q}$ the mean excitation cross-section for electron, v the drift velocity of electron, n the electron density, k the mobility of electron and E the electric field intensity. If the electron temperature does not vary so appreciably, it may be justified that $\bar{Q}$ is constant. Therefore, in this approximation, we can say that the light intensity wave can be given by the product of the electric field intensity wave and the electron density wave. The former is a travelling wave which moves towards the cathode and its amplitude will depend on the quantity of the positive ions in front of the anode remaining to be neutralized, and the latter is a wave which is expressed by a periodic function of time only and whose wave form is presumably similar to that of current. These two waves, of course, must have the same frequency as that of current.

§ 7. Conclusion

In the same manner as the case of glow discharge, the moving striations have been observed in arc discharge which was burned in a tube like fluorescent lamp with a self-heated oxide-coated cathode. This means that the cause and the characteristic properties of this phenomenon should be essentially the same in both discharges. From the patterns of light oscillations at various points of the positive column we have visualized a light intensity wave which travels towards the cathode changing its amplitude and velocity. The velocity of such a wave is apparently different from that of the moving striation. From the natures of this light intensity wave it has been deduced that there exist an electric field intensity wave travelling towards the cathode and an electron density wave which modulates the preceding wave periodically. Thus the light intensity wave occurs due to the interaction between these two waves. Not only the moving striations but also the visual appearance like stationary striations are apparent manifestations of this interaction. From the analysis of the moving striations we can get the informations of the movement of space charge in plasma.

In our experiment we could not detect a negative space charge wave which moves from the cathode towards the anode. But we believe that such a negative space charge wave corresponds presumably to the electron density wave mentioned above and, as the velocity of this wave is very fast, it is difficult to catch this wave accurately.

Concerning about the characteristic properties of moving striations deduced from our assumption that the light intensity wave is given by the product of the electric field intensity wave and the electron density wave, we shall discuss in detail in the following paper.

Moving Striations due to Space Charge Waves

By HIROSI YOSHIMOTO, MITUO SATO and YASUHIRO NAKAO

Department of Physics, Faculty of Science, Okayama University

(Received February 7, 1957)

In the positive column there exists a light intensity wave travelling towards the cathode. This wave is assumed to be proportional to the product of the electron density wave and the electric field wave. The equation for such a light intensity wave is considered. All the characteristic properties of the moving striations deduced from the analysis of the equation are presented here and are in favor to those of the observed moving striations. From the phenomena of the moving striations, the informations of the space charge waves in plasma can be obtained.

§ 1. Introduction

As shown in the preceding paper¹⁾, the phenomenon of moving striations is one manifestation of a travelling light intensity wave considered to occur due to the interaction between the electron density wave and the electric field wave in the positive column. We assume the light intensity wave to be

proportional to the product of the electron density wave and the electric field wave.

In this paper we deduce the characteristic properties of moving striations from this assumption. For the sake of simplicity, the analysis is carried out for the essentially one-dimensional case in which there is no average charge density in the positive column and

the electric field wave travels towards the cathode keeping its amplitude and velocity constant.

§ 2. Light Intensity Waves in Uniform Plasma

The electron density wave is assumed to be a wave given by

$$n(t) = n_0 \left\{ 1 + \sum_k \eta_k \sin(k\omega t + \varepsilon_k) \right\}, \quad (1)$$

The electric longitudinal field wave is assumed to be the wave travelling in the $+x$ direction with a constant propagation velocity v_0 given by

$$E(x, t) = E_0 \left\{ 1 + \sum_k \zeta_k \sin(k\omega\tau + \delta_k) \right\}, \quad (2)$$

where

$$\tau \equiv t - \frac{x}{v_0}. \quad (3)$$

Here, ω is the angular frequency of the electric oscillation, ε_k and δ_k are the phase constants of the k th harmonics of the two waves, η_k and ζ_k are fractions of the amplitudes of the k th harmonics, n_0 is the mean electron density, and E_0 is the mean electric field. According to our assumption mentioned above the fundamental formular of light intensity wave is given by

$$L = nE = L_0 \left\{ 1 + \sum_k \eta_k \sin(k\omega t + \varepsilon_k) \right\} \cdot \left\{ 1 + \sum_k \zeta_k \sin(k\omega\tau + \delta_k) \right\}, \quad (4)$$

where

$$L_0 = n_0 E_0.$$

From (4) we can see first that this wave travels towards the cathode with periodically varying amplitude and with the same propagation velocity as that of the electric field wave.

§ 3. Analysis of Light Intensity Wave

The right side of Eq. (4) can be divided into three terms as follows.

$$L = \bar{L}(x) + L_0 A(t) + L_0 B(x, t), \quad (5)$$

where

$$\bar{L}(x) = L_0 \left\{ 1 + \frac{1}{2} \sum_k \eta_k \zeta_k \cos \left(k\omega \frac{x}{v_0} - \delta_k + \varepsilon_k \right) \right\}, \quad (6)$$

$$A(t) = \sum_k \eta_k \sin(k\omega t + \varepsilon_k), \quad (7)$$

$$B(x, t) = \sum_k \zeta_k \sin(k\omega\tau + \delta_k) - \frac{1}{2} \sum_k \eta_k \zeta_k \cos(k\omega t + k\omega\tau + \delta_k + \varepsilon_k)$$

$$+ \sum_{(k \neq l)} \eta_k \zeta_l \sin(k\omega t + \varepsilon_k) \sin(l\omega\tau + \delta_l). \quad (8)$$

Here it must be noted that the third term in the right side of (8) doesn't contain the products of the same order harmonics.

Since the time averages of functions (7) and (8) vanish, the time average of L is just equal to $\bar{L}(x)$. This means that the visual appearance of the positive column should be not uniform and similar to that of stationary striations. The schematic characters of the three terms (6) to (8) match to those of the three components obtained in our experiment. For the sake of simplicity, we take only the fundamental harmonics $k=1$ into account, as

$$n(t) = n_0 \{ 1 + \eta \sin(\omega t + \varepsilon) \}, \quad (1')$$

$$E(x, t) = E_0 \left\{ 1 + \zeta \sin \left(\omega t + \frac{\omega}{v_0} x + \delta \right) \right\}, \quad (2')$$

and

$$\bar{L}(x) = L_0 \left\{ 1 + \frac{1}{2} \eta \zeta \cos \left(\frac{\omega}{v_0} x - \delta + \varepsilon \right) \right\}, \quad (9)$$

$$A(t) = \eta \sin(\omega t + \varepsilon), \quad (10)$$

$$B(x, t) = \zeta \sin(\omega\tau + \delta) - \frac{1}{2} \eta \zeta \cos \left(2\omega t - \frac{\omega}{v_0} x + \delta + \varepsilon \right), \quad (11)$$

omitting suffix 1.

§ 4. Travelling Part of Light Intensity Wave

Eq. (11) can be rewritten as

$$B(x, t) = \beta \sin \phi, \quad (12)$$

where

$$\beta \equiv \zeta \left\{ 1 + \frac{1}{4} \eta^2 + \eta \sin(\omega t + \varepsilon) \right\}^{1/2}, \quad (13)$$

$$\phi \equiv \omega \left(t - \frac{x}{v_0} \right) + \delta - \frac{1}{2} \eta \cos(\omega t + \varepsilon) + \frac{1}{8} \eta^2 \sin 2(\omega t + \varepsilon) - \dots \quad (14)$$

We see that the function $B(x, t)$ represents a travelling wave which moves towards the cathode changing its amplitude as well as velocity. The amplitude β is a function of t only, and its maximum or minimum occur in phase with those of electron density n . Its maximum and minimum values are $(1 + 1/2 \cdot \eta) \zeta$ and $(1 - 1/2 \cdot \eta) \zeta$ respectively. So that the value of η can be determined from the ratio of the maximum value to the minimum

value measured experimentally. As

$$\omega t = 2n\pi + \frac{1}{2}\pi - \varepsilon$$

at the maximum of the amplitude β , this gives

$$B(x,t) = \zeta \left(1 + \frac{1}{2}\eta\right) \cos\left(\frac{\omega}{v_0}x - \delta + \varepsilon\right). \tag{15}$$

By comparing (15) with (9), it will be known that the two waves $\overline{L}(x)$ and $B(x,t)$ are in phase at this time. This means that at the brightest or darkest points of the stationary striations the amplitude of the wave $B(x,t)$ is maximum or minimum. In our experiment, we have obtained also these relations.

Differentiating (14) with respect to t , we obtain the phase velocity v of the travelling wave $B(x,t)$ as follows.

$$v = v_0 \left\{ 1 + \frac{1}{2}\eta \sin(\omega t + \varepsilon) + \frac{1}{4}\eta^2 \cos 2(\omega t + \varepsilon) - \dots \right\} \tag{16}$$

$$= v_0 \left\{ 1 + \frac{1}{2}\eta \sin(\omega t + \varepsilon) \right\}, \tag{16-a}$$

being neglected the second and the higher power of η .

By comparing (16-a) with (1)', we see that the phase velocity v changes periodically in phase with the electron density $n(t)$ as shown in Fig. 1(a). At the instant when $n(t)$ is maximum or minimum the velocity v is also maximum or minimum. These features can be observed in our experiment. If the value of η is negligibly small, the velocity of the travelling wave $B(x,t)$ is nearly constant

Fig. 1.

and equal to the velocity v_0 of the electric field wave.

In the preceding paper we have mentioned that the zero-level of the travelling wave oscillates periodically up and down. This point can also be explained clearly by (10) and (12). These two equations correspond just to the two components into which the a.c. part of the light intensity wave was divided. When the amplitude β of the travelling wave $B(x,t)$ is maximum or minimum,

$A(t)$ is equal to η or $-\eta$. The former case means that the zero-level of the travelling wave is maximum at the positive side of the stationary zero-level, and the latter case means that it is minimum at the negative side.

§ 5. Time-dependent Part of Light Intensity Wave and Moving Striations

We will consider the moving striations. (10) and (11) can be rewritten as

$$\begin{aligned}
 A(t) + B(x, t) &= \{\eta \sin(\omega t + \varepsilon) + \zeta \sin(\omega \tau + \delta)\} \\
 &\quad - \frac{1}{2} \eta \zeta \cos(\omega t + \omega \tau + \delta + \varepsilon) \\
 &= \chi \sin(\omega t + \varepsilon - \varphi) \\
 &\quad + \xi \cos\left(2\omega t - \frac{\omega}{v_0} x + \delta + \varepsilon - \pi\right), \quad (17)
 \end{aligned}$$

where

$$\chi = \left\{ \eta^2 - \zeta^2 + 2\eta\zeta \cos\left(\frac{\omega}{v_0} x + \varepsilon - \delta\right) \right\}^{1/2}, \quad (17-a)$$

$$\xi = \frac{1}{2} \eta \zeta. \quad (17-b)$$

The first term in the right side of (17) contains φ as a phase angle. This φ is a function of x and its expression changes with the relative magnitude of η and ζ as follows.

In the case, $\eta > \zeta$, φ is a periodic function of x , as

$$\begin{aligned}
 \varphi &= \frac{\zeta}{\eta} \sin\left(\frac{\omega}{v_0} x + \varepsilon - \delta\right) \\
 &\quad - \frac{1}{2} \left(\frac{\zeta}{\eta}\right)^2 \sin 2\left(\frac{\omega}{v_0} x + \varepsilon - \delta\right) - \dots \quad (18)
 \end{aligned}$$

In the case, $\eta < \zeta$, φ is an increasing function of x , as

$$\begin{aligned}
 \varphi &= \left(\frac{\omega}{v_0} x + \varepsilon - \delta\right) - \frac{\eta}{\zeta} \sin\left(\frac{\omega}{v_0} x + \varepsilon - \delta\right) \\
 &\quad + \frac{1}{2} \left(\frac{\eta}{\zeta}\right)^2 \sin 2\left(\frac{\omega}{v_0} x + \varepsilon - \delta\right) - \dots \quad (19)
 \end{aligned}$$

Let

$$\left. \begin{aligned}
 \frac{\omega}{v_0} x + \varepsilon - \delta &\equiv \theta_0, & \theta_0 - 2\varphi &\equiv \theta, \\
 \theta_0 - \varphi + \frac{\pi}{2} - \varepsilon &\equiv \omega t_0, & t - t_0 &\equiv t', \\
 A(t) + B(x, t) &\equiv \Gamma \cos \Phi.
 \end{aligned} \right\} \quad (20)$$

We then obtain from (17)

$$\Gamma \cos \Phi = \chi \cos(\omega t' + \theta) + \xi \cos(2\omega t' + \theta). \quad (21)$$

In order to make clear the characteristic properties of the moving striations, it is important to know the time when $\Gamma \cos \Phi$ takes its maximum value. Now, differentiating (21) with respect to t , we can obtain

$$\begin{aligned}
 \frac{d}{dt}(\Gamma \cos \Phi) &= \omega \left\{ \chi \cos\left(\omega t' + \theta + \frac{\pi}{2}\right) \right. \\
 &\quad \left. + 2\xi \cos\left(2\omega t' + \theta + \frac{\pi}{2}\right) \right\} = \omega \Gamma' \cos \Phi', \quad (22)
 \end{aligned}$$

where

$$\Gamma' \equiv (\chi^2 + 4\xi^2 + 4\xi \cos \omega t')^{1/2}, \quad (22-a)$$

for the case $\chi > 2\xi$,

$$\begin{aligned}
 \Phi' &= \omega t' + \theta + \frac{\pi}{2} + 2 \frac{\xi}{\chi} \sin \omega t' \\
 &\quad + 2 \left(\frac{\xi}{\chi}\right)^2 \sin \omega t' + \dots, \quad (22-b)
 \end{aligned}$$

and for the case $\chi < 2\xi$,

$$\begin{aligned}
 \Phi' &= 2\omega t' + \theta + \frac{\pi}{2} - \frac{1}{2} \frac{\chi}{\xi} \sin \omega t' \\
 &\quad + \frac{1}{8} \left(\frac{\chi}{\xi}\right)^2 \sin \omega t' - \dots \quad (22-c)
 \end{aligned}$$

The value of Γ' is always positive is so far as $\chi \geq 2\xi$. So the maximum or minimum value of $\Gamma \cos \Phi$ will be obtained from the condition: $\cos \Phi' = 0$. And it will be immediately known that $\Gamma \cos \Phi$ takes its maximum value, if

$$\Phi' = 2n\pi + \frac{\pi}{2}. \quad (23)$$

This equation yields for the case $\chi > 2\xi$,

$$\omega t = 2n\pi + \left(\frac{\pi}{2} - \varepsilon\right) + \varphi - 2 \frac{\xi}{\chi} \sin \omega(t - t_0) + \dots, \quad (24)$$

and for the case $\chi < 2\xi$,

$$\begin{aligned}
 \omega t &= n\pi + \left(\frac{\pi}{2} - \varepsilon\right) \\
 &\quad + \frac{\theta_0}{2} + \frac{\chi}{4\xi} \sin \omega(t - t_0) + \dots \quad (25)
 \end{aligned}$$

The coefficients of the sine terms in Eqs. (24) and (25) are smaller than unity. So neglecting the sine terms, we can say that the maxima of light intensity oscillation appear at interval of one or a half period respectively, that is, for the case $\chi > 2\xi$, only one maximum will be observed within one period of the current oscillation while, for the case $\chi < 2\xi$, two maxima will be observed.

§ 6. Relation between χ and ξ

From Eq. (17-a) we see that

$$\text{max. value of } \chi = \eta + \zeta > \eta \zeta = 2\xi$$

as $\eta < 1$ and $\zeta < 1$, and

$$\text{min. value of } \chi = |\eta - \zeta|.$$

Here

$$\eta - \zeta \geq \eta \zeta (= 2\xi) \quad (1 > \eta > \zeta)$$

and

$$\zeta - \eta \geq \eta \zeta (= 2\xi). \quad (1 > \zeta > \eta)$$

For the case $|\eta - \zeta| = 2\xi$,

$$\eta = \frac{\zeta}{1 - \zeta}, \quad (\eta > \zeta) \tag{26}$$

thus $1 > \eta > 0$ and $0.5 > \zeta > 0$, and

$$\eta = \frac{\zeta}{1 + \zeta}, \quad (\eta < \zeta) \tag{27}$$

thus $0.5 > \eta > 0$ and $1 > \eta > 0$. If

$$\eta > \frac{\zeta}{1 - \zeta} \quad (\eta > \zeta)$$

or

$$\eta < \frac{\zeta}{1 + \zeta} \quad (\eta < \zeta),$$

we obtain

$$\eta - \zeta > \eta\zeta \quad (\eta > \zeta)$$

or

$$\zeta - \eta > \eta\zeta \quad (\eta < \zeta)$$

respectively. Fig. 2 shows these circumstances graphically. If the point $(\eta\zeta)$ is in the domain A or D, $\chi > 2\xi$ throughout the positive column. While, if the point $(\eta\zeta)$ is in

Fig. 2.

the domain B or C, in the positive column there are two sorts of regions, that is, the regions in which $\chi > 2\xi$, and the regions in which $\chi < 2\xi$. Fig. 1(b) shows this example. From this figure we see that these two sorts of regions situate alternately in the positive column. This is the reason why two different types of the light oscillation pattern (the one has only one maximum within one period and the other has two maxima) are observed in the positive column, and at the same time this is also the reason why the curve of the

movement of striation is discontinuous. If χ is always larger than 2ξ throughout the positive column, only the type of the oscillation pattern having one maximum will be observed, and the curve of the movement of striation will be continuous.

§ 7. Movement of Striations

From (24) and (25) we can know the movement of striation. This movement will show quite different features according to whether η is larger or smaller than ζ . This is due to the facts that, as already mentioned, φ is a periodic or monotonic function of x according to the relative magnitude of η and ζ .

1. The case: $\eta > \zeta$. Neglecting the terms of the second and the higher power of ζ/η in (18) for the sake of simplicity, we obtain

$$\varphi = \frac{\zeta}{\eta} \sin \left(\frac{\omega}{v_0} x + \varepsilon - \delta \right) = \frac{\zeta}{\eta} \sin \theta_0. \tag{28}$$

If $\chi > 2\xi$ throughout the positive column, inserting (28) into (24) we obtain

$$\begin{aligned} \omega t = 2n\pi + \left(\frac{\pi}{2} - \varepsilon \right) + \frac{\zeta}{\eta} \sin \theta_0 \\ - 2 \frac{\xi}{\chi} \sin \omega(t - t_0) + \dots \end{aligned} \tag{29}$$

If $\chi \gg 2\xi$, this yields approximately

$$\omega t = 2n\pi + \left(\frac{\pi}{2} - \varepsilon \right) + \frac{\zeta}{\eta} \sin \theta_0. \tag{29-a}$$

Thus the maxima of the light intensity oscillation appear nearly at the same time throughout the positive column, and those phase differences will be shown as a periodic function of x . In such a case, therefore, the so-called "moving striation" will not appear, and the striation seems to move periodically back and forth according to the increase of x .

If there exist the regions of $\chi < 2\xi$ in the positive column, the curve of the movement of the striation is discontinuous as shown in Fig. 3. In these regions the striations move towards the cathode with a velocity nearly equal to $2v_0$. Thus in such a case the moving striation will appear.

2. The case: $\eta < \zeta$. From (19) we obtain approximately

$$\varphi = \theta_0 - \frac{\eta}{\zeta} \sin \theta_0. \tag{30}$$

If $\chi > 2\xi$ throughout the positive column, the curve of the movement of the striation is continuous.

Fig. 3.

Inserting (30) into (24) we obtain

$$\omega t = 2n\pi + \left(\frac{\pi}{2} - \varepsilon\right) + \theta_0 - \frac{\eta}{\zeta} \sin \theta_0 - 2\frac{\xi}{\chi} \sin \omega(t-t_0) + \dots \quad (31)$$

If $\chi \gg 2\xi$, this yields approximately

$$\omega t = 2n\pi + \left(\frac{\pi}{2} - \varepsilon\right) + \theta_0 - \frac{\eta}{\zeta} \sin \theta_0. \quad (31-a)$$

As θ_0 is a monotonic function of x , this equation shows that t increases with x . Therefore, the striation moves towards the cathode and its velocity is more or less v_0 . If $\eta \ll \zeta$, the velocity is just equal to v_0 , and according to the increase of the value of η , it will become to change periodically. And, when the value of η becomes larger than $\zeta/(1+\zeta)$, in the positive column there appear the regions in which $\chi < 2\xi$, and the curve of the movement of the striation will become discontinuous. In such regions the velocity of the moving striation is nearly equal to $2v_0$. Thus, in this case ($\eta < \zeta$) the moving striations are always observed.

The coefficients η and ζ correspond to the modulation factors of the two waves (the electron density wave and the electric field intensity wave) respectively. Therefore, we can say that the features of the moving striations are greatly influenced by the relative magnitude of the modulation factors of these two waves as follows. When the modulation factor of the electron density wave is far greater than that of the field intensity wave, the moving striations will not be observed. And, when the modulation factor of

the former wave is smaller than that of the latter wave, the moving striations will be always observed. Moreover, when the magnitudes of the modulation factors of the two waves are comparable, the moving striations will be observed and the movement of the striation will be shown by curve segments.

§ 8. Relation between the Phases of the Minima of the Light Oscillations and those of the Electron Density Wave

In contrast to (23), the phases of the minima of the light oscillations are

$$\phi' = 2n\pi + \frac{\pi}{2} + \pi. \quad (32)$$

This equation yields for the case $\chi > 2\xi$,

$$\omega t = \pi + 2n\pi + \left(\frac{\pi}{2} - \varepsilon\right) + \varphi - 2\frac{\xi}{\chi} \sin \omega(t-t_0) + \dots, \quad (33)$$

and for the case $\chi < 2\xi$,

$$\omega t = \pi + n\pi - \varepsilon + \frac{\theta_0}{2} + \frac{\chi}{4\xi} \sin \omega(t-t_0) - \dots, \quad (34)$$

corresponding to (24) and (25) respectively. While the phases of the minima of the electron density wave are given by

$$\omega t = \pi + 2n\pi + \left(\frac{\pi}{2} - \varepsilon\right). \quad (35)$$

Comparing (35) with (33) it will be known that, if $\eta > \zeta$, the minima of the light oscillations coincide nearly with that of the elec-

tron density wave and they seem only to oscillate periodically back and forth at definite points in the oscillation patterns. Alternatively, if $\eta < \zeta$, the minima of the light oscillations move towards the cathode with increasing x . These relations hold for the case $\chi > 2\xi$.

Next, we shall consider the case $\chi < 2\xi$. In this case, as already mentioned, the schematic characters of (34) are hardly affected by the relative magnitude of η and ζ , because (34) does not contain the term φ . The regions where $\chi < 2\xi$ situate always at the vicinity of the points at which the value of θ_0 is $(2n+1)\pi$ (refer to Fig. 1(b)). Thus the term $\theta_0/2$ in (34) has its value nearly equal to $(n+1/2)\pi$. This means that, though the light oscillation patterns in such regions have two minima within one period of the oscillation, one of these two minima always coincides nearly with the minima of the electron density wave.

§ 9. Electron Density Wave and Current Oscillation

As already mentioned, the modulation factor of the electron density wave η and then that of the electric field intensity wave ζ can be determined, if we measure the ratio of the maximum value to the minimum value of β given in (13). On the other hand, the modulation factor of the current oscillation is obtained from the oscillographic pattern of the current. Table I shows these modulation

Table I

Current (amp.)	E-Wave ζ	n -Wave η	Current Wave η'

factors obtained in our experiment. From this table we see that the modulation factor of the electron density wave is always nearly equal to that of the current wave. Here it should be noted that the modulation factor shows only the magnitude of the fundamental wave. If we consider our experiment from

the viewpoint of the relationship between the phases of minima of the light oscillation and the electron density wave, the current wave seems to correspond to the electron density wave. Therefore, we may take the current wave instead of the electron density wave. However, as already mentioned in the preceding paper, the wave form of the current does not coincide with that of the electron density, though these wave forms are similar to each other. Fig. 4 shows this example.

Fig. 4.

From this figure we see that the discrepancies between these two waves are remarkable at the earlier part of the period and negligibly small at the later part. From the harmonic analysis of these waves, the electron density wave seems to be obtained by neglecting the third and the higher harmonics of the current wave. At all events, the two wave forms are not identical, but the more the current changes slowly, the more the two wave forms will be similar to each other. In the discharge space the total energy consumed in unit time is equal to the product of current and field intensity. On the other hand, in our theory the energy radiated as light is proportional to the product of electron density and field intensity. Therefore, the wave form of the electron density allows to estimate the manner of contribution of the current to the light emission.

§ 10. Conclusion

The light intensity wave has been assumed to be represented by the product of the electric field intensity wave and the electron density wave. This basic assumption explains all the experimental results and establishes the characteristic properties of the moving

striations as well as the stationary striations. We believe that in the positive column there exists a space charge wave travelling towards the cathode. This seems to play an essential role for the phenomena of moving striations irrespectively of whether the discharge may be arc or glow.

Flow Formation with Suction or Injection

By R. S. NANDA

*Department of Mathematics, Indian Institute of Technology,
Kharagpur, India*

(Received March 15, 1958)

The problem of boundary layer control with suction or injection is discussed for the cases, (1) flow formation between two planes at a finite distance apart, (2) flow formation in the annular space between two concentric circular cylinders.

Exact solutions of the full Navier-Stokes equations are obtained in both the cases. Results obtained by Hashimoto for an infinite flat plate are deduced as a special case.

§ 1. Introduction

With the aim of reducing the drag suffered by a body and increasing the maximum lift several methods have been devised for the purpose of artificially preventing separation and delaying transition to turbulence. The method of suction has been found particularly useful. Many authors have studied steady boundary layer problems with a normal velocity imposed on the body. In view of its immense utility, especially in the field of aeronautical engineering, it is worthwhile considering unsteady boundary layer problems with suction.

Hasimoto¹⁾ has recently considered the unsteady motion of an infinite flat plate with suction or injection. He has obtained exact solutions of the Navier-Stokes equations for the cases when suction velocity is constant and when it varies as $t^{-1/2}$.

In the present paper we consider, (1) for-

mation of couette motion and (2) flow formation in the annular space between two concentric circular cylinders, when one of the parallel boundaries is kept fixed and the other is started to move with a velocity $U(t)$ and simultaneously a normal velocity $V(t)$ is imposed on the moving boundary. The case (1) is shown to agree with Hashimoto's results for h , the distance between the two plates, tending to infinity.

§ 2. Formation of Couette Motion

Let us consider the unsteady motion of an incompressible viscous fluid between two parallel flat plates. Let h be the distance between the plates. We take a system of axes fixed in space; x -axis coinciding with one of the plates and y -axis normal to it. Let the plate $y=0$ be started at $t=0$ along x -axis with a velocity $U(t)$ and let the plate $y=h$

be kept fixed. Since the plates are infinite in length, all the physical quantities are independent of x . The Navier-Stokes equations and the equation of continuity reduce to

$$\frac{\partial u}{\partial t} + v \frac{\partial u}{\partial y} = \nu \frac{\partial^2 u}{\partial y^2}, \quad (1.1)$$

$$\frac{\partial v}{\partial t} + v \frac{\partial v}{\partial y} = \nu \frac{\partial^2 v}{\partial y^2} - \frac{1}{\rho} \frac{\partial p}{\partial y}, \quad (1.2)$$

$$\frac{\partial v}{\partial y} = 0 \quad (1.3)$$

The boundary conditions to be satisfied are

$$0 \leq y \leq h \quad u = v = 0 \quad t \leq 0,$$

$$\left. \begin{array}{l} \text{At } y=0 \quad u=U(t); \quad v=V(t); \\ \text{At } y=h \quad u=0 \end{array} \right\} t > 0. \quad (1.4)$$

Equations (1.3) and (1.4) give

$$v = V(t). \quad (1.5)$$

Equations (1.2) and (1.5) then give

$$p = p_0 - \rho y \frac{dv}{dt}$$

where p_0 is the value of p at $y=0$ and ρ is the density of the fluid.

Equations (1.1) and (1.5) give

$$\frac{\partial u}{\partial t} + V \frac{\partial u}{\partial y} = \nu \frac{\partial^2 u}{\partial y^2}. \quad (1.6)$$

We shall now solve this equation in the cases $V = V_0 = \text{constant}$ and $V \propto t^{-1/2}$.

The case $V = V_0$

In this case let us first find a solution in the form

$$u = U(t)F(y).$$

Substituting in (1.6) we get

$$\frac{U'}{U} = \nu \frac{F''}{F} - \frac{VF'}{F}. \quad (1.7)$$

Let

$$\frac{U'}{U} = A \quad \text{i.e.} \quad U = U_0 \exp(At).$$

Then (1.7) reduces to

$$F'' - 2BF' - K_1 F = 0, \quad (1.8)$$

where $\frac{V}{\nu} = 2B$; $\frac{A}{\nu} = K_1$. Boundary conditions to be satisfied are $F(0) = 1$; $F(h) = 0$. Solution of (1.8) satisfying the boundary conditions is

$$F(y) = \alpha \exp[y(B + \sqrt{B^2 + K_1})] + B \exp[y(B - \sqrt{B^2 + K_1})], \quad (1.9)$$

where

$$\alpha = \frac{-\exp[-h\sqrt{B^2 + K_1}]}{\exp[h\sqrt{B^2 + K_1}] - \exp[-h\sqrt{B^2 + K_1}]},$$

$$\beta = \frac{\exp[h\sqrt{B^2 + K_1}]}{\exp[h\sqrt{B^2 + K_1}] - \exp[-h\sqrt{B^2 + K_1}]}.$$

In order to obtain a general solution for the plate velocity as a general function of time we apply Laplace Transforms.

Let

$$u^*(y, p) = \int_0^\infty \exp(-pt) u dt$$

Equation (1.6) reduces to

$$\frac{d^2 u^*}{dy^2} - 2K \frac{du^*}{dy} - \frac{p}{\nu} u^* = 0, \quad (1.10)$$

where

$$K = \frac{V_0}{2\nu}.$$

The boundary conditions to be satisfied are

$$\left. \begin{array}{l} u^*(0, p) = U^*(p), \\ u^*(h, p) = 0. \end{array} \right\} \quad (1.11)$$

Thus the solution of (1.10) satisfying (1.11) can be written as

$$u^* = U^* \exp(Ky) \left[\frac{\exp[(y-h)\sqrt{K^2 + p/\nu}] - \exp[-(y-h)\sqrt{K^2 + p/\nu}]}{\exp[-h\sqrt{K^2 + p/\nu}] - \exp[h\sqrt{K^2 + p/\nu}]} \right] \quad (1.12)$$

We are now to get the inverse of (1.12). The expression within brackets on the right hand side of Eq. (1.12) can be expanded in an infinite series and hence, we get

$$\begin{aligned} & L^{-1} \left[\frac{\exp[(y-h)\sqrt{K^2 + p/\nu}] - \exp[-(y-h)\sqrt{K^2 + p/\nu}]}{\exp[-h\sqrt{K^2 + p/\nu}] - \exp[h\sqrt{K^2 + p/\nu}]} \right] \\ &= \frac{\exp(-K^2 \nu t)}{2\sqrt{\pi \nu t^3}} \left[\sum_{n=0}^{\infty} (2nh + y) \exp\left[-\frac{(2nh + y)^2}{4\nu t}\right] - \sum_{n=0}^{\infty} [(2n+1)h - y] \exp\left[-\frac{\{(2n+1)h - y\}^2}{4\nu t}\right] \right] \end{aligned}$$

Finally making use of convolution theorem we get

$$u = \frac{\exp(Ky)}{2\sqrt{\pi\nu}} \int_0^t \frac{U(t-\tau) \exp(-K^2\nu\tau)}{\tau^{3/2}} \left[\sum_{n=0}^{\infty} (2nh+y) \exp\left[-\frac{(2nh+y)^2}{4\nu\tau}\right] - \sum_{n=0}^{\infty} [2n+1]h-y \exp\left[-\frac{\{(2n+1)h-y\}^2}{4\nu\tau}\right] \right] d\tau \quad (1.14)$$

As $h \rightarrow \infty$

$$u \rightarrow \frac{\exp(Ky)}{2\sqrt{\pi\nu}} \int_0^t y \exp\left(-K^2\nu\tau - \frac{y^2}{4\nu\tau}\right) \frac{U(t-\tau)}{\tau^{3/2}} d\tau,$$

which agrees with the result given by Hasimoto. Flow formation without suction can also be obtained from (1.14) by putting $K=0$ and $U=U_0$.

This gives

$$u = U_0 \left[\sum_{n=0}^{\infty} \operatorname{erfc}(2n\eta_1 + \eta) - \sum_{n=0}^{\infty} \operatorname{erfc}((2n+1)\eta_1 - \eta) \right],$$

a result agreeing with Schlichting,²⁾ where $\eta = y/2\sqrt{\nu t}$; $\eta_1 = h/2\sqrt{\nu t}$.

The frictional drag D per unit area of the plate is given by

$$D = \frac{u}{2\sqrt{\pi\nu}} \int_0^t \frac{U(t-\tau) \exp(-k^2\nu\tau)}{\tau^{3/2}} \left[\sum_{n=0}^{\infty} \exp\left(-\frac{n^2 h^2}{\nu\tau}\right) \left[\frac{2n^2 h^2}{\nu\tau} - 2nhk - 1 \right] - \sum_{n=0}^{\infty} \exp\left[\frac{(2n+1)^2 h^2}{-4\nu\tau}\right] \left[\frac{(2n+1)^2 h^2}{2\nu\tau} + kh(2n+1) - 1 \right] \right] d\tau. \quad (1.15)$$

The case $V \propto t^{-1/2}$

As in Ref. (1) we take

$$u = U(t)G(\eta),$$

where

$$\eta = \frac{y}{2\sqrt{\nu t}}.$$

Equation (1.6) then takes the form

$$\nu G'' = 4\nu t \frac{U'}{U} G - 2\eta\nu G' + 2V\sqrt{\nu t} G'. \quad (1.16)$$

In order that this may be reducible to an ordinary differential equation, we take

$$4\nu t \frac{U'}{U} = A, \quad 2V\sqrt{\nu t} = B.$$

In particular, taking

$$A = 2\nu\alpha, \quad B = 2\sqrt{\nu} V_0,$$

we have

$$U = U_0 t^{\alpha/2}; \quad V = \frac{V_0}{\sqrt{t}}.$$

Equation (1.16) then becomes

$$G'' + 2(\eta - \eta_0)G' - 2\alpha G = 0, \quad (1.17)$$

where

$$\eta_0 = \frac{V_0}{\sqrt{\nu}}.$$

Putting

$$G = \exp(-\xi^2)Z$$

where

$$\xi = \eta - \eta_0,$$

this gives

$$\frac{d^2 Z}{d\xi^2} - 2\xi \frac{dZ}{d\xi} - 2(1+\alpha)Z = 0. \quad (1.18)$$

Solution of (1.18) is $Z = \frac{d^\alpha \omega}{d\xi^\alpha}$ where ω satisfies the differential equation

$$\frac{d^2 \omega}{d\xi^2} - 2\xi \frac{d\omega}{d\xi} - 2\omega = 0. \quad (1.19)$$

Hence, the solution of (1.17) becomes

$$G = \exp[-(\eta - \eta_0)^2] \frac{d^\alpha}{d\eta^\alpha} [K_1 \exp[(\eta - \eta_0)^2] \times \int \exp[-(\eta - \eta_0)^2] d\eta + K_2 \exp[(\eta - \eta_0)^2]] \quad (1.20)$$

where K_1 and K_2 are constants to be evaluated from the boundary conditions

$$G(0) = 1; \quad G(\eta_1) = 0, \quad (1.21)$$

where

$$\eta_1 = \frac{h}{2\sqrt{\nu t}}.$$

For the Rayleigh's³⁾ case of impulsive start $U = U_0$ the expression (1.20) satisfying (1.21) becomes

$$G(\eta) = \frac{\operatorname{erf}(\eta_1 - \eta_0) - \operatorname{erf}(\eta - \eta_0)}{\operatorname{erf}(\eta_0) + \operatorname{erf}(\eta_1 - \eta_0)}.$$

In order to get the case of a flat plate we

again make $h \rightarrow \infty$ and get

$$G(\eta)=\frac{\operatorname{erfc}(\eta-\eta_0)}{\operatorname{erfc}(-\eta_0)}$$

which is the same as Hasimoto's result.
If the plate $y=0$ is started with a uniform acceleration (i.e. $\alpha=2$) we get

$$G=\exp [-(\eta-\eta_0)^2] \frac{d^2}{d \eta^2}\left[K_1 \exp \left\{(\eta-\eta_0)^2\right\} \int \exp \left\{-(\eta-\eta_0)^2\right\} d \eta+K_2 \exp \left\{(\eta-\eta_0)^2\right\}\right] \quad(1.22)$$

where K_1 and K_2 are given by

$$K_1=\frac{[1+2\left(\eta_1-\eta_0\right)^2]}{2 N}, \quad K_2=\frac{-[1+2\left(\eta_1-\eta_0\right)^2 x_1+\left(\eta_1-\eta_0\right) \exp \left[-\left(\eta_1-\eta_0\right)^2\right]]}{2 N}$$

$$N=\left[\left(1+2 \eta_0^2\right)\left[1+2\left(\eta_1-\eta_0\right)^2\right]\left[x_0-x_1\right]-\eta_0 \exp \left(-\eta_0^2\right)\left[1+2\left(\eta_1-\eta_0\right)^2\right]-\left[1+2 \eta_0^2\right]\left[\eta_1-\eta_0\right] \exp \left[-\left(\eta_1-\eta_0\right)^2\right]\right]$$

and

$$x_0=\left[\int \exp \left[-\left(\eta-\eta_0\right)^2\right] d \eta\right]_{\eta=\eta_0} ; \quad x_1=\left[\int \exp \left[-\left(\eta-\eta_0\right)^2\right] d \eta\right]_{\eta=\eta_1}$$

§ 3. Flow through Concentric Circular Cylinders

We shall now consider the unsteady motion of an incompressible fluid confined between two concentric circular cylinders of radii a and b ($b > a$). We introduce cylindrical co-ordinates x, y, θ , x -axis coinciding with the common axis of the cylinders. Let the cylinder $y=a$ be started at $t=0$ with a velocity $U(t)$ along x -axis and the cylinder $y=b$ be kept fixed. A normal velocity $V(t)$ imposed on the moving cylinder represents suction. Let u, v, w be the components of the velocity in the directions of x, y and θ increasing respectively. Evidently $w=0$. All the physical quantities are independent of x and θ . The equations of motion and the equation of continuity reduce to

$$\frac{\partial u}{\partial t}+v \frac{\partial u}{\partial y}=\nu\left[\frac{\partial^2 u}{\partial y^2}+\frac{1}{y} \frac{\partial u}{\partial y}\right] \quad(2.1)$$

$$\frac{\partial v}{\partial t}+v \frac{\partial v}{\partial y}=-\frac{1}{\rho} \frac{\partial p}{\partial y}+\nu\left[\frac{\partial^2 v}{\partial y^2}+\frac{1}{y} \frac{\partial v}{\partial y}-\frac{v}{y^2}\right] \quad(2.2)$$

$$\frac{\partial v}{\partial y}+\frac{v}{y}=0 \quad(2.3)$$

and the boundary conditions are

$$\left.\begin{array}{lll} a \leq y \leq b & u=v=0 & t \leq 0 \\ \text { At } y=a & u=U(t) ; & v=V(t) \\ \text { At } y=b & u=0 ; & \end{array}\right\} t > 0 . \quad(2.4)$$

Equations (2.3) and (2.4) give

$$v=\frac{a V}{y} \quad(2.5)$$

Equations (2.2) and (2.5) then give

$$\frac{p-p_0}{\rho}=\frac{V^2}{2}\left(1-\frac{a^2}{y^2}\right)+a \frac{d V}{d t} \log \frac{a}{y},$$

where p_0 is the value of p at $y=a$ and ρ is the density of the fluid.

Equations (2.1) and (2.5) give

$$\frac{\partial u}{\partial t}+\frac{a V}{y} \frac{\partial u}{\partial y}=\nu\left[\frac{\partial^2 u}{\partial y^2}+\frac{1}{y} \frac{\partial u}{\partial y}\right] . \quad(2.6)$$

We shall now solve this equation in the case when $V=V_0=\text { constant }$. This equation can be easily solved by the method of separation of variables.

We write

$$u=U(t) G(y) .$$

Equation (2.6) then becomes

$$\frac{U'}{\nu U}=\frac{G''}{G}+\frac{1-R G'}{y G}, \quad(2.7)$$

where

$$R=a V / \nu$$

Taking

$$U' / U=A \quad \text { i.e. } \quad U=U_0 \exp (A t),$$

equation (2.7) reduces to

$$G''+\frac{1-R}{y} G'-\frac{A}{\nu} G=0 . \quad(2.8)$$

The boundary conditions to be satisfied are

$$G(a)=1, \quad G(b)=0 . \quad(2.9)$$

The solution of (2.8) satisfying (2.9) is

$$G = y^{R/2} [\alpha I_{R/2}(\sqrt{A/\nu}y) + \beta K_{R/2}(\sqrt{A/\nu}y)], \quad (2.10)$$

where

$$\alpha = \frac{\alpha^{-R/2} K_{R/2}(\sqrt{A/\nu}b)}{I_{R/2}(\sqrt{A/\nu}a) K_{R/2}(\sqrt{A/\nu}b) - I_{R/2}(\sqrt{A/\nu}b) K_{R/2}(\sqrt{A/\nu}a)},$$

$$\beta = \frac{-\alpha^{-R/2} I_{R/2}(\sqrt{A/\nu}b)}{I_{R/2}(\sqrt{A/\nu}a) K_{R/2}(\sqrt{A/\nu}b) - I_{R/2}(\sqrt{A/\nu}b) K_{R/2}(\sqrt{A/\nu}a)}.$$

$I_{R/2}$ and $K_{R/2}$ are modified Bessel functions of order $R/2$.

To obtain the general solution when $U = U(t)$ we make use of Laplace transforms. Let us write

$$u^*(y, p) = \int_0^\infty \exp(-pt) u(y, t) dt.$$

Equation (2.6) then becomes

$$\frac{d^2 u^*}{dy^2} + \frac{1-R}{y} \frac{du^*}{dy} - \frac{p}{\nu} u^* = 0$$

the solution of which is easily found to be

$$u^* = y^{R/2} [BI_{R/2}(\sqrt{p/\nu}y) + CK_{R/2}(\sqrt{p/\nu}y)],$$

and since $u^*(a, p) = U^*(p)$ and $u^*(b, p) = 0$ we have

$$U^*(p) = a^{R/2} [BI_{R/2}(\sqrt{p/\nu}a) + CK_{R/2}(\sqrt{p/\nu}a)],$$

and

$$0 = BI_{R/2}(\sqrt{p/\nu}b) + CK_{R/2}(\sqrt{p/\nu}b).$$

Solving we have finally

$$u^* = \frac{U^*(p) y^{R/2}}{a^{R/2}} \left[\frac{K_{R/2}(\sqrt{p/\nu}b) I_{R/2}(\sqrt{p/\nu}y) - K_{R/2}(\sqrt{p/\nu}y) I_{R/2}(\sqrt{p/\nu}b)}{I_{R/2}(\sqrt{p/\nu}a) K_{R/2}(\sqrt{p/\nu}b) - I_{R/2}(\sqrt{p/\nu}b) K_{R/2}(\sqrt{p/\nu}a)} \right]. \quad (2.11)$$

Now by the inversion theorem

$$L^{-1} \left[\frac{K_{R/2}(\sqrt{p/\nu}b) I_{R/2}(\sqrt{p/\nu}y) - K_{R/2}(\sqrt{p/\nu}y) I_{R/2}(\sqrt{p/\nu}b)}{I_{R/2}(\sqrt{p/\nu}a) K_{R/2}(\sqrt{p/\nu}b) - I_{R/2}(\sqrt{p/\nu}b) K_{R/2}(\sqrt{p/\nu}a)} \right]$$

$$= \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} \left[\frac{K_{R/2}(\sqrt{p/\nu}b) I_{R/2}(\sqrt{p/\nu}y) - K_{R/2}(\sqrt{p/\nu}y) I_{R/2}(\sqrt{p/\nu}b)}{I_{R/2}(\sqrt{p/\nu}a) K_{R/2}(\sqrt{p/\nu}b) - I_{R/2}(\sqrt{p/\nu}b) K_{R/2}(\sqrt{p/\nu}a)} \right] e^{pt} dp, \quad c > 0$$

We write $p = -\nu\alpha^2$. Then

$$I_{R/2}(\sqrt{p/\nu}a) K_{R/2}(\sqrt{p/\nu}b) - I_{R/2}(\sqrt{p/\nu}b) K_{R/2}(\sqrt{p/\nu}a)$$

$$= -\frac{\pi}{2} [J_{R/2}(a\alpha) Y_{R/2}(b\alpha) - J_{R/2}(b\alpha) Y_{R/2}(a\alpha)]$$

Let the zeros of $J_{R/2}(a\alpha) Y_{R/2}(b\alpha) - J_{R/2}(b\alpha) Y_{R/2}(a\alpha)$ be $\alpha_1, \alpha_2, \dots$.

Then the poles of the integrand are given by $-\nu\alpha_1^2, -\nu\alpha_2^2, \dots$.

Let R_n denote the residue at $-\nu\alpha_n^2$

Then

$$R_n = \frac{-\pi\nu\alpha_n^2 J_{R/2}(b\alpha_n) J_{R/2}(a\alpha_n)}{J_{R/2}^2(a\alpha_n) - J_{R/2}^2(b\alpha_n)} [J_{R/2}(y\alpha_n) Y_{R/2}(b\alpha_n) - J_{R/2}(b\alpha_n) Y_{R/2}(y\alpha_n)] e^{-\nu\alpha_n^2 t}$$

Making use of the convolution theorem we get

$$u = - \frac{\pi \nu}{a^{R/2}} \int_0^t y^{R/2} U(t-\tau) \sum_{n=1}^\infty \alpha_n^2 e^{-\nu \alpha_n^2 \tau} \left[\frac{J_{R/2}(y \alpha_n) Y_{R/2}(b \alpha_n) - J_{R/2}(b \alpha_n) Y_{R/2}(y \alpha_n)}{J_{R/2}^2(a \alpha_n) - J_{R/2}^2(b \alpha_n)} \right] J_{R/2}(b \alpha_n) J_{R/2}(a \alpha_n) d\tau .$$

In conclusion, I wish to express my sincere thanks to Dr. Y. D. Wadhwa for suggesting the problem and to Prof. B. R. Seth for his valuable guidance throughout the work.

The Magnetic Field at the Nucleus of Sm^{+++} induced by Paramagnetism of 4f-electrons

By Junjiro KANAMORI and Kenzo SUGIMOTO

Department of Physics, Osaka University, Osaka

(Received, April 22, 1958)

Recently, one of the present authors (K.S.) reported¹⁾ the gyromagnetic ratio of the first excited state (122 kev.) of nuclide Sm^{162} , which was determined by investigating the influence of an external magnetic field on the angular distribution of de-excitation radiation following Coulomb excitation. As briefly discussed in the previous paper¹⁾, the electronic magnetic moment of Sm^{+++} (of which the ground state is $^6\text{H}_{5/2}$) induces a magnetic field at the nucleus, which gives rise to some complicity in the final interpretation of the experimental results. The purpose of this note is to give more detailed discussion on the calculation of the induced field.

In the present case, we assume that the nucleus interacts with a thermal average of the electronic magnetic moment. (The validity of this assumption was discussed in the previous paper¹⁾.) Thus we take the thermal average of the interaction between the nucleus and the 4f-electrons over the electronic states. The Hamiltonian of the nucleus in external field is given by

$$\begin{aligned}\mathcal{H} &= \mathcal{H}_0 + \mathcal{H}_1 + \mathcal{H}_2 \\ &= \mathcal{H}_0 - \mu_n \mathbf{H}_{ex} \cdot \mathbf{I} - \mu_n \mathbf{H}_{in} \cdot \mathbf{I},\end{aligned}\quad (1)$$

where $\mathcal{H}_0$ is the electronic energy which determines the thermal distribution among the electronic states; $\mathbf{H}_{ex}$ the external field; $\mathcal{H}_2$ the hyperfine coupling between the nucleus and the electrons. The effective Hamiltonian of $\mathcal{H}_2$ in the Russell-Saunders scheme is given by²⁾

$$\begin{aligned}\mathcal{H}_2 &= -\mu_n \mathbf{H}_{in} \cdot \mathbf{I} = 2\mu_n \mu_B \langle 1/r^3 \rangle [(\mathbf{L} \cdot \mathbf{I}) \\ &+ \xi \mathbf{L}(\mathbf{L}+1)(\mathbf{S} \cdot \mathbf{I}) - (3\xi/2)\{(\mathbf{L} \cdot \mathbf{S})(\mathbf{L} \cdot \mathbf{I}) \\ &+ (\mathbf{L} \cdot \mathbf{I})(\mathbf{L} \cdot \mathbf{S})\}],\end{aligned}\quad (2)$$

$$\xi = (2l+1-4S)/S(2l-1)(2l+3)(2L-1) \quad (l=3),$$

where $\mathbf{L}$ is the total electronic orbital angular momentum; $\mathbf{S}$ the total electronic spin; $\langle 1/r^3 \rangle$ the average of the inverse cubic power of the distance between the nucleus and the 4f-electrons. Using J, M quantization scheme of the electronic states,

where $\mathbf{J}$ is the total electronic angular momentum, and neglecting the effect of the crystalline field which is not important at room temperature, the thermal average of $\mathbf{H}_{in}$ is calculated to be

$$\begin{aligned}\langle H_{in}^z \rangle &= -\mu_B H_{ex} \cdot \sum_{J,M} \exp(-W_{0J}/kT) \cdot \\ &\times [(\langle H_{in}^z \rangle_{JM} g_J M)/kT + \sum_{J' \neq J} \langle S_{J' M}^z H_{in}^z \rangle_{JM} \\ &+ H_{in}^z \langle S_{J' M}^z S_{J' M}^z \rangle / \Delta W_{J' J}] \\ &\div \sum_{J,M} \exp(-W_{0J}/kT),\end{aligned}\quad (3)$$

where W_{0J} is the energy of each J level; g_J its g -factor; $\Delta W_{J' J} = W_{0J'} - W_{0J}$; the z -axis is chosen as the direction of the external field.

In the case of Sm^{+++} , as van Vleck discussed in detail in the problem of its susceptibility³⁾, we cannot confine ourselves to the lowest J level in the summation in (3), because at room temperature both the population of the upper levels with large g -factors and the mixing of different J states caused by the external field make important contributions to $\langle H_{in}^z \rangle$. These effects destroy the proportionality of the susceptibility and the quantity $\langle H_{in}^z \rangle$ to inverse temperature, which would follow, if the upper levels were not considered. The explicit form of $\langle H_{in}^z \rangle$ for Sm^{+++} is given by

$$\begin{aligned}\langle H_{in}^z \rangle / H_{ex} &= (0.6227/T) \cdot \langle 1/r^3 \rangle \cdot 10^{-24} \\ &\times [7.746 + 37.10e^{-7/T} + 76.4e^{-16/T} \\ &+ 132e^{-27/T} + \dots \\ &- 2.378(1 - e^{-7/T})/T \\ &- 3.02(e^{-7/T} - e^{-16/T})/T \\ &- 2.92(e^{-16/T} - e^{-27/T})/T + \dots] \\ &\div [3 + 4e^{-7/T} + 5e^{-16/T} + \dots],\end{aligned}\quad (4)$$

Fig. 1. Temperature variation calculated for the induced magnetic field " H_{in} " at the nucleus of Sm^{+++} .

* This assumption is also supported by recent work of Goldring and Scharenberg. We thank Dr. R. P. Scharenberg for sending us the preprint of their work.

where y is $|\lambda|/2kT$ and λ is the coefficient of the spin-orbit coupling. In the numerical calculation, we insert $\langle 1/r^3 \rangle = 51(\pm 13) \text{ \AA}^{-3}$ after Elliot and Stevens⁴⁾ and either values, $220k$ and $191k$ for $|\lambda|/2$ after van Vleck³⁾. The result is shown in Fig. 1.

In the case of other rare earth ions except Eu^{++} and Pm^{+++} we can simplify (3) as follows:

$$\begin{aligned} \langle H_{in}^2 \rangle &= 2\mu_B^2 \langle 1/r^3 \rangle \cdot C g_J J(J+1)/kT, \\ C &= [(2-g_J) + \xi L(L+1)(g_J-1) \\ &\quad - (3\xi/2)\{J(J+1) - L(L+1) - S(S+1)\}], \\ g_J &= 1 + [J(J+1) - L(L+1) + S(S+1)]/2J(J+1). \end{aligned} \quad (5)$$

For instance, the induced field at the nucleus of Nd^{+++} is obtained as

$$\langle H_{in}^2 \rangle = (392/T) \cdot H_{ex}, \quad (6)$$

where we used $\langle 1/r^3 \rangle = 40(\pm 10) \text{ \AA}^{-3}$ after Elliot and Stevens.⁴⁾

We thank Prof. T. Nagamiya for kind discussions.

Plasma Oscillation in the Electrically Conductive Tin Oxide Film

By Kozo ISHIGURO, Taizo SASAKI,
Toshihiro ARAI and Isamu IMAI

Department of Physics, College of General
Education, University of Tokyo

(Received April 16, 1958)

In the previous paper¹⁾, the optical and electrical properties of the free electrons in the electrically conductive tin oxide films were reported. According to the conclusion of the paper that the effective mass m^* of the electrons in the conduction band should be 0.15~0.20 times of the free electron mass m , the complex refractive index of the specimen No. 15 was recalculated with the constants given under the column of $m^*=0.2m$ of Table I of that paper.

The formulae used to calculate n and k are;

$$n^2 - k^2 = A_v - \frac{v_p^2}{v^2 + v_A^2}$$

$$2nk = \frac{v_p^3}{v^2 + v_A^2} \cdot \frac{v_A}{v}$$

where

$$A_v = \frac{7.851}{2.430 - (v/10^{15})^2}$$

$$v_p = \left(\frac{Ne^2}{\pi m^*} \right)^{1/2} = \text{plasma frequency} = 1.84 \times 10^{14} \text{ sec}^{-1}$$

$$v_A = \frac{1}{2\pi\tau} = \text{relaxation frequency} = 4.37 \times 10^{13} \text{ sec}^{-1}$$

and the results are given in column 4 and 5 of Table I of the present paper.

It was shown recently by H. Fröhlich and H. Pelzer²⁾, and also by J. Hubbard³⁾ that the probability of the energy loss of a fast charged particle suffering a long range collision with free electrons in a solid was proportional to $2nk/(n^2+k^2)^2$. The numerical values of this quantity are also tabulated in the column 6 of Table I of the present paper and the curve plotted against the photon energy is shown in Fig. 1. The curve has a very sharp maximum at $h\nu_{\text{max}} = 0.41 \text{ eV}$, indicating that the energy loss of the electron beam penetrating the specimen would be observed in steps of $h\nu_{\text{max}}$. It should be noticed that as it was pointed out by Nozière and Pines⁴⁾, the real plasma frequency v_{max} does not coincide with the so-called plasma frequency v_p but is shifted to $v_p/1.84$ or $v_p/(A_v)^{1/2}$, in which A_v represents the contribution of the valence and core electrons to the dielectric constant of the present specimen. It is also shown that as the half value width of the absorption band of the electron energy spectrum is given by $nkh\nu_{\text{max}}$, we can evaluate the lifetime τ of the plasma wave⁵⁾ in

the present specimen as $\tau = \hbar / nk\hbar\nu_{\max} \approx 2.6 \times 10^{-16}$ sec.

Such an aspect of the plasma oscillation is already pointed out by Fröhlich and Pelzer²⁾ for Ag, but on the other materials, especially for semiconductors, no example has been as yet reported.

Since tin oxide film does not show any remarkable optical absorption due to lattice vibration be-

tween $0.32 \sim 200 \mu$ except the two bands at $\lambda = 33 \mu$ and 39μ (Fig. 1)* and the intrinsic absorption edge due to the transition between the valence and conduction band lies at $\lambda = 0.32 \mu$, it is free from any disturbances interacting with the plasma oscillation at $\lambda \approx 3 \mu$, and the density of the free electrons in tin oxide is easily controlled by heat treatments. Therefore, the conductive tin oxide film presents an interesting example to study the plasma oscillation in a relatively simplified condition except that the impurity scattering of electrons is rather the predominant mechanism over the scattering caused by the lattice vibration to determine the electrical properties¹⁾.

The authors should like to express their thanks to Prof. H. Kanazawa of our institute for his theoretical help and the introduction to the references.

Magnetic Annealing of Fe₃Al Single Crystal

By Kenzō SUZUKI

Department of Physics and Chemistry,
Gakushuin University, Mejiro,
Takyo, Japan

(Received May 29, 1958)

Recently, the magnetic annealing effect of cubic solid solution has been studied in detail by Chikazumi¹⁾ on the single crystal of Ni₃Fe and by Yamamoto, Taniguchi and Aoyagi on the single crystal of Ni-Co alloy.²⁾ Their results were in rather good agreement with the theory, which was developed by Néel³⁾ and independently by Taniguchi-Yamamoto.⁴⁾ For the purpose of observing the same effect on the body-centred cubic crystal, which was expected to be insensitive to the annealing in $\langle 100 \rangle$ magnetic field, the author investigated this effect on Fe₃Al crystal.

The specimen used was Fe₃Al (110) disk (10.61 mm in diameter and 0.32 mm in thickness). First the specimen was heated up to 650°C and annealed for 30 minutes, and then it was cooled down at a controlled rate to room temperature in a magnetic field. After cooling the torque was measured. Then this torque data was analyzed by means of Fourier analysis and the anisotropy energy measured was separated into field-induced anisotropy E_u and usual crystal anisotropy E_k . Fig. 1 shows the obtained E_u and E_k vs θ_t curves for the cooling rate 3°C/min, where θ_t is the direction of annealing field. The $\Delta\theta$ is also plotted against θ_t in Fig. 2,

Fig. 1. E_u and E_k vs θ_t curve.

- (a): Theoretical curve with $A_1=0$, $A_2=9.8 \times 10^3$ erg/cc.
 (b): Experimental curve with $A_1=2.9 \times 10^3$ erg/cc, $A_2=9.8 \times 10^3$ erg/cc.

Fig. 2. $\Delta\theta$ vs θ_t curve.

where $\Delta\theta$ is the deviation angle between the annealing field direction θ_t and the minimum point θ_0 of E_u , i.e. $\Delta\theta=\theta_t-\theta_0$.

The anisotropy induced by magnetic annealing are generally represented by the formula.

$$E_u = -A_1 \sum_i \alpha_i^2 \beta_i^2 - A_2 \sum_{i,j} \alpha_i \alpha_j \beta_i \beta_j, \quad (1)$$

where α_i and β_i are the direction cosines of intrinsic magnetization and magnetic field of annealing respectively, and A_1 and A_2 are the factors specified by the crystal structure. According to Néel and Taniguchi-Yamamoto's theory, A_1 should be zero for b.c.c. crystal, so E_u must vanish for the $\langle 100 \rangle$ magnetic annealing. The theoretical curves are also shown in Fig. 1 and Fig. 2. It was found, however, by the present experiment that the $\langle 100 \rangle$ magnetic annealing does give rise to a finite value of E_u , as seen in Fig. 1. The experimental curves in Fig. 1 and Fig. 2 was well fitted by Eq. (1) by assuming $A_1=2.9 \times 10^3$ erg/cc and $A_2=9.8 \times 10^3$ erg/cc. The finite value of A_1 can be interpreted by assuming the contribution of the 2nd nearest neighbor interaction. Since 2nd nearest neighbor atoms form a simple cubic lattice, the anisotropy due to 2nd nearest neighbors should be represented only by A_1 term. Therefore the A_1 term in experimental E_u is to be understood as the result of the anisotropic distribution of 2nd nearest neighbors.

By using experimental A_1 and A_2 values, we can obtain the ratio of the coefficient of dipole-dipole interaction between the 1st nearest neighbors l_1 to that between 2nd ones l_2 ,

$$l_1:l_2 = \frac{3}{4} \sqrt{\frac{A_2}{A_1}} = 1.35, \quad (2)$$

the value of which would be rather reasonable. It should be pointed out that the contribution from 2nd nearest neighbors was also verified by the experiment of magnetic anisotropy induced by cold rolling on Fe₃Al single crystals.⁵⁾

The author sincerely thanks to Prof. S. Chikazumi for his kind advice and important suggestions in the course of this investigation.

Magnetic Properties of Nickel and Cobalt Ferrite-Chromite Series

By Syohei MIYAHARA and Tachiro TSUSHIMA

Department of Physics, Faculty of Science,
Hokkaido University, Sapporo, Japan

(Received May 26, 1958)

Though Néel's theory on ferrimagnetism explains successfully the ferrimagnetism of various ferrites,¹⁾ it does not succeed to explain sufficiently the magnetic character of chromites; especially the spontaneous magnetizations of chromites at absolute zero temperature were not explained as the difference of the moments of two sublattices. Thus, the problem of chromites are thought to be rather complicated. In this note an experimental study on magnetic properties of nickel and cobalt ferrite-chromite series is reported, that might make certain contribution to the problem of the ferrimagnetism of chromite.

Chemical formula of the samples is given by Ni (or Co) $\text{Fe}_{2-t}\text{Cr}_t\text{O}_4$, where t varies from 0 to 2. NiFe_2O_4 was made from the mixed solution of NiCl_2 and FeCl_3 , and NiCr_2O_4 was also prepared from the solution of NiCl_2 and CrCl_3 . Other samples of nickel series were made by mixing NiFe_2O_4 and NiCr_2O_4 in stoichiometric ratios.

The specimens of cobalt series were made from powders of extra-pure CoO , Fe_2O_3 and Cr_2O_3 . All samples were heated at 1100°C for about ten hours in air, then quenched to room temperature and were identified by the X-ray diffraction patterns.

Magnetizations at various temperatures from liquid nitrogen to about 900°K were measured by Gouy's method. The maximum field strength used is about 8000 oersted, which is strong enough to saturate the specimens.

Saturation magnetization *vs* temperature curve shows normal form and decreases the magnitude as chromium content increases. Magnetizations at 0°K are obtained by extrapolating the curve from nitrogen temperature. Their changes with chromium content t are shown in Fig. 1.

The variation of lattice parameters with chromium content t is shown in Fig. 2, from which we can find that nickel ferrite-chromite has inverse spinel structure as long as $t < 1.0$, and it changes gradually to normal as t further increases. On the other hand cobalt ferrite-chromite changes its structure from inverse to normal as t increases to 0.4 and remain normal for greater t .

If we assume that the chromium ion always occupies the octahedral site and nickel ion preferentially occupies the octahedral site²⁾, we can evaluate the difference of magnetic moments of the octahedral and tetrahedral sites of nickel ferrite-chromite.

When $t < 1$, it is expressed by $(2-2t)\beta$, which agrees well with the observed value; when $1 < t < 2$, it is expressed by $(4-4t)\beta$, which clearly differs from the observed value.

Fig. 1. Magnetization at 0°K in β .

- a) Nickel series
— observed
--- calculated
b) Cobalt series, observed

Fig. 2. Variation of lattice parameter with t .

Though we do not have enough information about cation distribution of cobalt ferrite-chromite to evaluate the magnetic moment, it is plausible to assume it to be a few Bohr-magnetons per atom. The magnetizations of the samples extrapolated to 0°K are, however, much less than the above value in the cobalt chromite side. This discrepancy should not be due to especially small magnetic moments of the ions, because it is confirmed³⁾ by the Curie constant that the ions have ordinary magnetic moments due to spins.

On Magneto-Acoustic Resonance in Metals

By Nobuo MIKOSHIBA

Electrotechnical Laboratory, Tokyo, Japan

(Received April 21, 1958)

Recently Pippard^{1),2)} has proposed a concept of magneto-acoustic resonance³⁾ for transverse acoustic waves to interpret the experiments of Bömmel,⁴⁾ who showed that the absorption coefficient in metals was markedly affected by the presence of a magnetic field. The object of this note is to point out the limitation of Pippard's concept and to propose other possible magneto-acoustic resonance for the absorption of longitudinal acoustic waves at low temperatures.

In general, the type of the interaction of acoustic waves with conduction electrons is different for three frequency ranges,⁵⁾ i.e.

- 1) the low frequency range: $\omega\tau \ll 1, kl < 1,$
2) the intermediate frequency range: $\omega\tau < 1,$
 $kl > 1$ and
3) the high frequency range: $\omega\tau > 1, kl \gg 1$

where ω and k are the angular frequency and the wave vector of acoustic waves; τ and l are the relaxation time and the mean free path of conduction electrons, respectively. From the relations $\omega = sk$ (s : sound velocity) and $l = \tau v_0$ (v_0 : Fermi velocity), we get

$$\omega\tau = \left(\frac{s}{v_0}\right)kl$$

(1)

(s/v_0 is for example 1/350 for Cu), which gives classification of three frequency ranges.

In the low frequency range we must treat acoustic waves *classically* as waves of a potential for conduction electrons. But in the high frequency range, we can treat them as a *coherent acoustic phonon beam* and then the type of the interaction become very similar to the electron-thermal phonon interaction.^{6),7),8)} Two approaches may be possible in the intermediate range; one is the approach from the low frequency range⁵⁾ and the other from the high frequency range.⁹⁾

Pippard's concept of magneto-acoustic resonance is based on the approach from the low frequency range. His resonance conditions are as follows (see Fig. 1):

- A) The mean free path of conduction electrons

Fig. 1.

Fig. 2.

must be larger than the dimensions of the circular orbits,

$$l > 2\pi r \quad \text{or} \quad \omega_c \tau > 2\pi$$

(2)

with the use of $r = v_0/\omega_c$ ($\omega_c = eH/m^*c$)

- B) The diameter of the circular orbits must be equal to

$$\frac{\lambda}{2}(2n+1) = \frac{\pi}{k}(2n+1), \quad n=0, 1, 2, \dots$$

(3)

where λ is the wave length.

C) Transverse waves can produce a transverse electric field, only when thermal phonons scatter conduction electrons to follow the ionic vibrations.⁵⁾ This scattering process is negligibly small in the high frequency range; however, some amounts of it may remain in the intermediate frequency range.

Then

$$\omega\tau < 1$$

(4)

is required.

Above three conditions are reduced to

$$\omega = \pi \left(n + \frac{1}{2} \right) \left(\frac{s}{v_0} \right) \omega_c, \quad \omega\tau < 1, \text{ and } \omega_c \tau > 2\pi$$

(5)

In such high frequency range as Pippard's concept breaks down, longitudinal waves rather strongly interact with conduction electrons in a transverse magnetic field (see Fig. 2). The electronic motion in the plane perpendicular to the magnetic field is quantized, if $\omega_c \tau > 2\pi$. When the energy of acoustic phonon $\hbar\omega$ is equal to the energy gap $n\hbar\omega_c$ ($n=1, 2, \dots$) between quantized oscillator states, a new magneto-acoustic resonance absorption may occur. This resonance conditions can be written as

$$\omega = n\omega_c, \quad \omega\tau > 1 \quad \text{and} \quad \omega_c \tau > 2\pi.$$

(6)

If $l \sim 10^{-2}$ cm at low temperatures, $\omega > 10^{11}$ sec⁻¹ is required for Cu. But for semi-metals the attainable frequency, 10^9 sec⁻¹, may be sufficient to observe the resonance.

We are indebted to Dr. M. Shibuya and Dr. W. Sasaki for their valuable discussions.

J. PHYS. SOC. JAPAN **13** (1958) 760~761**Space Charge Phenomena in Nitrobenzene under High Electric Field**By Pyong-un CHONG, Chiyoë YAMANAKA
and Tokuo SUITA*Department of Electrical Engineering,
College of Engineering,
Osaka University*

(Received April 15, 1958)

To study the dielectric breakdown in liquids, it is very important to investigate the prebreakdown phenomena which include essential mechanisms of destruction. We have studied the field distribution in nitrobenzene at room temperature using the Kerr electro-optical effect under conditions of D.C. and single rectangular pulse voltages.

We used a conventional setup²⁾ for optical measurement. The first slit, placed before the liquid cell, was 0.30 mm which was as wide as the gap length of the electrodes. The second slit, placed behind the cell, was 0.03 mm wide. It was made movable in the direction of the applied electric field by a micrometer, which enables to detect the transmitted light through one of ten sections between the electrodes.

The intensity of a light beam J under the electric field E , is given by

$$J = \frac{1}{2} J_0 \sin^2 (\pi B l E^2).$$

Where J_0 is the intensity of a incident light beam, B is Kerr constant (4.1×10^{-6} in esu for light of wavelength 5460 Å at 20°C) and l is the length of the electrodes in the direction of the light beam (~ 0.30 mm). The intensity of the transmitted light beam was measured by a multiplier phototube 931 A. So we can calculate the electric field distribution between the electrodes.

In carrying out the experiments we took care of the following points.

- We made the light beam parallel, uniform and not to be scattered by the electrodes very carefully. These were checked by measuring the light intensity of the ten sections between the electrodes with two Nicols made parallel without electric field.
- We changed the polarity of electrode and carried out the same procedure. In both cases we got almost the same results.
- In calculating the electric field strength from the intensity of the transmitted light beam, we tried to estimate it in a several ways, and made it sure that the results were consistent with each other.

In Fig. 1 we show the electric field distribution, between the electrodes in $C_6H_5NO_2$. The increase of the field strength near the cathode was obviously seen. For example, under the application of 8 KV,

the field strength at the cathode section was more than 115% as high as the mean field strength. Almost the same results were obtained in D.C. voltages and single pulse voltages whose durations ranged from 25 μ sec to 100 μ sec. In the case of single pulse voltages the observed light pulse always indicated a time delay to reach a steady value as

Fig. 1. Field distribution under applying pulse voltages.

(a)

(b)

Fig. 2. Delay time of the light pulse under applying 25 μ sec pulse voltages.

shown in Fig. 2. The delay time became shorter as the higher pulse voltages were applied. These phenomena seem to be caused by the movement of the positive ions. If we estimate the mobility of the positive ion, from this model, it is the order of 10^{-3} cm²/sec.volt.. This value seems to be a little larger than those reported before^{3),4)}.

As there are many factors to cause the overestimation, it may be the upper limits of the positive ion mobility in $\text{C}_6\text{H}_5\text{NO}_2$.

We are now measuring the field distortion in nonpolar liquid containing dipolar solute molecules in connection with the experiments mentioned above.

Electric Breakdown and Conduction in BaTiO_3 Single Crystals

By Yoshio INUISHI and Shigeyuki UEMATSU
Faculty of Engineering, Osaka University

(Received April 9, 1958)

The nature of electric breakdown and conduction in single crystals of BaTiO_3 has been investigated¹⁾. BaTiO_3 single crystals were grown by Remeika's method and diffused edge silver electrodes were attached to them by evaporation technique. The temperature dependence of D.C. breakdown strength along C axis is shown in Fig. 1 with the scattering of data. The mean breakdown strength of $0.3 \sim 0.5$ MV/cm is rather insensitive to the temperature in comparison with large temperature dependence of low field conductance, although some drop in breakdown strength is seen above room temperature. It is interesting that no marked change in breakdown strength is seen at Curie temperature where the transition from ferro- to para-electric phase occurs.

The reported low value of breakdown strength^{2),3)} in BaTiO_3 ceramic ($0.02 \sim 0.05$ MV/cm) seems to suffer from secondary factors. The low field conductance σ obtained from final conduction current at 500 V application is shown in Fig. 2 as a func-

Fig. 2.

A possible mechanism may be the migration of K^+ ions introduced by KF. Fig. 3 shows the relation between final conduction current and applied field. At low field, Ohm's law is applicable. At higher field, however, current increases abruptly due to prebreakdown phenomena. From the temperature insensitivity of the breakdown strength, these prebreakdown current seems to be mainly electronic.

The measurements of photoconductivity and Hall effect are now in progress which, we expect, will

bring us much more information on electronic process in BaTiO_3 single crystals. We wish to express our cordial gratitude to Mr. Kisaka of Matsushita Electric Co. for providing BaTiO_3 single crystals.

Diffusion of Iron in Single Crystals of Copper

By YUZO TOMONO and AKIRA IKUSHIMA

Department of Physics, University of Tokyo

(Received April 4, 1958)

Transition elements, when they are dissolved dilutely in noble metals, exhibit anomalous behaviours in electrical and magnetic phenomena, and recently this problem has been investigated extensively. The experimental study on the diffusion of transition elements in noble metals also seems to offer one of the important informations about the problem mentioned above. And as the first step, the diffusion experiment of Fe^{55} in single crystals of pure copper was performed, and the following is the report of the result.

The specimens were prepared from 99.99% cop-

per. Single crystals were grown in H_2 atmosphere by Tammann and Bridgeman method. Crystals thus grown were cut and etched with dilute HNO_3 into the form of short cylinders of 13 m diameter and 10~20 mm length. Then, they were annealed to remove any residual strain at about 950°C for about 10 hours in H_2 atmosphere. A subsequent etching with dilute HNO_3 -alcohol solution showed that the specimens were still single crystals. The

Fig. 1. Typical penetration plots.

Fig. 2. Plot of $\log D$ vs $1/T$.

specimens were then plated electrolytically on their ends with the radioactive isotope Fe^{55} obtained from the Oak Ridge National Laboratory. The plating was made from a slightly basic FeCl_3 bath. During plating, the sides of the specimens were protected with vinyl tape. The thickness of the plated layer was estimated from the radioactivity to be about 5~10 Å.

Diffusion heat treatments were made in Argon

atmosphere of 200 mm Hg at 5 different temperatures. The temperature at the specimen was measured with a calibrated Pt-13% RePt thermocouple. An electronic recorder was used during the heat treatments to watch any temperature fluctuations.

After the heat treatment, the specimen was mounted on a precision lathe, and the material from each cut by lathe was collected in a glass dish. In order to avoid the positional error of the collected matter and also avoid the error due to the absorption of the radiation from Fe⁵⁵ tracer, the collected matter on the dish was dissolved with dilute HNO₃ and then dried by using an infrared ray lamp. The Geiger counter with the mica window of 1.18 mg/cm² thickness was used under the shield with the lead blocks.

Diffusion coefficients of Fe⁵⁵ in Cu.

Temperature (°K)	Diffusion time (sec.)	Diffusion coefficient
1320±2	5.40×10 ³	9.26×10 ⁻¹⁰
1261±2	2.16×10 ⁴	1.07×10 ⁻¹⁰
1225±2	6.88×10 ⁴	2.42×10 ⁻¹¹
1174±2	2.59×10 ⁶	8.84×10 ⁻¹²
1130±2	3.25×10 ⁶	2.10×10 ⁻¹²

The results thus obtained are shown in the table and the figures. The diffusion coefficient of Fe⁵⁵ in Cu is expressed as $D=D_0 \exp(-Q/RT)$ cm²/sec. with

$$\log_{10} D_0 = 6.21 \pm 0.87 \quad (D_0 \text{ in cm}^2/\text{sec.})$$

$$Q = 93020 \pm 4820 \text{ cal/mole.}$$

The errors are the probable errors. The activation energy and the entropy factor for the Fe⁵⁵ in Cu are fairly larger than that of Co⁶⁰ in Cu¹⁾ and Cu⁶⁴ in Cu²⁾. This tendency seems to be consistent with that of the residual resistivities due to solute transition elements in Cu³⁾. This result, however, disagrees with the data reported by Mackliet⁴⁾, and this discrepancy will be examined by the present authors. The diffusion experiment of Mn⁵⁴ in Cu is now in progress.

The authors wish to thank Drs. Kunitomi and Sakamoto for many valuable advices. This work was partly supported by the Scientific Research Expenditure from the Ministry of Education.

Beta and Gamma Ray Spectroscopy of Co⁶⁰

By Kazumasa KAMADA,* Tomoyuki TERANISHI**
and Yasukazu YOSHIZAWA

Department of Physics, Faculty of Science
Osaka University, Osaka

(Received May 27, 1958)

Beta ray and internal conversion electrons of 1.17 and 1.33 Mev gamma rays were measured by the two-directional focusing beta-ray spectrometer ($\rho=40$ cm).¹⁾ The observed values of the maximum energy of beta ray, E_β , K -shell and total conversion coefficients, α_K and α , and $K/L+M$ ratios are tabulated in Table I with values reported previously. Kurie plot of beta ray is shown in Fig. 1, where the deviation in the low energy part is due to the counter window thickness. The K -shell conversion coefficients are determined from the intensity ratio of the K electrons to the beta ray. K and $L+M$ lines are not completely separated, as shown in Fig. 2, but one could obtain these ratios assuming that the shape of $L+M$ line was same as that of K line. In Table I are shown the extrapolated values of Rose's recent theoretical $E2$ conversion coefficients²⁾ with the finite nuclear size effect for K - and L -shells and without this for M -shell.

Fig. 1. Kurie plot of beta ray.

It is interesting that the experimental values of α_K of both gamma rays are in agreement with the theoretical values within experimental error, but $K/L+M$ are not. Gamma transitions among the 4⁺, 2⁺ and 0⁺ states of Ni⁶⁰ have been pointed out to be pure electric quadrupole by angular correlation experiments and others. It has been shown by another experiment³⁾ that $K/L+M$ of $E2$ gamma transitions from the excited states of Cr⁵² have the

A Note on Direct Observation of Dislocations by Electron Microscopy

By Hatsujiro HASHIMOTO and Toshio NAIKI

Kyoto Technical University,
Sakyoku, Kyoto, Japan

(Received February 28, 1958)

It is widely known that Menter¹⁾ observed dislocations in phthalocyanine crystals by electron microscopy. Since one can understand his result by intuition, it has come to be generally believed that the electron microscopy can give the proof for the existence of dislocations. It must be noted, however, a dislocation appearing in an electron micrograph does not always represent a dislocation existing in the crystal lattice. The present authors demonstrated this by an analogy in light optics.

In our demonstration, a plane grating of 66 μ spacing was irradiated by an almost parallel light beam of wave-length 4,900 Å. This corresponds to the electron optical system where a thin sheet of phthalocyanine crystal (spacing 12 Å) is irradi-

ated by 80 K.V. electrons (wavelength $0.04 \text{ \AA}$). We covered one-half of the grating with a slightly wrinkled sheet of transparent paper, leaving the other half uncovered. We took some photographs of the grating at out-of-focus as well as in exact focus (Fig. 1). In exact focus (Fig. 1a), striations of the grating appear straight over the area of both covered and uncovered parts. At out-of-focus (Figs. 1b and c), however, the covered part is remarkably distorted while the uncovered part remains unchanged. In Fig. 1b, edge dislocations are appearing (indicated by arrows) and in Fig. 1c,

(a) $\Delta a = 0.0 \text{ mm}$

(b) $\Delta a = 1.0 \text{ mm}$

(c) $\Delta a = 9.4 \text{ mm}$

Fig. 1. Light optical demonstration. Images of a plane grating covered with wrinkled paper (left) and uncovered (right). Δa indicates defocus, *i.e.* distance between the object and the object plane.

the distortions of the lattice look like dislocations with screw components. Similar phenomena are also observed when small segments of filaments are laid on the grating or when the grating is painted with transparent enamel, leaving brush traces. In any case, irregularities larger than the spacing produce distortions of the lattice in defocused images, often including ghost dislocations.

In electron microscopy, films supporting speci-

mens often have defects and specimens are almost always covered with an uneven layer of contamination due to electron irradiation. Electron micrographs are usually taken at defocus of the order of 0.1μ which corresponds to that in our demonstration. For example, defocus of $\Delta a = 9.4 \text{ mm}$ (Fig. 1c) corresponds to that of $\Delta a = 0.34 \mu$ in the electron optical system. Thus it is highly probable that ghost dislocations appear in electron micrographs. According to our experiment, a ghost dislocation is usually accompanied by a diffuse region around or near it.

We feel that Menter's Figs. 6, 7 and 10 show true dislocations. However, we cannot entirely eliminate the possibility of ghost because diffuse regions similar to those observed in our demonstration are appearing in his micrographs. We examined many micrographs of dislocations taken in Japan²⁾ and found that some may possibly be ghosts. We think that a series of through-focus micrographs are needed to distinguish true dislocations from ghosts. The facts given in this paper are also applicable to dislocations in moiré fringes of crystal lattices^{3),4)} and images of superlattices^{5),6)}.

The authors express their sincere thanks to Professor Kenzo Tanaka, Professor Ryozi Uyeda and Professor Keinosuke Kobayashi for their kind discussions.

On the Auger Ejection of Electrons from Nickel by Inert Gas Ions

By Yoshiyuki TAKEISHI

Tokyo Shibaura Electric Co., 72, Horikawa-chō,
Kawasaki, Japan

(Received April 30, 1958)

We have approximately calculated distribution in kinetic energy and total yield, γ , of the secondary electrons ejected from nickel surface by inert gas ions (except Kr^+ ion) of lower energy. The methods of calculations were essentially similar to the used one in our previous study¹⁾ on clusly BaO-coated cathode, based upon the Hagstrum's one²⁾ for tungsten. In this report, we will use the same notations as defined in the previous paper.¹⁾

The type of electron ejection in the present case is assumed the Auger neutralization for each inert gas ion, provided that the work function, ϕ , and the width of conduction band, ε_F , for nickel are 4.84 eV³⁾ and 4.70 eV⁴⁾, respectively.

Then, neglecting the atomic energy level shifts near metal and the effects of the movement of incident ion, the distribution in energy, $N_i(\varepsilon_K)$, of electrons excited in the process of Auger neutralization is expressed as follows:

$$N_i(\varepsilon_K) = c_1 \rho(\varepsilon_K) \int_0^{\varepsilon_F} n_0(\varepsilon_1) n_0(\varepsilon_2) \times \delta(\varepsilon_K - \varepsilon_1 - \varepsilon_2 + \varepsilon_0 - E_i) d\varepsilon_1 d\varepsilon_2 \quad (1)$$

which corresponds to Eq. (23)' in the previous paper.¹⁾ Here ε_0 is $\varepsilon_F + \phi$, the energy difference between the zero vacuum level and the ground state in the conduction band, and E_i is the ionization energy of inert gas atom.

Assuming that $n_0(\varepsilon)$, the initial state density in the conduction band, is proportional to $\varepsilon^{1/2}$, and $\rho(\varepsilon_K)$, the density of final state, is given, as usual, by $c\varepsilon_K^{1/2}$, where c is a constant, $N_i(\varepsilon_K)$ can be calculated as follows:

$$\begin{aligned} N_i(\varepsilon_K) &= c_2 \cdot \pi / 2 \cdot \varepsilon_K^{1/2} \cdot (\varepsilon_K + \varepsilon_0 - E_i)^2, \\ &\quad E_i - \varepsilon_0 < \varepsilon_K < E_i - \varepsilon_0 + \varepsilon_F \\ &= c_2 \cdot \varepsilon_K^{1/2} [4 \{ \varepsilon_K - 1/2(\varepsilon_K + \varepsilon_0 - E_i) \} \cdot \\ &\quad \times \{ \varepsilon_F(\varepsilon_K + \varepsilon_0 - E_i) - \varepsilon_F^2 \}^{1/2} \\ &\quad + (\varepsilon_K + \varepsilon_0 - E_i)^2 \sin^{-1} \{ (\varepsilon_F - 1/2(\varepsilon_K + \varepsilon_0 - E_i)) / \\ &\quad (1/2(\varepsilon_K + \varepsilon_0 - E_i)) \}], \\ &\quad E_i - \varepsilon_0 + \varepsilon_F < \varepsilon_K < E_i - \varepsilon_0 + 2\varepsilon_F. \quad (2) \end{aligned}$$

In this calculation, the Auger transform was effectively used. Here, c_2 is the normalization factor and 1.197×10^{-3} for He^+ , Ne^+ , Ar^+ ions and 1.265×10^{-3} for Xe^+ ion.

For the above-calculated $N_i(\varepsilon_K)$ and the escape probability, $P_e(\varepsilon_K)$, the energy distribution, $N_0(\varepsilon_K)$, of electrons which escape from nickel surface, is obtained by

Fig. 1. Distribution in kinetic energy, $N_0(E_K)$, of secondary electrons.

$$N_0(\varepsilon_K) = N_i(\varepsilon_K) P_e(\varepsilon_K). \quad (3)$$

Assuming that the angular distribution of excited electron velocities is isotropic, $P_e(\varepsilon_K)$ is expressed by

$$P_e(\varepsilon_K) = \frac{1}{2} [1 - (\varepsilon_0/\varepsilon_K)^{1/2}], \quad \varepsilon_K > \varepsilon_0. \quad (4)$$

Upon this assumption, $N_0(\varepsilon_K)$ is calculated for each inert gas ion (except Kr^+ ion), as shown in Fig. 1, where the abscissa is scaled in $E_K = \varepsilon_K - \varepsilon_0$, that is, the kinetic energy of secondary electrons.

Finally, total electron yield, γ , per an incident ion, is easily obtained, by integrating $N_0(E_K)$ over E_K . γ values of 0.159, 0.128, 0.0506, and 0.0057 are obtained for He^+ , Ne^+ , Ar^+ , and Xe^+ ions, respectively.

In spite of the over-simplified calculations, the obtained values of γ can fairly explain the cathodic phenomena with nickel cathode in normal glow discharges in inert gases, which will be partially reported in the following paper.⁵⁾ However, the calculated $N_0(E_K)$ and γ should be justified by their direct measurements. Accordingly, we will leave the discussions after the direct measurements are done in future.

In conclusion, the author wishes to express his sincere thanks to Mr. K. Nomura and Mr. R. Satō for their encouragements throughout this work.

J. PHYS. SOC. JAPAN **13** (1958) 767~768**A Note on the Normal Cathode Fall in the Glow Discharges in Inert Gases**

By Yoshiyuki TAKEISHI

*Tokyo Shibaura Electric Co., 72, Horikawa-chō,
Kawasaki, Japan*

(Received April 30, 1958)

1. The normal cathode fall, V_{on} (obs.), has been measured for nickel cathode in glow discharges in He, Ne, Ar, and Xe gases, respectively (see Table I). Both cathode and anode were pure nickel and were same form of a dish, the diameter of which was 10 mm. The other experimental conditions and procedures were similar to that in our previous work.¹⁾ After sufficient stabilization of the cathode,

the *d. c.* tube drop,¹⁾ V_{on} (obs.), between anode and cathode was measured as the normal cathode fall.

2. We have attempted to obtain the theoretical normal cathode fall, V_{on} (cal.), for nickel, inserting the values of γ calculated in the preceding paper,²⁾ into the following equation:

$$\left. \begin{aligned} V_{on}(\text{cal.}) &= 3.0(B/A) \ln(1+1/\gamma)^{1)}, \\ \text{for He,} \quad &= 1.42(a_3/a_1) \ln(1+1/\gamma)^{3)}, \end{aligned} \right\} \quad (1)$$

for Ne, Ar, Kr, and Xe.

The latter expression has been introduced by Dote³⁾. It is resulted from modification in α/p expression; $\alpha/p = a_1 \{1 - \exp[-(E/p - a_2)/a_3]\}^{4)}$, $E/p \geq a_2$, where a_1 , a_2 , and a_3 are numerical constants which are cited in Table II. The results of calculations using Eq. (1), are shown in Table I.

Table I. Normal Cathode Falls (in volt).

Cathode		He	Ne	Ar	Kr	Xe
nickel	p in mmHg	20.6	17.7	16.5	—	15.1
	V_{on} (obs.)	145.0	143.0	142.5	—	196.5
	V_{on} (cal.)	149.2	146.5	142.0	—	205.0
	γ (cal.) ²⁾	0.159	0.128	0.0506	—	0.0057
clusty barium oxide	p	15.1	15.0	14.9	—	6.6
	V_{on} (obs.) ¹⁾	80.5	73.5	56.0	—	46.5
	V_{on} (cal.)	84.4	76.5	53.0	47.7	45.6
	γ (cal.) ¹⁾	0.481	0.480	0.476	0.474	0.471
tungsten	p	20.0	36.0	10.0	—	6.6
	V_{on} (obs.) ¹⁾	121.0	114.5	117.0	—	250 ?
	V_{on} (cal.)	116.4	118.1	114.4	128.3	173.3
	γ (obs.) ⁵⁾	0.290	0.213	0.095	0.050	0.013
molyb- denum	p	42	40	10	5.8	5.4
	V_{on} (obs.) ⁶⁾	109.5	107.0	103.6	120.0	134.4
	V_{on} (cal.)	113.7	108.0	103.7	115.9	152.6
	γ (obs.) ⁵⁾	0.300	0.254	0.122	0.069	0.022

3. By Eq. (1), V_{on} (cal.) has been computed again for tungsten cathode, using the corrected values of γ for 10 ev inert gas ions, reported by Hagstrum,⁵⁾ and also computed again for clusty BaO-coated cathode¹⁾ (see Table I).

4. We have also tried to compute V_{on} (cal.) for molybdenum cathode, using the values of γ for 10 ev ions measured by Hagstrum⁵⁾, and to compare V_{on} (cal.) with V_{on} (obs.), reported already by Juriaanse et al⁶⁾ (see Table I).

5. It is seen in Table I that V_{on} (cal.) are in good agreement with V_{on} (obs.) for four cathodes. However there are some disadvantages: (i) For nickel and clusty BaO-coated cathodes, the values of γ obtained by our over-simplified calculations were used. (ii) For tungsten and molybdenum, secondary electrons can be ejected by metastable Ne atoms⁷⁾, which may be present in close proximity to cathode in glow discharges, nevertheless this effect is not included in Eq. (1). (iii) Both

Table II. Numerical constants in α/p expression and Eq. (1).⁴⁾

	a_1	a_2	a_3
Ne	4.18	9.4	200
Ar	13.93	24.5	455
Kr	17.17	26.5	510
Xe	27.84	41.8	780

our calculations and Hagstrum's measurements were done for the "clean" surface adsorbed no molecules.

Here we will only point out next two points for those problems: (i) It is easily deduced from Eq. (1), that $\Delta V_{on}(\text{cal.})/\Delta\gamma = -1.42(a_3/a_1) \cdot 1/\gamma(1+\gamma)$, which indicates that the variation of 10% in γ gives the variation of at most several volt to V_{on} (cal.). (ii) It is supposed in our mind that in glow discharges, the ions impacting cathode sputter probably the

adsorbed molecules, and a considerably "clean" surface may be realized.

In conclusion, the author is grateful to Mr. K. Nomura and Mr. R. Satō for their encouragements during this work.

Electron Spin Resonance of Eu^{++} in Natural CaF_2

By On MATUMURA, Kazumi HōRAI
and Zen'emon MIDUNO

Department of Physics, Faculty of Science,
Kyusyu University

(Received April 7, 1958)

The electron spin resonance of natural CaF_2 crystals (Fluorite from Weardale, England) containing a small amount of Eu^{++} has been analysed at 3 cm wavelength at room temperature. The typical

spectrum is shown in Fig. 1.

Divalent europium has seven f electrons and a ground state of $^8S_{7/2}$. In the absence of external magnetic field, this state is split by a cubic crystal field into two twofold levels and one fourfold level. The overall separation is $8a$, where a is the crystalline cubic field splitting parameter¹⁾. The theoretical treatments were carried out by Kittel and Luttinger²⁾, and De Boer and Van Lieshout³⁾. Using their results, when the external magnetic field is perpendicular to $|001|$ axis, the resonance fields are obtained for $\beta H \gg a$ as,

$$M=1/2 \leftrightarrow -1/2:$$

$$H=H_0 - \left(\frac{35}{32} - \frac{1155}{16} \phi + \frac{10875}{32} \phi^2 \right) \left(\frac{a}{g\beta} \right)^2 \frac{1}{H_0}$$

$$M=\pm 3/2 \leftrightarrow \pm 1/2: H=H_0 \mp 3(1-5\phi) \left(\frac{a}{g\beta} \right) + \left(\frac{5}{8} - \frac{195}{4} \phi - \frac{2115}{8} \phi^2 \right) \left(\frac{a}{g\beta} \right)^2 \frac{1}{H_0}$$

$$M=\pm 5/2 \leftrightarrow \pm 3/2: H=H_0 \mp \frac{5}{2}(1-5\phi) \left(\frac{a}{g\beta} \right) + \left(\frac{115}{3} \phi - \frac{2275}{12} \phi^2 \right) \left(\frac{a}{g\beta} \right)^2 \frac{1}{H_0}$$

$$M=\pm 7/2 \leftrightarrow \pm 5/2: H=H_0 \pm 5(1-5\phi) \left(\frac{a}{g\beta} \right) + \left(\frac{5}{8} - \frac{285}{4} \phi + \frac{1725}{8} \phi^2 \right) \left(\frac{a}{g\beta} \right)^2 \frac{1}{H_0}$$

The parameter $\phi = \cos^2 \theta \sin^2 \theta$ where θ is the angle between the magnetic field and $|100|$ axis.

With $g=1.993$ and $a=0.0186 \text{ cm}^{-1}$, the calculated angular variation of the spectrum and the observed values for $H \perp |001|$ are shown in Fig. 2. The agreements seem to be almost satisfactory. The theoretical intensities of the fine structure components $M=7/2$; $M=-3/2$; $M=-5/2$; $M=1/2$; $M=5/2$; $M=3/2$; $M=-7/2$ are 7:15:12:16:12:15:7, and the observed intensity ratios are (measured from high to low fields) approximately 7:20:14:30:15:

Fig. 1.

18:7. The anomalous large intensity of the central line may be due to other impurities or imperfections in the crystals. In addition, some rather weak complicated lines are also observed. The full report will be given in the near future.

Fig. 2. Angular variation of the fine structure lines.

Measurement of the Thermal Conductivity in Semiconductors

By Riro Nii

Electrical Communication Laboratory,
Musashinoshi, Tokyo

(Received April 19, 1958)

We measured the thermal conductivity of Bi_2Te_3 and PbTe by Ångström method. The apparatus for our measurement is shown schematically in Fig. 1. The sample was soldered on the bar of copper which was wound by the heater I. The thermocouples T_1 and T_2 of Cu constantan were soldered at the positions shown in the figure. When the on off current of period 4 sec was added to the heater I, the sineous temperature wave passed through the sample and diminished to zero amplitude before reaching to the other end of the sample. Then the thermoelectric motive force of the T_1 and T_2 were given by the next forms.

$$V_1 = A \cos \omega t + C_1$$

$$V_2 = B \cos (\omega t - \beta) + C_2$$

And there exist the following relation between A , B and β .

$$\alpha = \frac{\omega l^2}{2 \ln^2 \frac{A}{B}} = \frac{\omega l^2}{2 \rho a} = \frac{K}{c \rho}$$

- where
- K : thermal conductivity

c : specific heat

ρ : density

α : temperature conductivity

Fig. 1. The apparatus for the measurement.

$$\frac{1}{2} \times \frac{1}{\alpha} \text{ sec/cm}^2$$

Fig. 2. Temperature conductivity of Bi_2Te_3 .

Hence the measurement of the ratio A/B and phase difference β gave independently the temperature conductivity. The agreement of the values of calculated from A/B and β was fairly good, but the accuracy of measurement was better for the case of the ratio A/B . The point in the figures 2 and 3 are the values calculated for the measurement of A/B .

At first we show in Fig. 2 the temperature dependence of $1/\alpha$ of Bi_2Te_3 . As is shown there, the curve bends at the temperature where the Hall coefficient of the same sample begins to decrease, and this behaviour corresponds to the results given by Goldsmid¹⁾ and Satterthwaite *et al.*²⁾

Next we show in Fig. 3 the temperature dependence of K of PbTe. The values of thermal conductivity K , were calculated from the measured values of α and the values of c and ρ . For the

Fig. 3. The thermal conductivity of PbTe.

values of specific heat c of PbTe, we used the values given by Parkinson *et al.*³⁾ below room temperature, and we assumed 12 cal./mol above

room temperature. The dotted curve in Fig. 3 is the results given by Joffé.⁴⁾ He suggested from his results the heat conduction by excitons in PbTe, but our sample did not show the abnormal bend of thermal conductivity by excitons. The $1/K$ curve of our samples deviates from a straight line at higher temperature where the samples become intrinsic. Price⁵⁾ considered the energy transport by a bipolar diffusion due to a recombination of electrons and holes for Boltzmann statistics and gave a formula for the additional heat conductivity. The agreement between our results and the values of K calculated from the Price's formula is rather well.

Elastic and Inelastic Scattering of Protons from Neon

By Michiya KONDO and Takashi YAMAZAKI

Department of Physics, Faculty of Science, Osaka University, Osaka

(Received April 7, 1958)

The angular distributions of protons elastically scattered from Ne and inelastically scattered from Ne^{20} ($Q = -1.63$ MeV) were measured from 30° to 165° in the laboratory system at bombarding energies of 4.7, 4.9, 5.1, 5.3 and 5.5 MeV. Photographic plates were employed for the detection of scattered particles. The distributions for the elastic scattering of protons varied markedly with the primary energies, while the five distributions for the inelastic scattering had roughly similar shapes.

§ 1. Introduction

The angular distributions of inelastically scattered protons have been studied about several light elements and the asymmetric distributions about the centre-of-mass scattering angle $\theta = 90^\circ$ were obtained except a few cases. To explain these angular distributions, the theories based on the mechanisms of compound nucleus formation,^{1), 2), 3)} direct nucleon-nucleon interaction,^{4), 5), 6)} and surface interaction,^{7) 8)} were considered. There are, however, many complexities on applying these theories. Even though only the compound nucleus mechanism is assumed among them, for instance, there exist some types of distributions. If the reaction proceeds through a single compound level, the angular distribution is expected to be symmetric about $\theta = 90^\circ$ and then the distribution is characterized by the spin and the parity of the compound level.³⁾ If the interferences with other overlapping levels are important, the distribution becomes asymmetric about $\theta = 90^\circ$ and will change remarkably with the incident energy. If a large number of overlapping levels are involved in the compound nucleus and interference terms can be neglected statistically, the distribution becomes symmetric about $\theta = 90^\circ$.^{1), 2)} Moreover, if the contributions of the direct interaction were superposed upon the mechanism of the compound nucleus formation, the distribution becomes more complex and it will be difficult to separate the contributions of each mechanism.

The angular distributions of protons elastically scattered and inelastically scattered from Ne^{20} , exciting it to 1.63 MeV, were measured at the proton energy of 9.5 MeV⁹⁾ and the symmetric distribution about 90° was obtain-

ed for the inelastic group. The distribution peaked in the forward direction were reported for the inelastic group at the proton energy of 4.2 MeV.¹⁰⁾ McManus¹¹⁾ has analyzed the 9.5 MeV data in terms of the direct interaction theory,⁴⁾ because the large anisotropy is quite unlikely from the statistical consideration. Butler also fitted his theory⁶⁾ on this data. A good agreement was obtained with these theories, but it could not be concluded that this reaction arises from a direct interaction.

In the present experiments the angular distributions of elastically and inelastically scattered protons from Ne^{20} were obtained in the energy region from 4.5 to 5.4 MeV. The excitation energy of the compound nucleus Na^{21} for 5 MeV protons is about 8 MeV and it is expected that the compound levels are rather widely spaced. In this case the statistical theory,^{1), 2)} of course, can not be applied but it must be needed to take account of the effects due to individual levels. And adding to this situation there might exist the contribution of the mechanisms other than compound process in this energy regions. However, a small number of inelastic scattering data^{10), 12), 13)} has been reported at relatively low bombarding energies and these data were taken only at a fixed incident energy.^{10), 12)} Therefore it is interesting to investigate the angular distributions at various incident energies.

§ 2. Experimental Arrangement and Procedure

The 5.7 MeV proton beam extracted from the Osaka 44-inch cyclotron was focused into the scattering chamber. The photographic emulsion technique was employed to study

the scattering of protons by neon. The arrangement of the scattering chamber, the beam collimating system and the beam integrating system was same as described in the previous papers.^{13),14)} As a gas target was used in this experiment, the detecting systems were slightly modified from that previously described.¹⁸⁾

The gas target system consisted of target cell, gas reservoir, mercury manometer and evacuating lead. The target cell was a brass cylinder of 7.5 cm in diameter, and the wall of the cylinder had a slot of 2.5 cm in width covered with aluminum foil of 9 micron thick allowing both the incident beam and the scattered particles to pass through. The axis of the cylinder was set at the center of the scattering chamber perpendicularly to the beam direction. The target system was filled with neon gas to the pressure of 15.0 cm Hg. The pressure was measured by the manometer and was constant within 1 per cent throughout the experiment. The energy loss of incident protons to reach the center of the gas target was about 200 keV.

The plate cameras used for the measurements of angular distributions and excitation function were same as the ones used for the foil-target experiments.¹⁸⁾ In the measurements of angular distributions with gas-target, an annular slit-system was set at the interior of the plate camera. This had slits at 7.5° intervals corresponding to each plate, and the slits have baffles to prevent the scattered protons entering into the plate through the other neighboring slits and to decrease the slit-edge scattering. The slits, 1.5 mm in width, were cut by a milling machine and the accuracy of the widths was within 1 per cent. This arrangement was shown in Fig. 1.

Fig. 1. The schematic diagram of scattering chamber and plate camera.

The position and the thickness of the target were defined by the width of the slit, the position of the slit, the scanned distance of the plate, and the position of the centre of the plate. These relations were illustrated in Fig. 2.

Fig. 2. Details of the detecting system. $2b$: 0.150 cm, r : 19.05 cm, d : 10.0 cm, t : 0.15 cm, α : 15.0°, l : 2.5 cm.

The differential cross section $d\sigma/d\Omega$ at the laboratory scattering angle θ_0 is given by

$$d\sigma/d\Omega = N_s \sin \theta_0 / N_i n G \quad (1)$$

where

$$G = 2b A \sin \alpha / rd \quad (2)$$

and N_s is the number of scattered particles obtained by scanning an area of A cm² on the plate. N_i is the number of incident particles and n the number of target atoms per cm³. $2b$ is the width of slit, α the glancing angle of plate, r the distance between the centre of the target and the centre of the plate, and d the distance between the slit and the centre of the plate.

The errors of relative cross sections from the glancing angle α were estimated to be less than 0.5 per cent and the errors from r and d were negligible. N_i and n were common to each scattering angle. The thickness of a edge of a slit was 1.5 mm, and the effect of this thickness to the relative cross section was negligible and was less than 1 per cent to the absolute value. Thus the whole systematic errors were estimated to be about one per cent in the relative cross section, combined the errors of the width of a slit. The absolute cross section, however,

might be accurate within ten per cent. The angular resolution was determined mainly by the scanned region of the plate and was about $\pm 1^\circ$. The angular setting of the camera was accurate within $1/2^\circ$.

The effective target thickness at the scattering angle θ_0 , T mg/cm², is expressed to be

$$T = 2br\rho/d \sin \theta_0 \quad (3)$$

where ρ is the density of the neon gas in milligramme per cubic centimeter. In the present experiments the target thickness was about 0.050 mg/cm² at the scattering angle $\theta_0 = 90^\circ$ and about 0.195 mg/cm² at $\theta_0 = 165^\circ$.

The plate camera for obtaining the excitation function was same as described before,¹³⁾ but in this experiment it also had a similar slit system as the one used for measuring the angular distribution. The other experimental arrangements and procedures were same as previously reported.¹³⁾ The incident energies could be reduced with 100 keV intervals by changing a thickness of absorber.

The emulsion used were Ilford C-2 of 200 μ and 100 μ and Fuji BT-6B of 150 μ in thickness.

§ 3. Results

Absolute cross sections could be obtained by observing the quantities involved in the formulae (1) and (2). As a check on the accuracy of the detecting system, the proton-proton scattering cross sections were measured at several scattering angles by using a propane gas as a target and an agreement with the interpolation of the available data

Fig. 3. The typical range distribution for the scattered protons from Ne, observed at the laboratory angle of 67.5° . 1 div.: 1.2 micron.

was obtained within the accuracy of 5 per cent.

The range distributions for the scattered protons by neon at $\theta_0 = 62.5^\circ$ are shown in Fig. 3. Since a natural neon gas was used for a target, a small amount of elastic group from Ne²² (9.7%) was contained within elastic group from Ne²⁰ (90.0%). Inelastic groups were resolved corresponding to the 1st excited state of Ne²⁰ ($Q = -1.63$ MeV) and the 1st excited state of Ne²² ($Q = -1.28$ MeV). Data were taken about the elastic group and the inelastic group from Ne²⁰, and about one thousand tracks were counted for each point.

Excitation curves for the Ne (p, p) Ne and Ne²⁰ (p, p') Ne²⁰ ($Q = -1.63$ MeV) were measured at a laboratory angle of 90° for the bombarding energies from 4.6 to 5.5 MeV. The bombarding energies were determined by considering both the thickness of absorbers and the range of tracks in emulsions. The energy spread of the incident protons were estimated to be less than 100 keV. The results are shown in Fig. 4.

Fig. 4. The excitation functions for the reactions Ne(p, p)Ne and Ne²⁰(p, p')Ne²⁰($Q = -1.63$ MeV) at the laboratory angle of 90° .

Angular distributions were measured at the five bombarding energies indicated in Fig. 4 by arrows. The distributions of the elastic groups are shown in Fig. 5 and the distributions of the inelastic groups from Ne²⁰ ($Q = -1.63$ MeV) are shown in Figs. 6 and 7. The cross sections of excitation curves and that of the angular distributions were consistent within expected experimental errors. The

angular distributions for inelastic scattering were fitted by the least square method with a series of the Legendre polynomials up to $P_4(\cos \theta)$. The coefficients of P_3 and P_4 have,

Fig. 5. The angular distributions of protons elastically scattered from Ne measured at $E_p=4.7, 4.9, 5.1, 5.3,$ and 5.5 Mev.

Table I. The coefficients of the Legendre polynomials obtained by expanding the angular distributions of inelastically scattered protons from Ne^{20} and the integrated cross sections as a function of incident proton energies.

E_p : bombarding energy of protons,
 A_L : the coefficient of $P_L(\cos \theta)$,
 σ_T : integrated cross section

E_p	A_0	A_1	A_2	A_3	A_4	$\sigma_T(\text{mb})$
4.7	30.8	2.7	-17.3	-4.2	-1.6	387
4.9	20.6	4.1	-15.4	-0.6	1.9	259

§4. Discussions

As shown in Fig. 4, the excitation curves of both the elastic and the inelastic scattering indicate the resonance character. The total cross sections for inelastic scattering (Table I) vary with the primary energy and have large values at 4.7 and 5.3 MeV. Since

the energy resolution of the primary beam was not so good, we can not conclude that these peaks are due to a single resonance. But it is expected that these peaks are caused by few resonances or a certain strong resonance among the weak ones. The same situations were observed in the similar experiments on Si and Mg.¹⁶⁾ The angular distributions of the elastic scattering illustrated in Fig. 5 show the strong interference between the coulomb and the nuclear scattering and vary remarkably with the primary energy. These may be explained by assuming the occurrence of resonance scatterings.

The angular distributions of inelastically scattered protons at five energies have similar shapes, although the integrated cross sections vary markedly with the incident energy. The coefficients of the odd terms of the Legendre polynomials are generally small as compared with that of even terms and therefore the distributions are nearly symmetric about 90°. The coefficients A_0 and A_2 are large in every case, but the coefficients A_4 are generally small and can be neglected by considering the experimental errors. The coefficients A_3 may also be neglected except the case of 4.7 and 5.3 MeV.

It is interesting that these distributions have similar shape to that obtained by Freemantle *et al.*⁹⁾ at 9.5 MeV, in spite of the different situations, that is in the present case few levels may be involved in the compound state while more levels may be involved in the case of 9.5 MeV. McManus¹¹⁾ analyzed 9.5 MeV data in terms of direct interaction theory. The theories of direct interaction type^{4),7)} predict an angular dependence of inelastic differential cross section as follows

$$d\sigma/d\Omega \propto \sum_L K_L j_L(qR)^2 \tag{4}$$

where $q=|\mathbf{k}_i-\mathbf{k}_0|$ is the momentum change between incident and outgoing proton, R is the nuclear radius, j_L is the spherical Bessel function of order L , and L is restricted to

$$|\mathbf{J}_i+\mathbf{J}_f+\mathbf{1}|_{\max} \geq L \geq |\mathbf{J}_i+\mathbf{J}_f+\mathbf{1}|_{\min}$$

We cannot fit the present data with this theoretical distribution using the same parameter as McManus', because the present incident energy differs from that of Freemantle *et al.*⁹⁾ and a momentum change q at the same scattering angle differs from that of

9.5 MeV. Even if the other direct interaction theories are applied in this case, the rapid variation of the cross sections with the bombarding energy may not be explained. Moreover, it is difficult to assume the strong interference between compound nucleus and direct interaction mechanisms suggested by Greenless *et al.*¹⁶⁾ in the case of Mg²⁴. On the other hand, we can easily explain these features by assuming that only the compound nucleus mechanism contributes to this reaction, but we cannot exclude the existence of the direct interaction mechanisms.

If we assume only the compound nucleus formation, we can discuss the natures of the compound levels. As was mentioned above, it is expected that a single or few levels may contribute to the reaction, then the interference with the other neighbouring levels will appear in the angular distribution. However, the fact that the odd terms of the Legendre polynomials (Table I) are small shows the interferences between the levels of different parities to be small. When it is assumed that only a single incoming orbital angular momentum l , spin and parity of the compound level J_π , outgoing orbital angular momentum l' , outgoing channel spin s' contribute to the angular distribution, we can determine the shape of the distribution using the Blatt and Biedenharn's formula.³⁾ Spins and parities of Ne²⁰ for the ground and the 1st excited states are already known as 0+ and 2+ respectively. From the fact that the coefficients A_4 are very small as compared with the coefficients A_2 and from the values of A_2/A_0 , the following cases will be probable

l	J_π	l'	s'	A_2/A_0
2	3/2+	2	5/2	-0.71
1	3/2-	1	3/2	-0.80
(1	3/2-	3	5/2	-0.20)
3	5/2-	1	5/2	-0.91

and observed A_2/A_0 are as follows

E_p	A_2/A_0
4.7 MeV	-0.56
4.9 MeV	-0.75
5.1 MeV	-0.58
5.3 MeV	-0.75
5.5 MeV	-0.50

We have neglected in the above calculations the even terms which are caused by the other types of proton waves or by the inter-

ferences between these proton waves. Actually the coefficients of these terms may be involved in the observed A_0 and A_2 , but these can not be eliminated from the observed values. Therefore there are some ambiguities when the observed A_2/A_0 are compared with the theoretical ones. We also cannot know about the existence of the interference terms between the levels of same parities, while we see the interference terms between the levels of different parities being small. Consequently there may exist the levels of same parities in the energy region investigated here, i.e. the peaks at 4.7 and 5.3 MeV are due to the single level or the superposition of the above indicated levels of same parities. These conditions are different from that of the similar experiments on Mg^{24} ($0+ \rightarrow 2+$), where a large odd terms have been observed.^{13), 16)}

Angular Distribution of Protons Inelastically Scattered from Si^{28} and Mg^{24}

By Shotaro YAMABE, Michiya KONDO, Takashi YAMAZAKI
and Atsutomo TOI*

Department of Physics, Faculty of Science, Osaka University, Osaka

**Department of Nuclear Engineering, Faculty of Engineering,
Osaka University, Osaka*

(Received April 7, 1958)

The angular distributions and the excitation curves of protons inelastically scattered from Si^{28} ($Q = -1.78$ MeV) and Mg^{24} ($Q = -1.37$ MeV) have been measured in the energy range $E_p = 4.8$ to 5.7 MeV. A broad resonance was observed in each excitation functions. The angular distributions in Mg^{24} show an asymmetry about the centre-of-mass scattering angle $\theta = 90^\circ$ and a strong dependence with the energy of incident protons, while in Si^{28} the angular distributions are rather symmetric than in Mg^{24} .

§ 1. Introduction

The angular distribution of the protons inelastically scattered from Si^{28} , being left in the 1.78 MeV level, was measured by Conzett at proton energy of 12 MeV.¹⁾ He interpreted his result with the combination of a distribution symmetric about 90° and a distribution expected from a theory of the direct interaction.^{2), 3)} Similar experiments on the 1.37 MeV level of Mg^{24} were performed by many investigators at proton energies from 4.7 MeV to 18 MeV.^{1), 4), 12)} These results are all asymmetric about the centre-of-mass scattering angle $\theta = 90^\circ$. In the 10 MeV region^{8), 9), 11)} the angular distributions change markedly with the incident proton energies. To explain this circumstance, Greenless *et al.*¹¹⁾ suggested an interference effect between the process of compound nucleus formation and direct interaction. Yoshida¹³⁾ gave the treatment which regards the inelastic scattering of nucleons by a nucleus at medium energy as the surface interaction, and applied this theory to proton scattering by Mg^{24} at 10 MeV.⁹⁾ He showed that the strong angular dependence of the inelastic scattering was due to the surface interaction while the main contribution came from the compound nucleus.

In the region of the incident proton energies up to 5.7 MeV, the excitation curve of the 1.78 MeV gamma rays following the inelastic scattering of protons from Si^{28} were studied^{14), 15)}. For the incident protons near 5 MeV, the excitation curves of the protons inelastically scattered from Mg^{24} , exciting to 1.37

MeV, were measured.^{12), 16)} They show the resonance features. In this relatively low incident energy region the excitation energies of the compound nucleus are considerably low for Mg^{24} and Si^{28} , so it would be expected that so many levels were not excited. The main feature will be explained by considering the overlapping of a few levels, if the compound nucleus formation is the predominant process in this energy region. But the possibility of direct interaction might be considered adding to the compound process.

In this paper the angular distributions for Si^{28} ($Q = -1.78$ MeV) were studied at 5.3, 5.4 and 5.5 MeV. The angular distributions for Mg^{24} ($Q = -1.37$ MeV) at 4.8 and 5.7 MeV were also measured as the extension of the previous investigation performed at 5.1 and 5.4 MeV¹²⁾ by one of the present authors.

§ 2. Experimental Arrangement and Procedure

The 44-inch Osaka University Cyclotron was used to provide a beam of 5.7 MeV protons. The experimental arrangement and procedure were same as the previous experiments.^{12), 17)} The detectors were the Ilford C-2 nuclear emulsions, 200 microns and 100 microns thick, and the Fuji ET-6B nuclear emulsions, 70 microns thick.

For the study of silicon a foil of fused silica, 0.9 mg/cm² thick, was used. The magnesium target of 1.2 mg/cm² thick was prepared by vacuum evaporation onto a glass plate and was peeled off by a blade of a

safety razor. These targets were self-supporting and were set at 45° with respect to the beam direction. The beam current was collected by the Faraday cup connected to $0.025\mu\text{F}$ polystyrene condenser and was measured by electrometer.

§ 3. Results

The range distribution of the scattered protons from silicon dioxide is shown in Fig. 1. Because of the large amount of oxygen in the target, the elastic scattering for silicon could not be resolved at small angles. The proton group of the first excited state at 1.78 MeV for Si^{28} (92.27%) was resolved from other inelastic proton groups for Si^{29} (4.68%) and Si^{30} (3.05%) except the proton group of 2.03 MeV state for Si^{29} . The contribution of this group for Si^{29} to the group of 1.78 MeV state for Si^{28} is considered to be almost negligible from the range distribution. A small amount of contamination of hydrogen was found in this target.

In the case of magnesium the proton group of the first excited state at 1.37 MeV for Mg^{24} (78.60%) is resolved from the other inelastic proton groups for Mg^{25} (10.11%) and Mg^{26} (11.29%), and the elastic proton groups. A small amount of contaminations of oxygen and hydrogen was found in the magnesium target. As the elastic proton groups for magnesium

and oxygen could not be resolved at small scattering angles, the angular distributions of the elastic scattering of protons from magnesium could not be obtained. The uncertainty in the absolute cross section was estimated to

Fig. 2. The excitation function for $\text{Si}^{28}(Q = -1.78 \text{ MeV})$ at the laboratory angle of 90° . The errors are only the statistical ones.

Fig. 1. The range distribution of protons scattered from SiO_2 , observed at the laboratory angle of 150° (1 div = 1.27μ). The scanning area for the inelastic groups is 18 times of that for the elastic groups.

be about 20% both for the excitation functions and the angular distributions, and it was caused mainly from the non-uniformity of the target thickness.

The excitation function obtained for $\text{Si}^{28}(Q = -1.78 \text{ MeV})$ at the laboratory scattering angle $\theta_0 = 90^\circ$ is shown in Fig. 2. There is a resonance feature at the incident proton energy of 5.4 MeV. This agrees with the result obtained by Okada and others¹⁴⁾ by studying the gamma-rays following the inelastic scattering of protons from Si^{28} . The angular distributions of protons were measured at incident energy of 5.3, 5.4 and 5.5 MeV. They are shown in Fig. 3.

The shape of the angular distributions does not change strongly near the peak of the resonance. At the forward angles the background increased mainly due to the elastic

protons which had escaped from the emulsion surfaces. Moreover the proton groups due to the other levels of silicon, the amount of which was uncertain, were superposed on it. Therefore the estimation of the background at the forward angles has some ambiguity.

The excitation function¹²⁾ previously obtained for Mg²⁴ (*Q*=−1.37 MeV) is illustrated in Fig. 4. There seems a resonance feature at the incident proton energy of 5.1 MeV. The angular distributions of the inelastically scattered protons were obtained at incident energies of 4.8 and 5.7 MeV. These results

are shown in Fig. 5 together with the previously obtained results¹²⁾ at 5.1 and 5.4 MeV. These curves show apparent asymmetries about 90° and the shape changes with variation of incident proton energy.

All angular distributions were expanded into a series of Legendre polynomials by means of the least square method. These coefficients and the integrated cross sections are listed in Table I. The curves in Figs. 3 and 5 are calculated from the coefficients given in Table I.

§ 4. Discussions

A. Silicon

The excitation curve of Si^{28} obtained in this experiment shows a resonance feature, and the resonance at 5.4 MeV is very strong. This is also seen in the gamma-rays following

the inelastic scattering of protons.¹⁴⁾ This indicates the existence of the contribution from the compound process, and it is expected that a single or a few levels may be excited. The shape of the angular distribution varies gradually near the peak of the resonance, that is, the tendencies between the expansion coefficients are similar at 5.3, 5.4 and 5.5 MeV. Then, assuming that only the compound nucleus formation contributes to the reaction and a single level contributes mainly to this process, the spin and the parity of the compound state will be assigned by the application of the formula of Blatt and Biedenharn¹⁸⁾ to the angular distribution.

The angular distribution of silicon at the resonance of 5.4 MeV protons could be fitted by the Legendre polynomials up to $P_4(\cos \theta)$. If the spin of the compound level is $1/2$ or $3/2$, the term $P_4(\cos \theta)$ should vanish. If it is $7/2$, the coefficient of $P_2(\cos \theta)$ should be positive. It is improbable that the spin of this state is larger than $7/2$, because the penetrability of protons for such a state of large spin is small. In the case of $5/2^+$, assuming that a process due to the emission of d-wave proton is predominant, and mixing the contributions of outgoing channel spin $3/2$ and $5/2$ to the reaction in a suitable ratio, the coefficients of $P_2(\cos \theta)$ and $P_4(\cos \theta)$ are shown to be negative. In the case of $5/2^-$, the sign of the coefficients of even terms in Legendre expansion can be explained by assuming the contribution from outgoing channel spin $5/2$ to be predominant. Therefore, this angular distribution may be explained by assuming the spin $5/2$ for the compound state P^{29} corresponding to the resonance at 5.4 MeV, but the parity of this state cannot be determined from this angular distribution because of the complexity of the channel spins and the interferences of different proton waves. Okada and others¹⁴⁾ measured the angular distribution of the gamma rays following the inelastic scattering of protons from Si^{28} at incident energy of 5.4 MeV, and assigned $5/2^+$ for this level. This is not inconsistent with our result.

B. Magnesium

The excitation curve of Mg^{24} also has a resonance feature, and the shape of the angular distribution shows a strong dependence

on the energy of incident protons. These variations of the cross section and the angular distribution can be explained by the compound process, and it seems that the reaction does not proceed through a single level of the compound nucleus because of the presence of large odd term $P_1(\cos \theta)$.

The angular distribution at 4.7 MeV measured by Rhoderick⁶⁾ shows a peak in the forward direction. Our distribution at 4.8 MeV has a slight rise in the forward direction and a minimum at about 80° . As the incident energy increases, a resonance feature appears in the excitation curve. But the angular distribution at 5.1 MeV shows an apparent asymmetry about $\theta=90^\circ$. The angular distribution at 5.7 MeV is quite similar to that at 5.1 MeV. However, between these energies the coefficient of $P_1(\cos \theta)$ in the expansion of the angular distribution changes its sign, and the distribution falls in the backward direction.

The angular distribution at 5.1 MeV can be fitted by the Legendre polynomials up to $P_2(\cos \theta)$. Since the coefficients of P_3 and P_4 are regarded as zero and the coefficient of P_2 is negative, it would be expected to be $3/2$ for the spin of the compound state contributed mainly to the reaction. But the process through the outgoing channel spin $5/2$ from the compound state $5/2^-$ is also probable. As the angular distribution has the strong interference term between the levels of different parities and the process is rather complex, it is difficult to determine uniquely the nature of the compound nucleus from this distribution by using the formula¹⁸⁾ which has many adjustable parameters. Miura and others¹⁹⁾ also measured the angular distribution of gamma rays following the inelastic scattering of protons from Mg^{24} at 5.1 MeV.

An Experimental Study of Extensive Air Showers

By Saburo MIYAKE, Kensaku HINOTANI, Tatsunosuke KANEKO
and Itsuo KATSUMATA

Institute of Polytechnics, Osaka City University, Osaka

(Received April 8, 1958)

An observation of extensive air showers has been performed at Mt. Norikura (2840 m above sea level and 25°N geomagnetic latitude) by the aid of two multiplate cloud chambers, sparsely distributed 90 GM counters and two sets of counter hodoscope pile. In this experiment, the structure of the air shower in the neighbourhood of shower axis was mainly investigated.

For each observed air shower, the shower size, N , and the location of the shower axis were estimated. The air showers were divided into three groups characterized by the core structure which depends upon the shower size. The first group is of the small size shower (less than 1.5×10^5) which has comparatively poor core which fluctuates by the behaviour of a few high energy particles. The second group is of the middle size shower ($1.5 \times 10^5 - 5.5 \times 10^5$) in which the decaying nuclear component and the electron component are in state of equilibrium, and the electron component laterally distributes as proportional to $1/r$ in particle density and $1/r^2$ in energy flow near shower cores. The third group is of the large size shower (larger than 5.5×10^5) which contains many high energy nucleons and they are thought to be yet in the state of active nuclear cascade.

Integral size spectrum was obtained as $6.1 \times 10^{-9} (N/10^5)^{-1.6} \text{ cm}^{-2} \text{ sec}^{-1} \text{ sr}^{-1}$ for the showers with a total number of particles $1.5 \times 10^5 - 5.5 \times 10^5$ and for large size showers the exponent of the spectrum increases with shower size reaching about -1.9 at $N=10^6$.

§ 1. Introduction

The showers studied here are known as extensive air showers, usually abbreviated as EAS. It is now evident that EAS are produced by ultra energetic primary particles whose energies are of the order of magnitude of 10^{14} to 10^{18} ev. The phenomena are understood as extremely energetic nucleonic cascade of which the electron cascade is an outgrowth. Some natures of EAS at various altitude have been investigated by many authors¹⁾; i.e. Density distribution, size-frequency distribution, angular distribution, attenuation length and so on. The EAS were so far detected and studied mainly by means of the electron component, but the chief concern may be now about the experimental information pertained to the high energy mesons and nucleons that are only a minute portion of all the particles. To gain the information about ultra energetic nuclear interactions, the other trials to observe the direct information, as in the case of nuclear emulsion, can not be expected due to the small frequency of the event. Some

authors²⁾ have reported their theoretical calculations to explain the structure of EAS using the appropriate theory of multiple meson production assuming the interaction cross section and inelasticity at the collision of high energy nucleon and air nuclei. But little information is available as yet on the exact nature of the core of EAS which act essential part in the development of the EAS. One cannot be satisfied by experiments of the first approximation and by qualitative agreement between a theory and limited amount of experimental data near the shower axis. Though the detecting efficiency of the shower cores is low, it may be important to derive the experimental information concerning a small region in the EAS very near the central axis. A practical upper limit of the primary energies of events that can be studied in such detail is about 10^{16} ev because of the limited frequency with which shower axes hit very close to a particular detecting equipment.

The purpose of the present study is to observe the structure of the cores of EAS.

Total number of particles, the angle of incidence, the position of the axis, etc. are given for each EAS so that the view about the structure of the core depending upon these characters can be obtained. The present experiment has been done by the counter hodoscope and multiplate cloud chambers at 2840 m above sea level and 25°N geomagnetic latitude.

§2. Experimental Method and Apparatus

A schematic diagram of the layout of various pieces of the apparatus in a horizontal plane is shown in Fig. 1, and a more detailed discription of the individual part is given below. Firstly, it was necessary to have a "core selector" (abbreviated CS below) so that the distances from the other detecting apparatus to the cores of the EAS should not be large. Three air shower trays arranged on three apices of an equilateral

triangle with a side of 4 m (abbreviated AS-1, AS-2 and AS-3 below) are used to catch EAS and to produce the master pulse by the coincidence with CS. A cross sectional diagram of the CS is shown in Fig. 2. The type of CS in this experiment is similar to Cocconi's one³⁾. A five-fold coincidence of any two counters among four counters inside the shield and the three AS trays which consist of each 5 counters was interpreted as indicating a shower core which strikes nearby. The counters used in CS and AS trays were each of area 120 cm², and the shield was 10cm Pb on the top, 10 cm Pb on the sides and at the ends, and 5 cm Pb underneath the counters. Since most of the showers are nearly vertical, the effective shield was 10 cm Pb.

A position (r, θ) of EAS core and a total number, N , of ionizing particles in EAS were determined by using 90 GM counters on a square lattice. Density gradients of charged particles along to the orthogonal axes (x and y axis) can be obtained from the data of the counter hodoscope and the position of EAS axis is deduced by the use of experimental result of the lateral distribution⁴⁾. From the position of the core and the mean density of charged particles at CS, the total electron number of EAS is estimated. Each counter was connected to each neon bulb which shows the discharge of the counter, and they were driven by the triggering when the master pulse took place.

The apparatus labeled CL-1 and CL-2 in Fig. 1 were multiplate cloud chambers located near CS (1 m and 1.5 m apart from CS along to x and y axis respectively). The chambers were photographed from the perpendicular directions each other. The zenith angles of EAS, the nature of the penetrating particles (mainly that of N component), and the energies of electrons and photons in EAS are known from these cloud chambers. The sensitive area of each chamber is 0.119 m² and 0.116 m² with 10% error respectively. CL-1 contains five sheets of 1 cm Pb plate and CL-2 contains four sheets of 0.5 cm Pb plate and three sheets of 1 cm Pb plate.

Another associated pieces of apparatus were two penetrating particle detectors labeled P-1 and P-2 which show the particle density penetrating two layers of lead (15 cm and 25 cm Pb). Front view and side view of their

Fig. 2. Cross-sectional diagram of P-1, P-2 and CS.

sections are shown in Fig. 2. Each counter was connected to hodoscope and the record of the hodoscope was triggered by the master pulse. These detectors were placed at two different distances from CS, so that the density of penetrating particles could be observed as a function of the air shower size and the distance from shower core.

§ 3. Determination of the Position of Core and the Shower Size

Using the lattice counters, the particle density, ρ , is given by the following equation;

$$\rho = \frac{1}{S} \ln \frac{n}{n-m}, \quad (1)$$

where S is a sensitive area of the counter, n is a total number of the counters in the area and m is a number of discharged counters. And for the density on the limited region in the area (when the number of the counters used is smaller than 10) the following equation was used

$$\bar{\rho}(n, m) = \frac{1}{S} \frac{n C_m \sum (-1)^i \{m C_i / (n-m+i)\}}{1/(n-m)}. \quad (2)$$

Assuming that the lateral distribution function does not depend on the size and Zenith angle of the EAS, the electron density, $\rho(r)$, at a distance r from the shower core can be expressed by the following equation;

$$\rho(r) = N\varphi(r), \quad (3)$$

where N is a total number of particles and $\varphi(r)$ is a lateral distribution function. The density, ρ , and the density gradients $d\rho/dx$ and $d\rho/dy$, are obtained from the data of lattice counters. So, position of the core axis, x and y , should be obtained mathematically for given function, $\varphi(r)$.

Practically, φ has, however, very complex form and so the experimental distribution function, $1/r$, was used in this experiment because the observed function is $r^{-0.96 \pm 0.06}$ in the region of distance, which covers the present experiment, of about 2 to 15 m from the shower core⁴⁾. Then Eq. (3) is modified into following expression;

$$\rho(r) = A/r = N\varphi(r), \quad (4)$$

where A is a constant which have relation, $kA = N$ and k is determined as 616 by numerical integration of experimental lateral distribution curve⁴⁾. From Eq. (4) r and θ can be

easily obtained as follows;

$$r = \frac{\rho(x)}{\sqrt{(\partial\rho/\partial x)^2 + (\partial\rho/\partial y)^2}}, \quad \theta = \tan^{-1} \frac{\partial\rho/\partial y}{\partial\rho/\partial x}, \quad (5)$$

where $\rho(r)$ is a particle density at CS. The size (total number of the shower particles) N , is given by a value of $k \cdot r \cdot \rho(r)$.

On a occasion that a core falls within 2 m from CS, (in the region of lattice counters) x and y coordinates of the core are obtained from maximum points in histograms of the electron density along to the both axes, and the $\rho(r)$ is given by a mean value of densities at the center of each coordinate.

In the event that a shower core hits near CS or boundary of the lattice counter arrangement, the size N is determined as $\rho(r) \times (1/2$ or $2/3) \times L$ respectively where L is a half length of the side of the arrangement.

The obtained distance, r , contains the error of about 50 cm in the region of the lattice counter and about 30% errors on the outer domain of the area.

The above analysis is not applied to so large showers that the most of the lattice counters were discharged. These events will be caused by the density larger than about 1000 particles per m² over the lattice counter region.

§ 4. Examination of the Lateral Distribution

The assumption, in the preceeding section, that the average lateral distribution of the particles is proportional to $1/r$, is examined by the data of multiplate cloud chamber. In order to estimate a fluctuation of local density of the particles, the top space of the multiplate cloud chamber in which the tracks of 20~30 particles were observed was divided equally and the number of tracks in each space was counted. The histogram in Fig. 3 shows the frequency distribution of track number observed at the left half of the top space of CL-2. In the figure, a normalized binominal distribution in the case which total number is ten, fit well the histogram. This figure shows that the tracks at the top space randomly distributed in the unit of about two tracks. The distribution of the particles observed in cloud chamber should be corrected for the transition effect by the roof of the chamber (0.55 cm Fe). Under the chamber roof, a particle should multiply into about 1.44 using the Bethe's multiplication factor

$M_f=1+2(1-7.2/Z)t/X_0$ as cited by Williams⁶⁾. In the factor, Z is the atomic number and t/X_0 is the thickness in radiation length of the wall materials traversed. From the multiplication factor, the distribution of the particles in the atmosphere is roughly considered to be random distribution in the unit of about 1.5 particles in average.

Fig. 3. The histogram shows the frequency distribution of track number observed at the left half of the top space of CL-2. The dotted line shows a normalized binomial distribution in the case of total number 10. This figure shows that the tracks at top space randomly distribute in the unit of about two tracks.

The particle density in the top space of the cloud chamber was compared with the expected density which is estimated from the size and the location of the shower axis obtained with the lattice counter's data using the lateral distribution function of $1/r$.

§ 5. The Lateral Distribution of Energy Flow

(1) A character of the core detector

Coincidences of counters shielded by thick lead plate may be caused in general either by a high energy electron or photon striking the lead, or by a local shower generated by a meson or nucleon contained in EAS. The coincidences by a penetrating shower are expected very few, because the density of meson and nucleon component in EAS at mountain altitude is only an order of one-hundredth of electron photon component which has only 10 to 100 particles in the area of CS. Five-fold coincidences used in the present experiment represent EAS which contains many high energy electrons and photons that can

not be scattered far from the core of the EAS. Under the lead absorber more than 20 cm thickness, the coincidences represent preferably penetrating component. These explanation are clearly shown by the absorption curve of EAS by lead⁶⁾.

Under the thick absorber (about 10 radiation length or more) the shower particles decreases exponentially according to $k_0 \exp(-0.24 t)$ and k_0 is approximately proportional to initial energy of the primary particle⁷⁾. The absorption curve of EAS has also such relation from 0 to about 20 cm lead, but, in the case of EAS, k_0 is thought to be correspond to sum of the energies of shower particles. In other words, the coincidence of CS indicates EAS containing a energy flow more than a certain value on CS. In the present experiment, the critical value of the energy flow for coincidence is estimated at about 50 Gev/m² from the lead layer of 10 cm and particle density of about 40/m² under the lead absorber.

(2) The lateral distribution of energy flow

As shown in the preceding section, the detection of EAS by CS depends mainly upon the integrated energy flow of the electron photon component. Fig. 4 shows the relation of observed frequencies of EAS axes versus distances between EAS axes and CS. It shows that the frequency of EAS axes detected in area of $2\pi r dr$ between r and $r+dr$ is proportional to the area up to about 2.5 m and at further distance the frequency decreases according to $r^{-2}dr$. We can deduce the lateral

Fig. 4. The observed number of showers for all sizes as a function of the distance, R , of their axis from the CS.

distribution of the energy flow of the showers, if it was a smooth function of r without consideration of the fluctuation of the energetic particles and its amplitude was proportional to the primary energy of the shower. Because, the observed frequency is estimated as follows;

$$F(r)dr = 2\pi r dr k \int_{E_0}^{\infty} E^{-(\gamma+1)} dE = 2\pi dr r k' E_0^{-\gamma} \\ (=Kr^{-2}dr), \quad (6)$$

where E_0 is a critical energy of EAS which triggers CS at distance r from the core. Therefore, the function should be proportional to $r^{-3/\gamma}$. Using known exponent γ of the primary energy spectrum of 1.5 in the energy region, the function is proportional to r^{-2} .

The distributions are also shown in Fig. 5 dividing into four groups: i.e. less than $1.5 \cdot 10^6$, $1.5 \cdot 10^6 - 5.7 \cdot 10^6$, $5.7 \cdot 10^6 - 1.5 \cdot 10^7$ and more than $1.5 \cdot 10^7$ respectively. From these figures, we can also deduce the lateral variation of energy flows of the EAS near shower cores (0–15 m) as follows. The effective detecting area for EAS of size N was determined from the distance r_m which gives a maximum frequency for each curve. Since they were the limits of the detection area for EAS of the minimum energy in each group, it is concluded from the observed value that r_m for each group has following relation in the limited energy region,

$$\pi r_m^2 = a N_m, \quad (7)$$

where a is a constant.

The detailed discussion comparing the electron photon component and nucleon or meson

component for triggering CS over a wide range of primary energies are complicated. But it is reasonable to consider that the present detector was triggered by a certain value of energy flow and the energy flow is distributed proportional to r^{-2} at least for EAS of the size of $1.5 \cdot 10^6$ to 10^7 particles. The distribution is also expected from electromagnetic cascade theory too, when the shower age is nearly equal to 1.

§6. Energy Spectrum of Electron Photon Component

The energy of a cascade shower was estimated by means of multiplate cloud chamber. Practical ones are the track length and electron number at the cascade maximum, both of which depend on the shower energy approximately linearly. Although track length is undoubtedly preferred from the view point of the fluctuation, but in order to obtain this quantity experimentally one must have the whole shower development available for observation. There are some difficulties in such a case that the energy of initial electron or photon is so high that the cascade development does not finish in the chamber, and so in this case estimated total number of electrons and the number at cascade maximum are used with some correction.

The track length p is given by a product of total number of track segments n_{total} and radiation length of a lead plate measured along the direction of the shower axis and then the energy is given by

$$E_0 = cp, \quad (8)$$

where c is a constant and has been estimated from conventional cascade theory⁷⁾⁸⁾ and cloud chamber experiments⁹⁾. In the present case, the value of the constant c was taken as 25 Mev from a thickness of a lead plate of 10 mm.

The number of electrons in the cascade maximum n_{max} is a quantity which represents the maximum observable number of fast electrons in the forward half hemisphere. The factor which should be multiplied on n_{max} was determined experimentally. Since a ratio of n_{total} to n_{max} was about 4.0 around 1 Gev and it increased very slowly with energy, the factor was estimated at 100 Mev. The error of the estimation of energy seems to be about

Fig. 5. The observed number of showers for each size group as a function of the distance, r , of their axis from the CS.

30% on the average for energies of 300 Mev to 10 Gev.

The integral energy spectra of electron photon component, for each group of size and various distances from shower axis, were

Fig. 6. The integral energy spectra of electron-photon component for group of size at various distance from shower axis.

- a) 1.5×10^5
- b) $1.5 \times 10^5 - 5.5 \times 10^5$
- c) $5.5 \times 10^5 - 1.5 \times 10^6$

shown in Fig. 6. In these figures, we can see that the exponent of the spectra varies from 1.0 to 1.3 according to the distances (2m to 8 m) from the shower axis.

In these figures, the points at 30 Mev are estimated from the number of the charged particles in the top space of the cloud chamber comparing with the integral energy spectrum, for energies smaller than critical energy in air, obtained by Richards and Nordheim¹⁰⁾, and the data at other energies contains both components of photons and electrons since shower primaries can not be distinguished whether they were photons or electrons.

The lateral distribution of the energy flow described in § 5 is also interpreted from the observations of the lateral distribution of the particles and of the energy spectra at the distances as follows;

1) In § 4, the lateral distribution of shower particles was estimated as r^{-1} on the average, but, as shown in Fig. 7, the distributions of various energy cut for group of each size have a tendency to be flatten in larger size

groups. It depends upon the detection efficiency of CS mentioned already. If we assume expediently that CS and the cloud chamber (particle detector) were placed at the same position, a frequency with which shower axes of size N hit the area between r and $r+dr$ is given by;

Fig. 7. The observed lateral distribution of the electron component of various energy cut for each group of size.

- a) 1.5×10^5
- b) $1.5 \times 10^5 - 5.5 \times 10^5$
- c) $5.5 \times 10^5 - 1.5 \times 10^6$

$$\left. \begin{aligned} f(N, r) dr dN &= 2\pi r dr F(N) dN & r^2 < kN \\ f(N, r) dr dN &= 0 & r^2 > kN \end{aligned} \right\}, \quad (9)$$

where $F(N)$ is a differential size spectrum which is expressed as $\text{const} \cdot N^{-\gamma-1}$. Then observed density $\rho_{\text{ob}}(r)$ at distance, r , is;

$$\rho_{\text{ob}}(r) = \frac{\varphi(r) \int_{N_1}^{N_2} N f(N, r) dN}{\int_{N_1}^{N_2} f(N, r) dN} \quad (10)$$

where $\varphi(r)$ is a distribution function ($\rho(r) = N\varphi(r)$) and N_1 and N_2 are lower and higher limit respectively in the range now concerned. In the region smaller than critical value r_1 ($r_1^2 = kN_1$) in which detection efficiency is 100%, observed density distribution is correctly proportional to $\varphi(r)$ as shown by the integration of Eq. (10);

$$\rho_{\text{ob}}(r) = \varphi(r) \frac{\gamma}{\gamma-1} \cdot \frac{N_1^{1-\gamma} - N_2^{1-\gamma}}{N_1^{-\gamma} - N_2^{-\gamma}} = \text{const} \cdot \varphi(r). \quad (11)$$

In the region that the distance, r , is larger than r_1 , the integration is as follows;

$$\rho_{\text{ob}}(r) = N_2 \left\{ \varphi(r) \frac{\gamma}{\gamma-1} \frac{(r/r_2)^{2-2\gamma} - 1}{(r/r_2)^{-2\gamma} - 1} \right\}, \quad (12)$$

where $r_2^2 = kN_2$. And the observed density distribution is somewhat differ from the true distribution. The observed value of group III for large r is increased by the reason shown in Eq. (12). Eq. (11) and the curves of group I and II, in the region larger than about 3 m, show that the real particle density distribution is proportional to r^{-1} .

2) If the differential energy spectrum was expressed as $f(r)E^{-s(r)-1}$, the observed energy flow distribution can be calculated as follows;

$$\int_{E_1}^{E_2} f(r) E^{-s-1} E dE = f(r) \frac{1}{1-s} (E_2^{-s+1} - E_1^{-s+1}) = \frac{k_1}{r^2}, \quad (13)$$

where E_1 and E_2 are energies determined from the integral energy spectrum in Fig. 6 as above assumption can be applied.

The observed density distribution is also similarly calculated;

$$\int_{E_1}^{E_2} f(r) E^{-s-1} dE = f(r) \frac{1}{-s} (E_2^{-s} - E_1^{-s}) = \frac{k_2}{r}. \quad (14)$$

From Eq. (13) and (14), the mean energy is obtained as;

$$\frac{1}{\overline{E}(r)} = \frac{s-1}{s} \cdot \frac{E_1^{-s} - E_2^{-s}}{E_1^{-s+1} - E_2^{-s+1}} = r \frac{k_2}{k_1}. \quad (15)$$

Under the practical conditions $s > 1$ and $E_1 \gg E_2$, Eq. (15) is simplified into following equation;

$$s = \frac{1}{1 - E_1 r (k_2/k_1)} \approx 1 + E_1 r \frac{k_2}{k_1}. \quad (16)$$

Substituting the present data as following

$$E_1 = 30 \text{ Mev}, \quad k_2 = 1000, \quad k_1 = 10^6,$$

then s varies for the variation of r from 0 to 10 m about 0.3, and this shows good agreement with the present data of energy spectra in various distances from the core.

§ 7. Number Spectrum of EAS

The total number of the ionized particles of the observed EAS was estimated by the method described in § 3. From the observed

integral number distribution shown in Fig. 8, the number spectrum can be obtained as follows, assuming that the differential number spectrum is given by a power law;

$$F(N) dN = S N^{-\gamma-1} dN, \quad (17)$$

Fig. 8. The observed integral number spectrum. The dotted line shows $N^{-0.5}$. The number spectrum should be corrected for detecting area.

where γ and S may be taken as constants over a limited range of N . The observed frequency of the showers with the size larger than N_0 is given by the integration of the product of Eq. (17) and detecting area (Eq. (7));

$$\int_{N_0}^{\infty} S N^{-\gamma-1} dN a N = S_0 a N_0. \quad (18)$$

From the experimental results described in § 5 (2), S_0 is obtained at $0.12 \text{ sec}^{-1} \text{ cm}^{-2}$.

The integral number spectrum is therefore,

$$3.8 \cdot 10^{-9} (N/10^5)^{-1.5} \text{ cm}^{-2} \text{ sec}^{-1},$$

within the range $1.5 \cdot 10^5 < N < 5.5 \cdot 10^6$. From the zenith angle distribution the effective solid angle of detection is 0.63 and so the integral number spectrum per steradian is

$$6.1 \cdot 10^{-9} (N/10^5)^{-1.5} \text{ cm}^2 \text{ sec}^{-1} \text{ sr}^{-1},$$

and for higher energy region the exponent increases with the size reaching about -1.9 at 10^6 .

The errors for above results can not be estimated correctly, but they seem to be about factor two and about a half for their upper and lower errors respectively.

§ 8. Meson and Nucleon Component

1) Composition of nucleonic component

Although several measurements of the ratio of neutral to charged N-particles has been reported⁽¹¹⁾, their variation with the shower size has not yet been investigated. So in this experiment, a very preliminary study of the

ratio was made by means of the multiplate cloud chamber.

For this purpose, 56 penetrating showers observed in the cloud chamber pictures were picked up, and the shower primary was investigated. Then, those events were omitted where the nature of the shower primary appeared doubtful because of possible obliteration of its track by the electron showers. Thus, only 49 events were classified. Among them, 17 cases had neutral primaries. Accordingly, a ratio neutral to charged primary was obtained at 0.53 ± 0.20 on the average of all showers.

To clarify the variation of the ratio with the shower size, the penetrating showers were classified with shower size, and the ratio was estimated at 0.72 ± 0.40 for shower size $N < 6 \cdot 10^5$ and 0.40 ± 0.24 for $N > 6 \cdot 10^5$. The ratio 0.72 is in agreement with earlier determinations¹¹⁾.

From the results, we can deduce a conclusion that a contribution of charged π -mesons among the EAS becomes predominantly with increasing shower size, even though the statistical precision is not enough.

2) Energy spectrum of nucleonic component

The energy of the penetrating shower observed in the cloud chamber is estimated from the energy of the electron shower associated with the penetrating showers ($\pi^0 \rightarrow 2\gamma$). Thus, the mean energy per secondary particle was estimated at 2.0 Gev. The energy per secondary particle was somewhat large for smaller multiplicity group than larger one, but the difference was not so much.

The energy spectrum is shown in Fig. 9 and a point plotted at 1 Gev was obtained from star frequency (the star means a nuclear interaction without more than one penetrating secondary particle, and the energy distributes around 1-2 Gev). The exponent of the integral energy spectrum was about -1.2.

Average energy of the observed penetrating showers belonged to the group of $N < 6 \cdot 10^5$ is 6.2 Gev and that for $N > 6 \cdot 10^5$ is 10.1 Gev.

3) Abundance and abundance ratio

By means of the hodoscope pictures of P-1 and P-2 detectors, a classification of the penetrating particles into "interacting" and "non interacting" particles is possible. In general, the former correspond to nucleon and

Fig. 9. The energy spectrum of nucleonic component which are obtained from the penetrating shower observed in the cloud chamber. A point plotted at 1 Gev was obtained from star frequency. Dotted line shows $E^{-1.2}$.

π meson component and the bulk of the latter correspond to μ -mesons. It should be considered that the latter category includes also all the charged nucleons and π -mesons which failed to interact, and that a corresponding number of unobserved neutrons has to be added to the total.

In the analysis of the hodoscope pictures, the event were classified as "non interacting" particles if one or two counters was discharged in two trays, and in such a way that a particle could reasonably be reconstructed comparing with the data from the cloud chamber. If more than two counters in first tray and more than three counters in second tray were discharged, and the projected zenith angles estimated from the pictures were nearly equal to ones from the cloud chamber, the events were classified as interacting particles which interact at the top layer of 15 cm Pb. If one counter in first tray and more than three counters in second tray were discharged, the events were also classified as interaction at second layer of 10 cm Pb.

Table 1. Composition of EAS near the shower axis at 2840 m elevation.

Group	I	II	III
Shower size	$1.3 \cdot 10^4 - 1.8 \cdot 10^5$	$1.8 \cdot 10^5 - 6.0 \cdot 10^6$	$6.0 \cdot 10^6 - 1.5 \cdot 10^8$
pp/el. (%)	1.55 ± 0.26	1.15 ± 0.11	0.92 ± 0.08
μ /el. (%)	0.85 ± 0.19	0.67 ± 0.09	0.60 ± 0.06
N/el. (%)	0.70 ± 0.17	0.48 ± 0.07	0.33 ± 0.05
N/pp. (%)	45.0 ± 17.6	41.9 ± 10.0	35.4 ± 7.9

A summary of the results of the analysis of the penetrating events observed by hodoscope is given in Table I. The results are qualitatively in agreement with Kasnitz *et al*⁽¹¹⁾ data.

4) Lateral distribution of penetrating particles

The lateral distribution of N-component was obtained separately from μ -mesons as shown in Fig. 10. The distribution of N-component should be corrected for saturation effect of the lattice counters and detection efficiency of CS. The correction is so complicate that the lateral distribution can not be corrected exactly. However, it may be natural to think that the obtained lateral distribution has a tendency to flatten the real distribution. As a result, it seems that the distribution is $1/r$ or somewhat more steep function of r .

is almost equal to one expected from the electromagnetic cascade theory for shower age 1, and so the angular distribution of the energy flow of secondaries in high energy interactions is thought to be considerably sharp. Therefore, in the high energy nuclear interactions which will develop into EAS, the greater part of the high energy secondaries will be contained in core region of about 2-3 m. The structure of observed small size shower (less than $1.5 \cdot 10^6$) is also similar to large showers, but one must noticed for inefficiency of detection caused by CS selection. The detection efficiency may be favour for young showers and small size showers seem to contain the showers of various ages and they have comparatively poor core (less than about 50 Gev/m²) in average.

The number spectrum and an analysis of nucleon component show that the EAS of large size is in the active state of development. So, in such a state, a greater part of shower energy is still reserved in core region. The observed number spectrum is somewhat different from one obtained by scintillation detector placed at large span. Namely, in a part of large size ($>6 \cdot 10^6$), the former spectrum is steeper than the latter. One of the reasons may be understood as that high energy nucleons are predominant (density of charged particles in core region is not so high expected by pure electromagnetic cascade theory) and the energy spectrum of high energy neutral π -mesons is steep. Although the population of the nucleons to shower electrons decreases as shower size becomes large, the observed mean energies of the nucleons rapidly increase. Nevertheless the maximum of the high energetic electron component which is favour to be detect by CS is higher altitude than maximum of total electron component about several radiation length. Then expected size is somewhat different by

Fig. 10. The lateral distribution of nucleonic component and μ -mesons.

§ 9. Discussion

In this experiment, the lateral distribution of energy flow has been obtained as r^{-2} for showers with size $1.5 \cdot 10^5 - 5.5 \cdot 10^6$. The result shows that the lateral distribution of electrons

the character of the detecting mechanisms and age of each shower.

If the average primary energy of EAS having a given number of charged particles at a particular depth in the atmosphere could be calculated, the number spectrum would lead directly to the energy spectrum of the cosmic ray primaries. But since the EAS do not develop and propagate like purely electronic cascade showers, and since the detailed features of the nuclear cascade are thought to be still largely unknown, one can not calculate with considerable reliability their relation theoretically.

Nevertheless, even if the calculation has been performed, the fluctuation problem in the very early stages of the shower's development and contribution of the heavy primary should be considered in the case when primary energy spectrum is derived. The fluctuation problem has been discussed by W. L. Kraushaar⁽¹²⁾ and he concluded that one tends to overestimate primary particle intensities by a factor of 1.4 if fluctuations are neglected. One of the author of this paper has analysed absorption length and the following result⁽¹³⁾ was obtained.

In lower atmosphere (lower than mountain altitude), under probably permissible approximation, the following relation was obtained;

$$\lambda_{\text{ob}} = L(1+r), \quad (19)$$

where λ_{ob} is a observed attenuation length of EAS and L is a interaction mean free path of the primary particles of EAS. And r means a ratio of the primary particles, which have higher energies than the estimated energies corresponding to the observed shower sizes, to the other observed showers. Therefore, the true energy spectrum can be obtained by multiplying the factor $r/(1+r)$. This shows that the observed size spectrum contains lower energy events than the estimated energies. Provided that λ_{ob} is 90 g/cm^2 ⁽¹⁴⁾ and L is 80 g/cm^2 for the EAS with size $3 \cdot 10^6 - 3 \cdot 10^7$, the correction factor is about 0.1. So, if above interpretation is correct, the intensity of primary particles with energy $10^{16} - 10^{17} \text{ ev}$ would be overestimated at about ten times.

The result of above correction shows a spectrum similar to obtained here but conclusions must be reserved because the estimation of sizes by the method used in the present

experiment is not so accurate especially in high energy region.

Preliminary discussions for high energy events are as follows;

1) Two cases of very high energy nuclear interactions were observed by the cloud chamber when shower axis was very near the chamber. And some cases shows in the chamber photographs that there is a high density region of electron component comparing to other region of same core, and the area of the region was thought to be about 1 m diameter. These discontinuities also depend upon probably very high energetic nucleons in the core although their amount may be very small. Occasionally these are thought to be survivals of the primaries and it seems to be possible to estimate the inelasticity in high energy nuclear interactions, but in this case as mentioned already, it must be care that there are young EAS which has been started at considerably deep atmosphere.

2) High energy electron component has been studied concerning to nucleon component, and crude conclusion is that a separated young cascade shower, which is distinguished by accompanied photons and electrons from old cascade showers in chamber photographs, were mainly due to γ rays produced by the decay of π^0 -mesons which were produced by nuclear interactions in air. It seems to be possible to estimate the intensity of high energy nucleons from these cascade showers. Detailed discussion will be appeared in next paper.

Finally, as a next step of experiment of EAS we are proceeding a plan that is to observe size dependency of observed absorption length and to investigate the behavior of N-component near shower core over determination of the shower age of each EAS. For this purpose we are now constructing very huge multiplate cloud chamber ($200 \times 127 \times 80 \text{ cm}^3$) which contains twenty-one sheets of lead plate of 1 cm thickness.

Recombination Centers in Germanium

By Jun'ichi OKADA

Matsuda Research Laboratory, Tokyo Shibaura Electric Co.,
Kawasaki-city, Japan

(Received April 30, 1958)

The dependence of carrier lifetime in pure germanium upon injection level has been studied using a photoconductivity decay method. The data are analyzed in terms of the recombination theory for transient conditions including the case of high injection level. The results show that at least two recombination levels exist in pure germanium: one is active in *n*-type and the other in *p*-type. The recombination level in *n*-type germanium is at 0.28 eV from the conduction band and the cross section for capture of holes A_p is about 4.7 times larger than that for capture of electrons A_n . On the other hand, the recombination level in *p*-type germanium is at 0.25 eV from the valence band or 0.31 eV from the conduction band and A_n/A_p is about 9.8.

§ 1. Introduction

Recent experiments on carrier lifetime in germanium have shown that several lattice imperfections act as recombination centers for electrons and holes. Among these imperfections, copper and nickel have been most extensively studied¹⁾⁻⁵⁾. For both impurities, the energy level was found to be close to the middle of the energy gap and the capture cross sections for electrons and holes were obtained. Similar properties have been found for "deep level" impurities, such as gold,

iron, cobalt and manganese⁶⁾. It has also been shown that dislocations play a prominent role for recombination processes^{6), 7)-9)}. Furthermore, the centers produced by thermal quenching¹⁰⁾ or by bombardment with high energy particles¹¹⁾ have been observed to act as recombination centers.

On the other hand, a number of studies have been made of recombination processes in pure germanium^{1), 5), 12)-16)}. Most of them are the measurements of the temperature dependence of carrier lifetime which yield

only the positions of recombination levels in pure germanium. However, since the other properties of these centers have scarcely been studied, it is difficult to identify these levels to the known levels or imperfections.

In order to extend the information concerning the properties of recombination centers in pure germanium, we have studied the dependence of carrier lifetime on the injection level and equilibrium carrier concentrations. Similar experimental work has been made of silicon by Bittmann and Bemski¹⁶⁾.

According to the theory given below, the carrier lifetime at very low injection levels depends strongly on the electron or hole population of the recombination centers and the carrier densities. On the other hand, at very high injection levels, the lifetime approaches the limiting value which can be determined only from the capture cross sections and the concentrations of recombination centers. Thus, analyzing our data, we can obtain the information concerning the energy levels and capture cross sections of the recombination centers in pure germanium.

§2. Theory

Assuming that only one set of recombination centers is active, the recombination process can be characterized by the effective capture cross sections for an electron and hole, A_n and A_p , the concentration of centers N_r , the energy level of centers E_r and the equilibrium electron and hole densities n_0 and p_0 .

In our experiments the time-decay of excess carriers injected by a pulse of light was measured. Thus it is interesting to solve the recombination equations of excess carriers Δn and Δp under transient conditions. According to the analysis given in the Appendix B, the effective time of decay τ at any time t is given by

$$\tau = \frac{\tau_0 + \tau_\infty \Delta\varphi}{1 + \Delta\varphi}, \quad (1)$$

where τ is defined by

$$\frac{1}{\tau} = - \left(\frac{1}{\Delta\varphi} \right) \frac{d\Delta\varphi}{dt}, \quad (2)$$

and

$$\Delta\varphi = \frac{\Delta n}{n_0 + p_0} = \frac{\Delta p}{n_0 + p_0}. \quad (3)$$

In this expression, τ_0 and τ_∞ are the limiting values of lifetime at very low and high injection

levels respectively, and are given by

$$\tau_0 = \tau_{p0} \frac{n_0 + n_1}{n_0 + p_0} + \tau_{n0} \frac{p_0 + p_1}{n_0 + p_0}, \quad (4)$$

and

$$\tau_\infty = \tau_{p0} + \tau_{n0}, \quad (5)$$

where

$$\left. \begin{aligned} \tau_{n0} &= \frac{1}{v_n A_n N_r}, \\ \tau_{p0} &= \frac{1}{v_p A_p N_r}, \end{aligned} \right\} \quad (6)$$

and

$$\left. \begin{aligned} n_1 &= N_C \exp [-(E_C - E_r)/kT], \\ p_1 &= N_V \exp [-(E_r - E_V)/kT]. \end{aligned} \right\} \quad (7)$$

Here N_C and N_V are the effective densities of states for conduction band and valence band respectively, E_C is the bottom energy of conduction band, E_V is the top energy of valence band, and v_n and v_p are the thermal velocities of electrons and holes respectively. These expressions are equivalent to the Shockley-Read expressions for steady-state lifetime¹⁷⁾ (see Appendix A) and provide means for determining the values of τ_0 and τ_∞ .

From Eqs. (4) and (5), the ratio τ_0/τ_∞ is given by

$$\frac{\tau_0}{\tau_\infty} = \frac{1}{1 + (\tau_{n0}/\tau_{p0})} \frac{n_0 + n_1}{n_0 + p_0} + \frac{1}{1 + (\tau_{p0}/\tau_{n0})} \frac{p_0 + p_1}{n_0 + p_0}. \quad (8)$$

In an n -type material, where $n_0 \gg p_0$, we have

$$\frac{\tau_0}{\tau_\infty} = \frac{1}{1 + r_n} + \frac{1}{1 + r_n} (n_1 + r_n p_1) \left(\frac{1}{n_0} \right), \quad (8a)$$

with a similar relation,

$$\frac{\tau_0}{\tau_\infty} = \frac{1}{1 + r_p} + \frac{1}{1 + r_p} (p_1 + r_p n_1) \left(\frac{1}{p_0} \right), \quad (8b)$$

for a p -type material, where $p_0 \gg n_0$. Here

$$\left. \begin{aligned} r_n &= \frac{\tau_{n0}}{\tau_{p0}} = \frac{A_p}{A_n}, \\ r_p &= \frac{\tau_{p0}}{\tau_{n0}} = \frac{A_n}{A_p}, \end{aligned} \right\} \quad (9)$$

with approximation $v_n = v_p$. Thus, the ratio of cross sections r_n (or r_p) and n_1 (or p_1) can be determined from the measurements of the dependence of τ_0/τ_∞ on electrical resistivity using Eq. (8).

§3. Experimental Method

The specimens used in this study were in the form of rods, about $0.3 \times 0.3 \times 1.3 \text{ cm}^3$, which were cut from single crystals of n -type

Sb-doped germanium and *p*-type Ga- or In-doped germanium. The rods were carefully etched with CP-4 solution and ohmic contacts were soldered on the two ends.

Carrier lifetimes were measured by observing the time-decay of photoconductivity. The schematic diagram of apparatus is shown in Fig. 1. One surface of rods was illuminated

Fig. 1. Schematic diagram of measuring circuit and equipment.

by a short pulse of light approximately 2 μ sec duration from a high pressure xenon spark tube which creates excess hole-electron pairs in the specimens. The resulting change $\Delta V(t)$ in the voltage across the rods, was displayed on the oscilloscope. In our experiments, a Tektronix type 545 oscilloscope was used in conjunction with a Tektronix type 53/54D plug-in unit.

The signal displayed on an oscilloscope is given by

$$\Delta V(t)=i\Delta R(t)$$

where $\Delta R(t)$ is the change in resistance of the specimen. As shown in Appendix C the time constant τ^* determined from $(1/\tau^*)=-(1/\Delta V)(d\Delta V/dt)$ is not equivalent to the carrier lifetime defined by Eq. (2). When the constant current is passed through the specimens, relation between τ and τ^* is given by

$$\tau=\left(1-\frac{\Delta V}{V_0}\right)\tau^*,\tag{11}$$

where V_0 is the voltage across the specimens in equilibrium state.

From an oscilloscope trace apparent lifetime τ^* was obtained at any time t and converted into τ by Eq. (11). Varing the intensity of pulsed light the effective carrier lifetime τ was measured as a function of $\Delta\phi$ calculated from ΔV .

Measurements were made at a temperature of 290°K. The values of fundamental parameters, such as mobilities and concentration products, were taken from the data of Morin

and Maita¹⁸⁾ except the density-of-state masses for electron and hole, for which the value $m_n=m_p=0.75m_0$ ¹⁹⁾ was used.

§ 4. Experimental Results

According to Eq. (1) a plot of $\tau(1+\Delta\phi)$ versus $\Delta\phi$ should yield a straight line with intercept τ_0 at $\Delta\phi=0$ and of slope τ_∞ . An example is shown in Fig. 2 for specimen which is *n*-type with $n_0=1.06\times10^{14}/\text{cm}^3$.

Values of τ_0 and τ_∞ obtained for a number of different specimens are summarized in Table I.

Fig. 2. Lifetime versus injected carrier density in *n*-type germanium ($1-n$).

Table I. Summary of data on carrier lifetimes in pure germanium. τ_{n0} and τ_{p0} were calculated from τ_∞ and cross section ratio. (τ_{p0}) was obtained from the temperature dependence of carrier lifetime in *n*-type germanium.

Sample	Carrier density $\text{cm}^{-3}\times10^{-14}$	τ_0 $\mu\text{ sec}$	τ_∞ $\mu\text{ sec}$	τ_{n0} $\mu\text{ sec}$	τ_{p0} $\mu\text{ sec}$	(τ_{p0}) $\mu\text{ sec}$
1- <i>n</i>	1.06	110	240	198	42	43
2- <i>n</i>	0.882	176	350	289	61	58
3- <i>n</i>	5.03	66	305	251	54	—
4- <i>n</i>	1.60	186	490	404	86	—
1- <i>p</i>	1.66	128	280	26	254	—
2- <i>p</i>	3.14	313	1120	104	1016	—
3- <i>p</i>	5.64	70	340	32	308	—

Fig. 3 shows the plot of τ_0/τ_∞ versus the reciprocal of the electron density for *n*-type specimens. According to Eq. (8a), this plot should be a straight line. Using this linear

relationship, values of r_n and n_1 (or p_1) were obtained from the intercept and slope of the line. In this analysis, the equation for determining n_1 has quadratic form. Thus, we have two values of n_1 or E_r (calculated from n_1 by Eqs. (7)). One corresponds to $E_r > E_i$

A similar plot for p -type specimens is shown in Fig. 4.

Results of our analysis are presented in Table II.

§ 5. Discussion

The experimental results presented above show that two recombination levels are operative in pure germanium: one in n -type germanium and the other in p -type germanium. However, it is difficult to distinguish between two possibilities as to the location of the recombination level in the lower or upper half of the energy gap from our experiments as any other information concerning the energy level is unknown.

Fortunately, for n -type germanium, we have the data on the temperature dependence of carrier lifetime as described in the preceding paper⁵⁾. They are shown in Fig. 5. In this

Fig. 3. τ_0/τ_∞ versus reciprocal of the equilibrium electron density in n -type germanium.

Fig. 4. τ_0/τ_∞ versus reciprocal of the equilibrium hole density in p -type germanium.

Table II. Results of analysis.

Type	Ratio of cross section $A_n:A_p$	Upper half of gap E_C-E_r eV	Lower half of gap E_r-E_V eV
n	1:4.7	0.28	0.32
p	9.8:1	0.31	0.25

(upper half of energy gap), and the other to $E_r < E_i$ (lower half of energy gap), where

$$E_i = \frac{1}{2}(E_C - E_V) + \frac{1}{2}kT \ln(N_V/N_C).$$

Fig. 5. $(\tau_0/\tau_{p0}-1)(n_0/T^{3/2})$ versus $1/T$.

case, the data are plotted as $(\tau_0/\tau_\infty-1)(n_0/T^{3/2})$ versus inverse absolute temperature to facilitate comparison with theory. The slope corresponds to about 0.29 eV. This value is to be compared with the values shown in Table II. Thus, within the experimental error, it can be concluded that the recombination level in n -type germanium is at 0.28 eV from the conduction band. In addition, it is possible to obtain τ_{p0} from the measurements of carrier lifetime of n -type germanium at low temperature⁶⁾. These values of τ_{p0} are also shown in Table I and are in good agreement with the values determined from τ_∞ and r_n .

It is interesting that the cross section ratio

of *n*-type germanium is opposite to that of *p*-type germanium. For *n*-type germanium the cross section for capture of holes is about 4.7 times larger than that for the capture of electrons. This result is to be expected if the recombination centers are acceptors so that the filled centers are negatively charged. Burton *et al.* have shown that copper and nickel act as the recombination centers of this sort¹¹. On the contrary, for *p*-type germanium, the capture cross section for electrons is about 9.8 times that for holes. This suggests that donorlike recombination centers are operative in *p*-type germanium. Similar results have been obtained for the recombination centers in both *p*- and *n*-type silicon by Bittmann and Bemski¹⁶.

From the values of recombination levels found in our experiments, $(E_C - E_r)^4 : (E_r - E_V)^4$ is 1:5 for 0.28 eV level in *n*-type germanium and 10:1 for 0.25 eV level in *p*-type germanium using $E_C - E_V = 0.70$ eV. These values are in good agreement with the values of r_n and r_p determined experimentally. Since any theoretical evidence is missing, this agreement may be fortuitous. However, if we accept this result, it is suggested that capture cross sections depend on the level of recombination centers with the relationship such as

$$A_n : A_p = (E_C - E_r)^4 : (E_r - E_V)^4.$$

It is interesting to identify the recombination levels found by our experiments to the known imperfections. A number of chemical impurities which possess more than one deep-lying level are known to act as recombination centers²⁰. If a single impurity is operative in both *n*- and *p*-type germanium, Ni ($E_{r1} = 0.30$ eV, $E_{r2} - E_V = 0.22$ eV) and Co ($E_{r1} = 0.30$ eV, $E_{r2} - E_V = 0.25$ eV) are responsible for the observed recombination levels. If two sorts of impurities are active, Cu ($E_{r1} = 0.26$ eV), Fe ($E_C - E_{r1} = 0.27$ eV), Ni and Co are responsible for *n*-type, and Ni and Co for *p*-type. However, since the data of the capture cross sections are missing, it is difficult to discuss further.

Moreover, while the analysis described above is based on the assumption that a single recombination level is active in a given conductivity type, a few specimens show that multiple recombination levels model is valid⁹. An example of this is shown in Fig. 6. In this case, simple linear relation is not obtain-

Fig. 6. Lifetime versus injected carrier density in *n*-type germanium (6-*n*).

ed. This deviation may be associated with multiple recombination levels, so no analysis has been made (see Appendix A).

Acknowledgements

The author would like to express his indebtedness to his co-workers at the Tokyo Shibaura Electric Co. for their aid in this work. In particular, he would like to thank Mr. Y. Ochiai for carrying out much of the labor of sample preparation and measurements.

Appendix A: Carrier Lifetime for Steady-State Conditions

In this appendix, we shall consider the carrier lifetime in a nondegenerate semiconductor where the recombination occurs through multiple-levels. We have previously dealt with the case of low disturbances in carrier densities where only first-order terms need be considered⁹. It is the purpose of this appendix to extend the simple theory to the case of large disturbances in carrier densities.

For large values of injected carrier densities, Eq. (8) in the preceding paper must be rewritten in the form

$$\left. \begin{aligned} \Delta R_{nj} &= \gamma_{nj} \{ N_{j0}^+ \Delta n - (n_0 + n_j + \Delta n) \Delta N_j^- \}, \\ \Delta R_{pj} &= \gamma_{pj} \{ N_{j0}^- \Delta p - (p_0 + p_j + \Delta p) \Delta N_j^+ \}, \end{aligned} \right\} \quad (A1)$$

where R_{nj} and R_{pj} are the net rates of capture of free electrons and holes respectively by *j*-level, γ_{nj} and γ_{pj} are the rates of capturing an electron and hole by a single *j*-

trap, N_j^- and N_j^+ are the concentrations of filled and unfilled recombination centers, N_j is the concentration of recombination centers, and Δn and Δp are the changes of carrier densities n and p of electrons and holes respectively. Here subscript 0 refers to the thermal equilibrium condition, and n_j and p_j are the densities of free electrons and holes, respectively, when the Fermi level equals to the effective energy, E_j , of j -level.

For the steady-state case ($\Delta R_{nj} = \Delta R_{pj}$), using the condition of electrical neutrality

$$\Delta n = \Delta p + \sum_j \Delta N_j^+ = \Delta p - \sum_j \Delta N_j^-, \quad (A2)$$

it is easy to show that the lifetimes of electrons and holes defined by

$$\tau_n = \frac{\Delta n}{\sum_j \Delta R_{nj}},$$

and

$$\tau_p = \frac{\Delta p}{\sum_j \Delta R_{pj}},$$

are of the form

$$\left. \begin{aligned} \tau_n &= \frac{1 + H_n}{\{(n_0 + \Delta n)(1 + H_p) + p_0(1 + H_n)\}H}, \\ \tau_p &= \frac{1 + H_p}{\{n_0(1 + H_p) + (p_0 + \Delta p)(1 + H_n)\}H}, \end{aligned} \right\} \quad (A3)$$

and the ratio of excess electrons and holes is given by

$$\frac{\Delta n}{\Delta p} = \frac{1 + H_p}{1 + H_n}, \quad (A4)$$

where

$$H_n = \sum_j \frac{\tau_{pj} N_{j0}^-}{B_j},$$

$$H_p = \sum_j \frac{\tau_{nj} N_{j0}^+}{B_j},$$

$$H = \sum_j \frac{\tau_{nj} \tau_{pj} N_j}{B_j},$$

and

$$B_j = \tau_{nj}(n_0 + n_j + \Delta n) + \tau_{pj}(p_0 + p_j + \Delta p).$$

If all N_j 's are small compared to any one of the quantities n_0 , p_0 , n_j , p_j ,

$$H_n \text{ and } H_p \ll 1$$

or

$$\Delta n = \Delta p,$$

In this case, we have single lifetime τ given by

$$\frac{1}{\tau} = \frac{1}{\tau_n} = \frac{1}{\tau_p} = \sum_j \frac{1 + \Delta\varphi}{\tau_{j0} + \tau_{j\infty} \Delta\varphi}, \quad (A5)$$

where

$$\tau_{j0} = \frac{\tau_{pj}(n_0 + n_j) + \tau_{nj}(p_0 + p_j)}{n_0 + p_0},$$

$$\tau_{j\infty} = \tau_{pj} + \tau_{nj},$$

$$\Delta\varphi = \frac{\Delta n}{n_0 + p_0},$$

and

$$\tau_{nj} = \frac{1}{\tau_{nj} N_j}, \quad \tau_{pj} = \frac{1}{\tau_{pj} N_j}.$$

This equation is the simple extension of the Shockley-Read equation for the dependence of lifetime upon carrier density¹⁷⁾.

Appendix B: Carrier Lifetime for Transient Conditions

For simplicity, we shall assume that a single recombination level is active. Then Eqs. (A1) and (A2) give

$$\left. \begin{aligned} -\frac{d\Delta n}{dt} &= \tau_n(N_0^+ + n_0 + n_1 + \Delta n)\Delta n - \tau_n(n_0 + n_1 + \Delta n)\Delta p, \\ -\frac{d\Delta p}{dt} &= \tau_p(N_0^- + p_0 + p_1 + \Delta p)\Delta p - \tau_p(p_0 + p_1 + \Delta p)\Delta n. \end{aligned} \right\} \quad (B1)$$

For the transient case, it is impossible to solve these equations exactly. We are interested in finding simple, approximate formula which may be used in analyzing experimental data.

We first define the effective time constants of decay at any time t to be

$$\left. \begin{aligned} \frac{1}{\tau_n} &= -\left(\frac{1}{\Delta n}\right) \frac{d\Delta n}{dt}, \\ \frac{1}{\tau_p} &= -\left(\frac{1}{\Delta p}\right) \frac{d\Delta p}{dt}, \end{aligned} \right\} \quad (B2)$$

As a further simplification, we shall assume that N_r is small so that we may neglect the

change in carrier densities produced by changing concentrations in the recombination centers. In this case, $\tau = \tau_n = \tau_p$ and $\Delta n = \Delta p$. From Eq. (B1), we find that τ is given by

$$\frac{1}{\tau} = r_n r_p \frac{N_0^+ N_0^- + N_0^- (n_0 + n_1 + \Delta n) + N_0^+ (p_0 + p_1 + \Delta p)}{r_n (N_0^+ + n_0 + n_1 + \Delta n) + r_p (N_0^- + p_0 + p_1 + \Delta p)}, \quad (B3)$$

for

$$\begin{aligned} & \{r_n (N_0^+ + n_0 + n_1 + \Delta n) + r_p (N_0^- + p_0 + p_1 + \Delta p)\}^2 \\ & \gg 4 r_n r_p \{N_0^+ N_0^- + N_0^- (n_0 + n_1 + \Delta n) + N_0^+ (p_0 + p_1 + \Delta p)\}. \end{aligned}$$

Neglecting N_0^+ and N_0^- , and putting $\Delta n = \Delta p$, we get

$$\tau = \frac{\tau_{p0}(n_0 + n_1 + \Delta n) + \tau_{n0}(p_0 + p_1 + \Delta n)}{n_0 + p_0 + \Delta n},$$

or

$$\tau = \frac{\tau_0 + \tau_\infty \Delta \varphi}{1 + \Delta \varphi}. \quad (B4)$$

Appendix C: Apparent Lifetime

The signal measured by the photoconductivity decay method is given by

$$\Delta V(t) = i \Delta R(t) \quad (C1)$$

where $\Delta R(t)$ is the change in resistance of the specimen. This change in resistance corresponds to the change in conductivity

$$\Delta \sigma = e(\Delta n \cdot \mu_n + \Delta p \cdot \mu_p). \quad (C2)$$

Experimentally, the apparent lifetime, τ^* , at any time t is given by

$$\frac{1}{\tau^*} = - \left(\frac{1}{\Delta V} \right) \frac{d \Delta V}{dt}, \quad (C3)$$

and in general differs from the effective lifetime τ defined by Eq. (B2). For convenience we define some dimensionless parameters as follows:

$$v = \Delta V / V_0, \quad r = \Delta R / R_0, \quad s = \Delta \sigma / \sigma_0, \quad (C4)$$

where subscript 0 refers to the equilibrium state. Then, from Eq. (C3)

$$\frac{1}{\tau^*} = - \left(\frac{1}{v} \right) \frac{dv}{dt}, \quad (C5)$$

and from Eqs. (B2) and (C2)

$$\frac{1}{\tau} = - \left(\frac{1}{s} \right) \frac{ds}{dt}, \quad (C6)$$

assuming that $\Delta n = \Delta p$.

When the specimen is driven by a constant current source,

$$v = r. \quad (C7)$$

Using the relation

$$r = s / (1 + s), \quad (C8)$$

we get from Eqs. (C5), (C6) and (C7)

$$\begin{aligned} \frac{1}{\tau^*} &= - \left(\frac{1}{v} \right) \frac{dv}{dt} \\ &= - \left(\frac{1}{r} \right) \frac{dr}{dt} = \frac{1}{1+s} \frac{1}{\tau}. \end{aligned} \quad (C9)$$

Thus, from (C7), (C8) and (C9), the relation between τ^* and τ is given by

$$\tau = (1 - v) \tau^*. \quad (C10)$$

One to One Correspondence between Etch Pits and Dislocations in KCl Crystals

By Masayoshi SAKAMOTO and Shunsuke KOBAYASHI

Department of Physics, Tokyo College of Science, Shinjuku-ku, Tokyo

(Received May 10, 1958)

Etch pits of KCl crystals obtained with dehydrated glacial acetic acid were observed. KCl is so soft, comparing with LiF, that dislocations are generated on it by slight mechanical shocks. Therefore, surfaces of KCl crystal are apt to be contaminated in the sense of the dislocation theory. It is supposed its depth usually reaches $100\ \mu$ or more and also most of these generated dislocations are surface half loops and isolated loops. One to one correspondence between etch pits and dislocations is discussed.

§ 1. Introduction

There have been some excellent reports on the etching of alkali halide crystals¹⁾. Recently, the authors could find a successive etching method for KCl crystals. From the observed results of these etching patterns, it is believed there should be one to one correspondence between etch pits and dislocations.

As KCl crystals are remarkably soft*, they should be treated very carefully during the preparation of specimens by cleavage and before and after the etching operation. Specimens increase pits density on their surface tremendously when they receive any slight mechanical shock from outside due to the operator's carelessness.

The same things also happen at the instant of cleavage when the cleavage front stops or when its speed drops below a certain value.

It is believed that most of these etch pits generated on the surface have resulted from dislocations consisting of surface half loops

and isolated loops close to the surface which were already reported by J. J. Gilman and W. G. Johnston regarding LiF crystals²⁾.

§ 2. Etching Method

KCl ingots produced from melt* were cleaved successively into small specimens of $5 \times 5 \times 10\ \text{mm}^3$. Glacial acetic acid fully dehydrated was used for etching and acetone for rinse after the etching**. The wet specimens just after rinse were dried by placing them upon a special kind of blotting paper. The last treatment seems to be most important throughout the whole process.

The duration of each etching was ranging from a few parts of a second to about 100 seconds. Specimens were remarkably dissolved at the initial instant by 10 cc etchant in a small bottle, but the dissolution tended to

* We used KCl ingots produced at Horiba Manufacturing Co. in Japan.

** Recently, we found a better etching reagent which is acetic acid saturated with Zn ions. Among several metal ions, Zn ion was the best.

* Values of σ_{11} were reported: $0.40 \times 10^{12}\ \text{dyne/cm}^2$ in KCl, $1.18 \times 10^{12}\ \text{dyne/cm}^2$ in LiF.

Fig. 2. An example of double etching. (1 sec.)

show a saturation in about 10 seconds.

Fig. 1 shows a typical example of successive etching. An etch pit appears in a pyra-

midal shape having a square base. The side edges of the base are parallel to $[100]$ type directions. When the intensities with which the etch pits are produced are thought to be equal, all the pyramids are of the same size [Fig. 2], but the shape and size of etch pits are not generally so simple. Fig. 2 is a picture of the second etching in double etching. After the fast first etching, the specimen was lightly pressed with a finger on a spot of its surface, and then it was etched again for a short time. In this picture, there were two kinds of etch pits with large basal square of the same size: one shaped like a perfect pyramid, the other flat-topped. Both of them had appeared as small pyramids of the same size when they were first etched. It is presumed that the causes which had produced the large perfect pyramids had continued to exist from the first etching till the second one, and that the causes which had produced the flat-topped pyramids vanished during this process. On the other hand, there is another kind of etch pits, also shaped like pyramids but smaller in size. Those small pyramids, shown in this picture, may be thought as new etch pits which have come out during the second etching. So these pits must have been

Fig. 3. Symmetric pattern of matching cleaved pieces.

Fig. 4. Asymmetric Pattern of matching cleaved pieces.

generated by the stresses given with a finger.

§ 3. Observed Results

(a) Symmetrical Pattern of Cleaved Pieces

When KCl crystals are carefully dealt with through the processes of cleavage and etching, perfectly symmetrical pattern of etching like Fig. 3 can be got at any time. If the specimens are treated without caution, it may be very difficult to obtain symmetrical pattern of matching cleaved pieces [Fig. 4]. Though these two pictures were those of matching cleaved pieces, there are some asymmetric pits near the boundary in these pictures.

(b) Effects of Slight Mechanical Shocks

In Fig. 5 two pictures are compared: one taken before, and the other after, the cleaved surface of the specimen was dropped from

the height of 1 cm on to the flat plate of an optical microscope in parallel with it. Pits density, which had been about $10^4/\text{cm}^2$ before the fall, increased to more than $10^6/\text{cm}^2$ after that. Especially, it is considered that numerous small surface loops must have been generated.

Fig. 6 shows a side picture of one of the spots where the specimen was stressed by a metal pincet with a minimum pressure barely enough to hold it. Picture (a) shows the specimen before holding, and (b) after that. In picture (a) pits density is about $10^3 \sim 10^4/\text{cm}^2$, but in (b) the generation of pits is remarkable and reaches deep. The white part on the left side of (b) means an off-focal region which resulted from this dilation. There also happened some breakdowns of the surface. Pits density near the surface is more than $10^8/\text{cm}^2$,

Fig. 5. Effect of a fall.
(a) Before the fall. (b) After the fall.

Fig. 6. Effect of a holding with a pincet.
(a) Before the holding. (b) After the holding.

which exceeds the resolving power of the microscope, and may reach $10^6/\text{cm}^2$ at the depth of about $250\ \mu$.

Fig. 7 shows the effect of rubbing. The

cleaved surface of the specimen was placed on a piece of silk cloth with its face downwards and then pulled in one direction for 3 cm as slightly as possible. Picture (a) shows

Fig. 7. Effect of a rubbing.
(a) Before the rubbing. (b) After the rubbing.

Fig. 9. Effect of an impact with a carborundum piece.
(a) Before the impact. (b) After the impact.

the specimen before the rubbing and (b) after that. Pits density of (a) is $10^3 \sim 10^4/\text{cm}^2$, but in (b) more than $10^8/\text{cm}^2$ close to the surface and about $10^6/\text{cm}^2$ in the interior. Effects

have reached the depth of 100μ . It must be noticed that a row of small pits along a cleavage step in (a) has vanished in (b). It is presumed that these pits resulted from shal-

Fig. 8. Effect of an impact with a small Ni-rod.

- (a) Before the impact.
- (b) After the impact. Etching of 1 sec.
- (c) Second etching after the impact (3 sec.).

low surface half loops.

Fig. 8 shows a picture of the successive etching when small Ni-rod, 4mm in length and 0.2mm in diameter, was dropped upon a cleaved surface from the height of 1 cm. Picture (a) was taken before the fall, (b) and (c) after that. Letter X-like pattern in (b) resulted from the impact of Ni top on the crystal surface. It is presumed that this pattern was consisted of rows of edge-type dislocations. In fact picture (c) seems to indicate that these generated pits consisted of dislocation loops.

Fig. 9 shows the pattern when carborundum particle, having

mean size 400μ [equal to about 65 mesh], was dropped upon the surface of the specimen from the height of 1 cm. The effect of this closely resembles the case of Fig. 8. Gilman and Johnston recognized this pattern with LiF up to 100 mesh carborundum but did not at 240 or more mesh. In the case of KCl, this was done up to 300 mesh [mean size 80μ] carborundum but not at 600 [mean size 40μ] or more mesh.

Fig. 13. An example of a cleaved surface impacted with small carborundum pieces.
(a) First etching. (1 sec.) (b) Second etching (2 sec.)

(c) Effects of Cleavage Itself

While an advancing cleavage front is accompanied by a stress field, numerous etch pits are generated especially in the regions

where a cleavage front advances slowly and once stops. Characteristics of these pits are those, as shown in Fig. 10, that these are lining up parallel to [100] direction and may be

Fig. 15. Effect of human breathing.
(a) Before the breathing. (b) After the breathing.

Fig. 16. Effect of water vapor.

Fig. 17. Effect of water.

thought to result from groups of screw-type dislocation loops. However, when an acting stress field is not uniform, this pattern may be in more complicated situation, including some paired etch pits presumed as groups of edge-type dislocation loops [Fig. 11]. When the velocity of a cleavage front advancing through crystal is more than a certain value, the generation of new pits will never happen.

(d) Existence of Surface Half Loop and Isolated Loop

Fig. 12 and Fig. 13 show that most of newly generated etch pits on the crystal surface were probably surface dislocation half loops and isolated dislocation loops close to the surface. In Fig. 12, when the etching exceeded a certain depth by successive etching, several pairs of etch pits vanished in the same field of this picture.

Fig. 13 shows the same thing. In a fast first etching of cleaved KCl surface especially, it is noticed there are many paired etch pits. It may be known that this situation is essentially the same in Fig. 1, 8, 9, 11 and 12. Therefore, we may the scheme of Fig. 14 in order to understand any asymmetrical

Fig. 14. Interpretation of asymmetric pattern of matching cleaved pieces.

A: Cleavage surface

B-B': Symmetrically etched surface

B-B': Asymmetrically etched surface

Small squares show etch pits

pattern of matching cleaved surfaces like Fig. 4. Also, completely symmetrical pattern may be obtained with fully cautious treatment

[Fig. 3].

(e) Effects of Breathing

KCl is so hygroscopic that the specimen should be protected against operator's breathing and other moistures. Fig. 15 (b) shows the case that the specimen accepted human breathing lightly on its surface and (a) the case not accepted. Fig. 16 shows the effect of water vapor. Fig. 17 shows the case that the specimen was once wetted and then dried out. These pictures are thought to be essentially the same.

§ 4. Discussions

It can not be thought that etch pits result from isolated impurities. Pits density of as grown crystals was usually about $10^4/\text{cm}^2$, but the impurities contained in used crystals were 0.00001 gr Ba, 0.00001 gr Ca and 0.00003 gr Fe per 100 gr KCl and therefore the number of expected defects due to these impurities will be about $10^9/\text{cm}^2$ or more.

It may not be insisted that etch pits must be present only when dislocations are accompanied by impurities as the situation of metals. Because edge-type patterns in Fig. 8 and 9 and screw-type patterns in Fig. 10 and 11 can be shown any time in the same specimen by the different stimulations respectively. This result was just the same even in the home-made crystals which were more impure.

§ 5. Conclusions

(a) Any etch pits can be pursued spatially by the successive etching [Fig. 1].

(b) When KCl crystals are treated carefully, a complete symmetrical etch pattern of matching cleaved pieces can always be taken [Fig. 3].

(c) When any paired etch pits vanish at the almost same time in the successive etching, it may be interpreted that these pits consisted of any dislocation loops [Fig. 12, 13].

(d) Especially, the surface of KCl crystal is apt to generate many surface half loops or isolated loops close to the surface by any slight mechanical shocks. This may be the reason why a symmetrical pattern of matching cleaved pieces could not be taken so easily [Fig. 4, 14].

(e) The observed results of etch pits did not give any inconsistent facts with the dis-

location properties.

According to the reasons mentioned above, it is believed that there exists one to one correspondence between etch pits and dislocations in KCl crystals.

The Internal Friction of Barium Titanate Ceramics*

By Takuro IKEDA

Kobayasi Institute of Physical Research, Kokubunji, Tokyo

(Received April, 10, 1957, Revised May 5, 1958)

The internal friction of BaTiO_3 ceramics has been studied under various conditions. It depends on temperature, biasing field and vibration amplitude, but is nearly independent of frequency and porosity. It is concluded that its main part is not caused by the ceramic and domain structures but is the property of the single domain crystal, which is of intrinsically dielectric origin, acting through piezoelectric coupling.

§ 1. Introduction

Barium titanate ceramics are much used as transducers for generation of ultrasonic waves. Considerable heat, however, is generated in the transducer at a high power level, and thus limits the maximum radiated power. The origin of this effect has been investigated by some authors. Baerwald and Berlincourt¹⁾ attributed it to the dielectric hysteresis, but its main cause was interpreted as the internal friction of BaTiO_3 ceramics by Hueter *et al*^{2), 3)} and the present author⁴⁾. The temperature rise of the transducer becomes remarkable near its resonance, while the unpolarized one shows no anomalous rise. An example of these measurements is shown in Fig. 1(a)⁴⁾; the solid and dotted lines are the temperature rise of polarized and unpolarized ceramics in an oil vessel, respectively. This dissipation of mechanical energy near the resonance must be represented by an internal resistance R_{int}

in the equivalent circuit in Fig. 1(b). (R_{el} : dielectric resistance, R_{rad} : acoustic radiation resistance).

Fig. 1. (a) Temperature rise of BaTiO_3 -ceramic-transducer.

(b) Its equivalent circuit.

Few papers refer to the internal friction of the BaTiO_3 ceramics. Mason⁵⁾ has reported that the dissipation of mechanical energy becomes smaller by aging. Hueter and Neuhaus⁶⁾ investigated the dependence of the ul-

* The summary of § 3 and 5 was read at the meeting of the Physical Society of Japan on 19th, July, 1956, and that of § 4 and 6 on 1st, Nov., 1956.

trasonic attenuation on temperature and biasing field by a pulse method, and attributed the anomalies in the biasing effect to the dislocations at the 90° domain boundaries on the basis of Mason's argument. However, this mechanism seems to be insufficient to explain the greater part of the attenuation.

The present paper attempts to study the subject in more detail; and at first to answer the question, whether the dissipation of vibrational energy in ceramic BaTiO_3 vibrator occurs mainly in the interior of grain crystallites, or it is caused by the ceramic structure. Dependence of the internal friction upon various parameters—temperature, frequency and porosity—will be examined, and as a result, it will be shown that the energy dissipation during mechanical vibration mainly occurs within each grain (§5). In order to find the origin of the internal friction in the grain crystallite, its dependence on biasing field and vibrational amplitude will be measured and, taking account of the following reasons, both internal friction and dielectric loss of the ceramics are examined in parallel.

A complication arises on account of the piezoelectric property of single crystal and pre-polarized ceramics of BaTiO_3 , since in the piezoelectric crystal we have no longer an unambiguous relation between stress and strain. Instead, we have several alternative sets of relations among the quantities—electric field, polarization, stress and strain, and different elastic coefficients corresponding to different electrical condition, which are in general complex. In such condition, the internal friction will also depend on the electrical condition of the crystal. For instance, the elastic loss factor, the “internal friction”, of an unplated bar of piezoelectric crystal will be the $\tan \delta$ of s^D , the elastic compliance coefficient for constant electric displacement, while the loss factor of a plated and short-circuited bar will be the $\tan \delta$ of s^B , the compliance coefficient for constant electric field. Similarly, $\tan \delta$ of the dielectric parameter, the “dielectric loss”, depends upon mechanical condition of the crystal; namely, the loss of free crystal is the $\tan \delta$ of ϵ^F , the “free dielectric constant”, and the loss of a clamped crystal is the $\tan \delta$ of ϵ^S , the “clamped dielectric constant”.

This situation gives rise to various possibilities in the interpretation of internal friction

of piezoelectric crystals, since energy dissipation of intrinsically dielectric origin can contribute to the internal friction under certain conditions. Namely, Mason⁷⁾ has shown for a plated 45°X -cut bar of Rochelle salt crystal that most of the dissipation of vibrational energy can be explained as the dielectric loss of the clamped crystal. Price⁸⁾ also confirmed Mason's view from the measurement of the attenuation of ultrasonic pulse in various directions.

Since the electromechanical coupling is very strong in the single domain crystal of BaTiO_3 , we expect an effect similar to that in Rochelle salt, and it is the purpose of this paper to find that the same consideration applies to the interpretation of internal friction of pre-polarized ceramic BaTiO_3 .

The internal friction and dielectric loss of the BaTiO_3 ceramics are found to be mostly caused by the dissipations within the grain crystallite, and the major contribution of the dissipation in the grain may be the average in some sense, involving mechanical and dielectric losses of single domain crystal. Observation of the internal friction and dielectric loss of the ceramics, taking account of the order of electromechanical coupling in the single crystal, leads to the conclusion that the main part of internal friction of ceramic BaTiO_3 is the dissipation of the dielectric origin.

Many reports have been published regarding the dielectric loss of the BaTiO_3 ceramics. The dielectric losses in the biased state of the BaTiO_3 ceramics were already investigated by Baerwald *et al.*¹⁾, but they appear to have confused the dielectric loss at low amplitude with that at high voltage accompanying the domain reversals. Accordingly, the bias dependence of the dielectric loss will be re-examined.

§2. Preparation of Samples and Experimental Procedure

(a) Preparation of Samples

Commercial BaCO_3 and TiO_2 have been mixed in 1 to 1 mole ratio, calcined at 1200°C , crushed and pressed, and sintered at $1400^\circ\sim 1450^\circ\text{C}$. Most of the samples have specific gravity 5.5~5.6, and the Curie points at about 116°C . Samples of various porosities have been prepared by sintering at various tem-

peratures. The specimens are in the shape of discs and bars. Silver electrodes have been glazed on the proper faces.

(b) Experimental Procedure

The internal friction Q_m^{-1} have been measured by the resonance-curve-method, composite-bar method and bridge (admittance-loop) method.

In the resonance curve method, the frequency of driving voltage of constant amplitude applied on the specimen (prepolarized ceramics), is varied and one observes the electric current passing through maximum and minimum. Denoting the maximum and minimum currents by I_m and I_n , and the frequencies corresponding to them by f_m and f_n , respectively, the internal friction Q_m^{-1} is obtained by the following formula:

$$Q_m^{-1} = \frac{2(f_n - f_m)}{f_m} \sqrt{\frac{I_n}{I_m}}. \quad (2.1)$$

This relation, however, holds true only in the case of small dissipation, and also requires a good sinusoidal wave-form of oscillator voltage. (Wave form distortion strongly affects the value of I_n .)

The composite-bar method consists in observing the resonance curve of a composite bar consisting of X-cut and Y-long quartz rod and the specimen cemented endwise⁹⁾. The internal friction is calculated by

$$Q_m^{-1} = \left(1 + \frac{m_q}{m_s}\right) \frac{2(f_n - f_m)(I_m I_n)^{1/2}}{f_0(I_m + I_n)}, \quad (2.2)$$

where m_q =mass of the quartz rod, m_s =mass of the specimen, f_0 =resonant frequency of the composite bar, and other symbols have the same meaning as above.

Q_m^{-1} was also measured by the bridge method using a radio frequency impedance bridge (made by Yokogawa Electric Works). Admittance-loop was traced and the internal friction was computed by

$$Q_m^{-1} = (f_2 - f_1)/f_0, \quad (2.3)$$

where f_0 is the resonant frequency, and f_1 and f_2 are quadrantal frequencies ($f_2 - f_1$ is the half-width).

Actually, the values obtained by the resonance curve method were often found to be larger by 20~40% than those from (2.3) on account of the distortion of wave form. Therefore, the bridge method was mainly adopted, and the resonance curve method was

used in a few cases, where corrections were made to make the value consistent with the bridge method values.

§ 3. Experimental. A. Dependence of Internal Friction of Ceramic BaTiO₃ upon Various Parameters

(a) Temperature Dependence

The temperature variation of the internal friction of the BaTiO₃ ceramics was examined by the composite bar method. The specimen was *ca.* 3×3×24 mm³ in size. Measurement was done at the frequency of about 90 Kc/s and at temperatures between 20° and 140°C. Experiments were made with unpolarized and remanent-polarized (and short-circuited) state of the specimen. The effect of the polarization is hardly found, as shown in Fig. 2. The

Fig. 2. Temperature variation of the internal friction.

values above T_C are not reliable and may be lower than shown, because of the error of small $f_n - f_m$ in Eq. (2.2), the distortion of oscillator wave form, and the incomplete cementing, etc.

Even in this curve, however, the internal friction above the Curie point T_C is several times smaller than that below T_C . The dotted curve shows the result for $(Ba_{0.96}Ph_{0.04})TiO_3$ by Hueter and Neuhaus⁹⁾, showing a similar behaviour.

(b) Frequency Dependence

Several prepolarized discs of BaTiO₃ cera-

mics with diameters of 18~58 mm were investigated in their radial and thickness modes of vibration. The internal frictions of these discs were measured with the impedance bridge at room temperature. The results are shown in Fig. 3. The dispersion of the measured values

Fig. 3. Frequency dependence of the internal friction.

are likely to be due to the differences of aging and the errors in plotting the admittance loops, etc. In the thickness vibration, it is difficult to measure Q_m^{-1} because of the coupling with higher radial modes.

The internal friction is seen to be nearly independent of frequency between 50 and several hundred Kc/s. Hueter *et al*⁶⁾, on the other hand, report nearly constant attenuation per wave length of ultrasonic pulses for frequencies between 1~50 Mc/s. So it may be said that the internal friction is independent of frequency over a very wide frequency range.

(c) Bias Dependence

Polarized ceramic disc 2 mm in thickness and 26 mm in diameter was used. After it was aged at 82°C for 45 hours, the variation of the internal friction was examined with varying positive bias by the resonance curve method. Fig. 4 shows the measuring circuit.

Fig. 4. Measurement of bias dependence.

The experiment was performed at 80°C. The Q^{-1} values obtained by this method and corrected as mentioned in § 2 are shown in Fig. 5. The biasing field was increased step by step, and the measurement was made in 6 to 10 minutes at each step. The internal friction

Fig. 5. Bias dependence of the internal friction. of ceramics is found to increase by about 40% at the bias of 6 KV/cm.

(d) Amplitude Dependence

In Fig. 6(a), V_o gives the voltage applied on the specimen. V_i gives the potential difference across a small resistance r , and is proportional to the electric current through the vibrator. At each constant voltage, the frequency of the oscillator is adjusted to f_m , the frequency corresponding to the maximum current, and the corresponding values of V_o and V_i were observed. The equivalent circuit is shown in Fig.6(b). It is now assumed that ω_0 , L , C and C_0 are independent of vibration amplitude and $1/\omega_0 C_0$ is larger than R_i . R_i is the internal resistance which is amplitude-dependent. When the amplitude of vibration

Fig. 6. (a) Measurement of amplitude dependence. (b) Equivalent circuit of the vibrator.

is small, R_t must be equal to the value obtained by the bridge method, $(R_t)_0$. Then

$(Q_m^{-1})_0 = \omega_0 C (R_t)_0$ and $Q_m^{-1} = \omega_0 C R_t$. (3.1)

Hence

$$Q_m^{-1} / (Q_m^{-1})_0 = R_t / (R_t)_0 \approx (I_m / V_v)_0 / (I_m / V_v)$$
$$= (V_t / V_v)_0 / (V_t / V_v) \quad (3.2)$$

When the mode of vibration is radial, the strain amplitude (effective value) at the centre is

$$S_0 = K I_p, \quad (3.3)$$

where I_p is the "piezoelectric current" through the LCR branch and K is the constant of specimen given by

$$K = \frac{4}{\omega_0 a^2} \frac{d_{31}}{\epsilon_3^F} \frac{1}{k_r^2} \frac{x_1}{J_1(x_1)}, \quad (3.4)$$

(a =radius of the disc, ϵ_3^F =free dielectric constant, d_{31} =piezoelectric constant, k_r =electromechanical coupling coefficient for radial vibration, x_1 =root of the Eq. $x J_0(x) = (1 - \sigma) J_1(x)$ where J_0 and J_1 are Bessel functions and σ is Poisson's ratio). At the frequency f_m , we have $I_m \approx (I_p)_{f_0} = V_v / R_t$; therefore, from (3.3),

$$S_0 \approx K V_v / R_t. \quad (3.5)$$

When V_t and V_v are measured with varying V_v , Q_m^{-1} and S_0 are determined at each amplitude by (3.2) and (3.5) by using the values of $(Q_m^{-1})_0$ and $(R_t)_0$.

Using the same specimen as employed in (c), the following values are chosen at 80°C;

$$\left. \begin{aligned} K &\approx 5.2 \times 10^{-4} \text{ (amp.}^{-1}\text{)}, \\ (R_t)_0 &\approx 40 \Omega, \\ 1/\omega_0 C_0 &\approx 450 \Omega. \end{aligned} \right\} \quad (3.6)$$

In the neighbourhood of 80°C, f_0 varies little

Fig. 7. Amplitude dependence of the internal friction.

with various V_v . From the measurement of V_t with varying V_v , Fig. 7 is obtained, using Eqs. (3.2), (3.5) and (3.6). The abscissa is shown in the strain amplitude S_0 (the effective amplitude) estimated approximately by (3.5). The internal friction is seen to increase rapidly at a certain strain amplitude.

(e) Porosity Dependence

Several specimens with disc shape were prepared at various sintering temperatures. Their apparent densities are 5.0~5.6 corresponding to different porosities, while the true density of the substance is 6.0. The internal friction was measured in radial vibrations by the resonance-curve method. The internal friction of a few specimens with lower densities could not be determined by that method, and so were measured by the composite bar method. Fig. 8 shows Q_m^{-1} and the radial

Fig. 8. Porosity dependence of the radial coupling coefficient and the internal friction.

coupling coefficient k_r , where the abscissa is shown in density instead of porosity. While k_r is considerably porosity-dependent, Q_m^{-1} is seen to be only slightly dependent on porosity in the range of this experiment.

§ 4. Experimental. B. Parallel Examination of the Internal Friction and Dielectric Loss

(a) Bias Dependence and Aging Effect

The specimen was the same disc as the one

used in § 3 (c). The dielectric $\tan \delta$, or Q_e^{-1} , was measured at 50 Kc/s with the impedance bridge under a biasing field. The result at 80°C is shown in Fig. 9. The measurement

Fig. 9. Bias dependence of the internal friction and dielectric loss.

was done step by step, and the plotted values obtained are those after about 5 minutes at each step. The curve of the internal friction Q_m^{-1} is taken from Fig. 5. The internal friction increases with the biasing field (by 40% larger at the d.c. field of 6 KV/cm), but the dielectric loss is nearly independent of the bias.

The aged sample was now biased and aged for several hours, and next, after the removal of the bias, it was aged again. This cycle was repeated several times and the internal friction and dielectric loss were measured

during these cycles. An example of the measurements is shown in Fig. 10. Internal friction in the aged condition also is seen to be larger in the biased state than in the unbiased state.

(b) Temperature Variation

The specimen was in the form of a bar made of prepolarized ceramics, about 0.8 mm thick, 2.6 mm wide and 18 mm long. The dielectric loss was measured by the impedance bridge, and the internal friction was obtained by the resonance-curve method in the longwise longitudinal vibration. Fig. 11 shows the results. The dotted curve at the higher temperature shows the dielectric loss of the unpolarized ceramics. These measurements show that the internal friction and dielectric loss vary in parallel.

§ 5. Considerations.—The Internal Friction of the “Ceramic” BaTiO₃

On the ground of these knowledges on the dependence of the internal friction, this and next sections will deal with the problems on the mechanism of the dissipation in the BaTiO₃ ceramics.

The measured internal friction ϕ^* ($\phi^* = Q_m^{-1}$) can be considered to consist of two parts: the internal friction in the grain crystallite ϕ_{gc} , and that due to the ceramic structure ϕ_{cer} . Namely,

$$\phi^* = \phi_{gc} + \phi_{cer} \tag{5.1}$$

The second part will be caused mostly in

Fig. 10. Aging effects of the internal friction and dielectric loss with and without the bias.

Fig. 11. Temperature variation of the internal friction and dielectric loss.

the grain boundary (ψ_{GB}). Its magnitude cannot be estimated directly, but it will be reasonable to assume that it does not change appreciably above and below Curie point; then, ψ_{cer} must be of the order of the internal friction above T_c , and is shown to be several times smaller than the value of ψ^* at room temperature. This means that most part of the internal friction of BaTiO₃ ceramics in the ferroelectric range is caused by the dissipation in the grain crystallite, ψ_{gc} . The dissipation due to the "ceramic" structure ψ_{cer} will not be important in BaTiO₃ ceramics.

Porosity dependence measurement, which was performed in order to find the contribution of ψ_{cer} , gave the internal friction which is nearly independent of porosity in the range examined. The result suggests again that the role of ψ_{cer} must be small.

The first term of (5.1)—the internal friction ψ_{gc} in the grain crystallite—consists of the dissipation at domain boundaries, ψ_{DB} , and the contribution from that of the single domain crystal, ψ_{SD} . ψ_{DB} is not evaluable but it can be assumed to be small in the aged condition. (Its order of magnitude may be smaller than ψ_{GB} , because the walls are thinner than grain boundaries.) ψ_{SD} will be the average of the mechanical dissipations in all domains with various orientations. Since the internal frictions of the unpolarized and prepolarized ceramics are nearly equal, the averaging taking account of the domain distributions may hardly affect ψ_{SD} .

Further considerations of ψ_{DB} and ψ_{SD} will be given in the following section.

§ 6. Discussions.—In Relation to the Dielectric Loss in the Single Crystal

(a) Piezoelectric Relation in the Dissipative Crystal

In the piezoelectric crystals, the relation between stress and strain is complicated because of the piezoelectric coupling between electric and mechanical quantities. Denoting the electric field, polarization, stress and strain by E , P , T and S , we have alternative sets of relations, such as

$$\left. \begin{aligned} T &= c^P S - aP \\ E &= \chi^c P - aS \end{aligned} \right\}, \quad (6.1)$$

or

$$\left. \begin{aligned} T &= c^S S - eE \\ P &= \kappa^c E + eS \end{aligned} \right\}, \quad (6.2)$$

corresponding to different choices of independent variables. One set is derivable from another, and there seems to be no general argument in favour of any one of these sets.

In the ferroelectric substances, the dielectric loss may occur on account of the lag of reorientation of dipoles, and this suggests that polarization P is the proper independent variable to represent electrical state. Strain S is chosen for the mechanical variable, since it seems to be the less ambiguous measure for the internal elastic state. Then, Eq. (6.1) becomes fundamental relation between E , P , T and S , where the elastic constant and clamped

inverse susceptibility are complex, so that

$$c^p = c' + jc'' \quad \text{and} \quad \chi^o = \chi' + j\chi'' \quad (6.3)$$

The piezoelectric coefficient a may also be complex and must be examined experimentally. However, the phase of a of the single domain crystal cannot be determined, using the present samples, which are of ceramic form. In the case of Rochelle salt, the piezoelectric coefficient f_{14} , which corresponds to a , has been shown to be unaffected by phase transition and considered as real by Mason⁷⁾. Although BaTiO₃ differs from Rochelle salt in several important points, it may not be too unreasonable to assume here that a is real. Tan δ 's of c^p and χ^o will be denoted by ψ and ϕ ;

$$\psi = c''/c' \quad \text{and} \quad \phi = \chi''/\chi' \quad (6.4)$$

(b) Internal Friction and Dielectric Loss

Tan δ of the elastic constant c^p for constant field and that of the free dielectric inverse susceptibility χ^o of the single domain crystal will be given by

$$\left. \begin{aligned} \psi(c^p) &= 1/(1-k^2) \cdot (\psi + k^2\phi) \\ \phi(\chi^o) &= 1/(1-k^2) \cdot (\phi + k^2\psi) \end{aligned} \right\} \quad (6.5)$$

where k is the appropriate electromechanical coupling coefficient and the second terms represent the piezoelectric coupling effect.

Although the elastic and dielectric constants of the ceramics may not be the simple averages of c^p and χ^o but depend on all the quantities, c^p , c^D , χ^o and χ^s of the single crystal, they may still be considered as the averages in some sense. Similar averaging may be considered for the phase of these quantities. Accordingly, denoting the internal friction and dielectric loss of ceramics by ψ^* and ϕ^* ($\psi^* = Q_m^{-1}$ and $\phi^* = Q_e^{-1}$), they will be expressed as

$$\left. \begin{aligned} \psi^* &= A(\psi + f\phi) + \psi' \\ \phi^* &= A'(\phi + f'\psi) + \phi' \end{aligned} \right\} \quad (6.6)$$

Experiments have shown that ψ^* as well as ϕ^* is almost the same for the unpolarized and the remanent-polarized states. The first term in the expression for ψ^* corresponds to ψ_{SD} in §5. ψ' represents the dissipation except that within each domain; i.e. the dissipation in the grain boundary, in the domain boundary, etc. ϕ' is similarly the dielectric loss due to the ceramic and domain structures.

In the prepolarized ceramics, the dissipation terms due to the macroscopic electromechani-

cal coupling must be added to both formulae ($B\phi'$ and $B'\psi'$ respectively). But, as the existence of the remanent polarization does not affect ψ^* and ϕ^* , these terms will not be considered here. (B and B' are of the order of k^{*2} , where k^* is the macro electromechanical coupling coefficient. As k^* is about 30%, these dissipations are at most 0.1×10^{-3} or less.)

The constants A , A' , f and f' are certain averaged values and must depend on the distribution of domain orientations. But the absence of the differences between the internal frictions of the unpolarized and prepolarized ceramics suggests that these constants are little influenced by the domain distributions.

The value of ψ' is supposed to be at most of the order of the value above T_c . Then it may be taken as

$$\psi' \lesssim (0.5 \sim 0.6) \times 10^{-3} \quad (6.7)$$

ϕ' may also be expected to be smaller than the dielectric loss above T_c , of which the dielectric tan δ of $\chi (= \chi^o = \chi^s)$ constitutes a main part; and then

$$\phi' \ll 0.6 \times 10^{-3} \quad (6.8)$$

At room temperature, the measured values of ψ^* and ϕ^* in sufficiently aged BaTiO₃ ceramics are

$$\left. \begin{aligned} \psi^* &\approx (3.1 \sim 3.8) \times 10^{-3} \\ \phi^* &\approx (6 \sim 7) \times 10^{-3} \end{aligned} \right\} \quad (6.9)$$

When the relations

$$A = A' \quad \text{and} \quad f = f' \quad (6.10)$$

are assumed, and the values

$$f \approx 0.45 \sim 0.5 \quad (6.11)$$

are chosen, then

$$\left. \begin{aligned} \psi &\text{ is almost negligible} \\ \phi &= (3 \sim 3.5) \times 10^{-3} \end{aligned} \right\} \quad (6.12)$$

Accordingly, most part of the internal friction ψ^* of the ceramics can be interpreted by the dielectric tan δ of χ^o in the clamped crystal, assuming a to be real.

(In the above discussions, the piezoelectric coefficient a has been assumed to be real. When a is complex and its tan δ is denoted by $\alpha/2$, another term $k^2/(1-k^2) \cdot \alpha$ must be added to both formulae in (6.5). Correspondingly, the term $Ag\alpha$ should be added to the first equation in Eq. (6.6) for ceramics and $A'g'\alpha$ to the second. But, if it is allowable to assume that $f = f' = g = g' \approx 0.45 \sim 0.5$, the magnitudes of ψ and α will be very small.)

This conclusion will be examined in the light of existing data on BaTiO_3 . The interrelation among dielectric, piezoelectric and elastic properties of BaTiO_3 crystal has been investigated theoretically by Devonshire¹⁰. He ascribed the anomaly of BaTiO_3 to the dielectric one, and assumed that the elastic compliances s^P 's for constant polarization did not vary at the transition. (It was shown that s^P varied at the transition by the amount corresponding to the change of the crystal lattice⁹). Its variation, however, is only of the order of 30%.) Accordingly, ψ , which is $\tan \delta$ of s^P , may be considered to be unchanged at the transition. Then, ψ may be smaller than 0.5×10^{-3} . As regards the electromechanical coupling coefficient, Mason *et al*¹¹ reported the value $k_{33} = 67.5\%$ for the single crystal. From the reports of Devonshire and Mason, the values of the piezoelectric coupling for the single crystals that $k_{33} \sim 65\%$, $k_{15} \sim 80\%$ and $k_{31} \sim 15\%$ will be used. As the constant f in Eqs. (6.6) is of the order of k^2 , it may be permissible to assume that f is nearly equal to 0.5. The author has tentatively extended Marutake's calculation¹² on the physical constants of BaTiO_3 ceramics to the case of complex coefficients, and has also obtained $A = A' \sim 1.9$ and $f = f' \sim 0.48$. Above conclusions may, therefore, be permissible.

The frequency independence of the internal friction can be understood from the frequency-independence of dielectric loss already reported.

Biasing field causes the increase of the internal friction, while the dielectric loss is nearly independent of the bias, and so the increase of the internal friction cannot be interpreted by a change of φ . This may be mainly due to the increase of ϕ_{DB} , which is presumably caused by the internal strains at the domain boundaries accompanying the 90° domain rotations (e.g. dislocations).

The amplitude dependence of the internal friction cannot be interpreted as that of φ , and it may be caused by the amplitude effect of the dissipation in the domain boundary or grain boundary. Further study will be desirable to elucidate these points.

The mechanism of the dielectric loss in the clamped crystal ($\tan \delta$ of χ'') is not yet clear. Direct measurement of the phase of a on single domain crystals is also very desirable.

§ 7. Conclusions

From the preceding experiments and discussions, the following results are obtained:

- (1) The internal friction of BaTiO_3 ceramics is dependent on vibration amplitude and biasing field, but independent of frequency and porosity in the range investigated.
- (2) The main part of the internal friction of BaTiO_3 ceramics is the average of the dissipation of mechanical energy in the single domain crystals, and the dissipation due to the "ceramic" and domain structures is small.
- (3) The dissipation in the single domain crystal cannot be considered to be the intrinsic mechanical loss, but considered to be caused by the dielectric $\tan \delta$ of χ'' of the clamped crystal, which acts through the piezoelectric coupling, assuming that the phase lag of the piezoelectric coefficient a is small.

In order to confirm the above conclusions, it is desirable that measurements are done on the internal friction, dielectric loss and the electromechanical coupling coefficients of the single crystal.

The author is very grateful for useful advice and discussions of Prof. H. Takahashi of the Tokyo University, and Dr. O. Nomoto and Mr. M. Marutake of the Kobayasi Institute. He also wishes to thank Mr. T. Nobuzawa and Mr. Y. Kanda of the Waseda University for their help to these experiments.

This study was supported partly by the Scientific Expenditure of the Ministry of Education.

The Thermoelectric, Galvanomagnetic and Thermomagnetic Effects of Monovalent Metals II

The Thermoelectric Powder for Anisotropic Media

By Mikio TSUJI

General Education Department, Kyushu University, Fukuoka

(Received April 23, 1958)

In the part I of this article, it has been shown that the thermoelectric power of monovalent metals at high temperatures is interpreted, at least semi-quantitatively, based on the spherical energy band model. However, it has also been shown that the model gives no possibility of the positive sign of the thermoelectric power of pure metals at low temperatures. Therefore, in this part II, the thermoelectric power at low temperatures is calculated for an arbitrarily anisotropic energy band. The results show that there is a possibility to give positive thermoelectric powder for pure metals at low temperatures if the shape of the energy surface is appropriate. The relation with the spherical band model used in I is discussed also.

§ 1. Introduction

In the previous paper¹⁾ (to be referred to as I), we have investigated the thermoelectric effect and the transverse galvano- and thermomagnetic effects of monovalent metals using the model of the general spherical energy band, and have given an interpretation of the positive thermoelectric powers and the negative Ettingshausen and Ettingshausen-Nernst coefficients of noble metals at high temperatures. For the thermoelectric power of pure metals at low temperatures, however, the model of spherical band has given no possibility of the positive sign which are observed actually for noble metals²⁾. As stated in I, for the change of the distribution function $f(\mathbf{k})$ of the conduction electrons due to the lattice scattering at high temperatures, each of the transitions to or from nearly all states ($\mathbf{k}'$) on the Fermi surface gives respective contribution to $(\partial f(\mathbf{k})/\partial t)_{\text{coll}}$, and so the anisotropy is averaged out in a certain extent. The situation is quite similar in the scattering due to the impurity atoms or lattice defects. In these cases, the spherical

band model is good, at least semiquantitatively, for the purpose of calculating the conductivities or thermoelectric power. (To calculate the magnetoresistance effect, it is necessary to take into account the anisotropy of the band structure even in these cases³⁾.) On the other hand, for the lattice scattering at low temperatures, only the electronic states ($\mathbf{k}'$) near the state $\mathbf{k}$ contribute to $(\partial f(\mathbf{k})/\partial t)_{\text{coll}}$, and therefore $(\partial f(\mathbf{k})/\partial t)_{\text{coll}}$ depends strongly on the local behaviour of the energy band near the state $\mathbf{k}$. Hence, in this case, the anisotropy of the band structure becomes important and the spherical band model becomes useless.

Therefore, in this paper, the electrical and thermal conductivities and the thermoelectric power of monovalent metals at low temperatures are calculated for an arbitrarily anisotropic energy band, and especially it is discussed qualitatively what kind of the band structure gives possibility of the positive thermoelectric power of pure noble metals at low temperatures. Since the effects of non-equilibrium distribution of the lattice waves give negative

contribution to the thermoelectric powers, the effects may be neglected for our purpose to investigate the possibility of the positive sign of the thermoelectric power.

Now, it is generally not easy to solve the Boltzman equation for the anisotropic energy band. Using the fact that the wave vectors of all the conduction electrons lie inside the Debye sphere of phonons for non-polar semiconductors, Radcliffe⁴⁾ has obtained the time of relaxation for arbitrarily anisotropic band structure. But his method can not be used in the case of monovalent metals.

Jones⁵⁾ has discussed qualitatively the thermoelectric power of noble metals based on the anisotropy of the band structure, but since his theory assumes the existence of the universal relaxation time, the theory can not be applied to the lattice scattering at low temperatures. However, the fact that the wave numbers of phonons which scatter the electrons are small compared to those of electrons on the Fermi surface makes the calculation tractable if we use the variational principle of Kohler⁶⁾ to obtain approximate solutions. Sondheimer's unpublished results of the calculation by such a method have been quoted by Wilson in his text-book⁷⁾. But the calculations have had an important error. This is easily seen from the fact

that the electrical conductivity σ given by (10.63.1) of Wilson's text becomes negative for a special case that the band structure is spherical and $(d^2E/dk^2)_{E=\zeta}$ is negative.

In §2 a transport equation for a pure metal of anisotropic energy band at low temperatures is derived, and the solution of this equation is given in §3, by using the variational principle. We discuss the results in §4 and show:

(1) that the qualitative behavior of the temperature dependence of the electrical and thermal conductivities is not modified essentially by the introduction of the anisotropy in the band structure,

(2) that the ratio of the electrical conductivity to the thermal conductivity at low temperatures is modified by the anisotropy, and

(3) that the thermoelectric power of pure metals at low temperatures is remarkably modified by the anisotropy, and if the feature of the band structure are appropriate, the thermoelectric power may become positive.

In §5, the effects of the impurity scatterings are calculated and the relation between the calculation in this paper and the spherical band approximation used in I is discussed. Thus the meanings of the parameters α and β appeared in I become clearer.

§2. The Transport Equation

If the electric field $\mathbf{F}$ and the temperature gradient ∇T are in x direction, Boltzmann's equation can be written in the form,

$$\frac{1}{\hbar} \frac{\partial E}{\partial k_x} \frac{\partial f_0}{\partial E} \left(eF + T \frac{\partial \zeta}{\partial x} \frac{1}{T} + \frac{E}{T} \frac{\partial T}{\partial x} \right) + \left(\frac{\partial f}{\partial t} \right)_{\text{coll}} = 0, \quad (1)$$

where $f(\mathbf{k})$ is the distribution function of electrons, f_0 the Fermi distribution ($=1/(e^{\eta}+1)$), $\eta=(E-\zeta)/\kappa T$, $-e$ the electronic charge, ζ the Fermi energy and the other symbols have their usual meanings. The collision term $(\partial f/\partial t)_{\text{coll}}$ is given by⁸⁾

$$\begin{aligned} \left(\frac{\partial f}{\partial t} \right)_{\text{coll}} = & \frac{C^2 \mathcal{V}}{16\pi^3 M \kappa T} \int \frac{q^2}{\nu_q} N_q [f_0(\mathbf{k}) \{1-f_0(\mathbf{k}+\mathbf{q})\} \delta(E_{\mathbf{k}}-E_{\mathbf{k}+\mathbf{q}}+\hbar\nu_q) \\ & + f_0(\mathbf{k}+\mathbf{q}) \{1-f_0(\mathbf{k})\} \delta(E_{\mathbf{k}}-E_{\mathbf{k}+\mathbf{q}}-\hbar\nu_q)] \{ \Phi(\mathbf{k}+\mathbf{q}) - \Phi(\mathbf{k}) \} d\mathbf{q}, \end{aligned} \quad (2)$$

where C is the interaction constant between electrons and lattice waves used by Wilson, $\mathcal{V}$ the volume of the unit cell, M the mass of lattice ion, $\mathbf{q}$ the wave number vector of phonon, ν_q the frequency of phonon, N_q the number of phonons of wave number $\mathbf{q}$, and Φ is given by

$$f = f_0 - \Phi \frac{\partial f_0}{\partial E} \quad (3)$$

In (2), we have assumed that C does not depend on $\mathbf{k}$. Strictly speaking, C may depend on $\mathbf{k}$ and $\mathbf{q}$, but at low temperatures we may assume that C depends only on $\mathbf{k}$. However,

the effect of the anisotropy is derived principally from the geometry of the energy surface, and so we may neglect the dependency of C on $\mathbf{k}$ for the purpose of qualitative discussion.

Now, we put the solution of (2) in the form

$$\phi = c(\eta) \frac{\partial E}{\partial k_z} \quad (4)$$

The exact solution of (2) can not be written in such a simple form as (4) if the energy band is not spherical, but the physical quantities such as the electrical and thermal conductivities and the thermoelectric power calculated by the variational method take the stationary values when the trial function of ϕ coincides with the exact solutions and so the physical quantities may be insensitive to the form of the trial function at least semiquantitatively. If we put (4) into (2), we can integrate with respect to the orientation of $\mathbf{q}$ and reduce the triple integral to a single integral as follows. We represent the vector $\mathbf{q}$ in the polar coordinates $(q, \vartheta, \tilde{\omega})$, in which the polar axis z' is taken in the direction of the outward normal vector $\mathbf{n}$ to the constant energy surface through the point $\mathbf{k}$ in the $\mathbf{k}$ -space, (directed to the higher energy side), and the azimuthal angle $\tilde{\omega}$ is measured from the axis x' which are in the plane determined by z' and x axes. (See Fig. 1.) The radius of curvature ρ of the intersected curve between the energy surface and the plane determined by $\mathbf{n}$ and $\mathbf{q}$ vectors is given by

$$\frac{1}{\rho} = \frac{1}{\rho_1} \sin^2(\tilde{\omega} - \psi) + \frac{1}{\rho_2} \cos^2(\tilde{\omega} - \psi), \quad (5)$$

where ρ_1 and ρ_2 are the two principal radii of curvature and ψ is the angle between x' axis and the direction which gives the principal curvature $1/\rho_1$. The signs of ρ , ρ_1 and ρ_2 are taken to be positive if the centers of curvature C , C_1 and C_2 lie inside the energy surface and negative in the opposite case. Considering that $q \ll k \sim |\rho|$, we assume that the center of curvature of the intersected curve between the constant energy surface through the point $\mathbf{k} + \mathbf{q}$ and the plane determined by $\mathbf{n}$ and $\mathbf{q}$ vectors coincides with the center of curvature C . (See Fig. 2.) Then the radius of curvature ρ' is expanded in the form

$$\rho' = \rho + \left(q \cos \vartheta + \frac{q^2}{2\rho} \right) - \frac{1}{2\rho} \left(q \cos \vartheta + \frac{q^2}{2\rho} \right)^2 + \dots, \quad (6)$$

in which it is noted that $q \cos \vartheta$ and q^2/ρ is the small quantities of the same order of magnitude from the energy conservation. The energy $E_{\mathbf{k}+\mathbf{q}}$ is expanded as

$$E_{\mathbf{k}+\mathbf{q}} = E_{\mathbf{k}} + \frac{\partial E}{\partial n} (\rho' - \rho) + \frac{1}{2} \frac{\partial^2 E}{\partial n^2} (\rho' - \rho)^2 + \dots, \quad (7)$$

Fig. 1.

Fig. 2.

where $\partial E/\partial n$ ($=|\text{grad}_k E|$) and $\partial^2 E/\partial n^2$ are the derivatives of the energy E_k in the direction of $\mathbf{n}$. From (6) and (7) we have

$$E_{\mathbf{k}+\mathbf{q}}-E_{\mathbf{k}}=\frac{\partial E}{\partial n}\left(q \cos \vartheta+\frac{q^2}{2 \rho}\right)+\frac{1}{2}\left(\frac{\partial^2 E}{\partial n^2}-\frac{1}{\rho} \frac{\partial E}{\partial n}\right)\left(q \cos \vartheta+\frac{q^2}{2 \rho}\right)^2 . \tag{8}$$

Using (8), we can rewrite the δ -function in (2) in the form,

$$\begin{aligned} & \delta\left(E_{\mathbf{k}+\mathbf{q}}-E_{\mathbf{k}} \pm h \nu_q\right) \\ &= \frac{1}{q(\partial E / \partial n)}\left\{1 \mp \frac{\partial^2 E / \partial n^2-(1 / \rho)(\partial E / \partial n)}{(\partial E / \partial n)^2} h \nu_q\right\} \delta\left(\cos \vartheta+\frac{q}{2 \rho} \mp \frac{h \nu_q}{q(\partial E / \partial n)}\right), \end{aligned} \tag{9}$$

in which we have used a theorem on the δ -function in which the argument is a quadratic form of a relevant variable. (See Eq. (11) in I.) In the term $\Phi(\mathbf{k}+\mathbf{q})-\Phi(\mathbf{k})$ in (2), if we use the form (4), there appear the terms of $\partial E / \partial k_x$ which are given by

$$\left(\frac{\partial E}{\partial k_x}\right)_{\mathbf{k}}=\frac{\partial E}{\partial n} \cos \theta, \tag{10}$$

and

$$\left(\frac{\partial E}{\partial k_x}\right)_{\mathbf{k}+\mathbf{q}}=|\text{grad}_{\mathbf{k}+\mathbf{q}} E|(\cos \varphi \cos \theta \pm \sin \varphi \cos \tilde{\omega} \sin \theta), \tag{11}$$

where φ is the angle shown in Fig. 2. The negative sign in (11) is taken in the case when the center of curvature C lies outside the energy surface. Now the contribution of the second term in the bracket of (11) vanishes when the Eq. (2) is integrated with respect to $\tilde{\omega}$, and so we neglect the second term hereafter. From the assumption that the two curves shown in Fig. 2 have a common center of curvature, we have

$$|\text{grad}_{\mathbf{k}+\mathbf{q}} E|=\frac{\partial E}{\partial n}+\frac{\partial^2 E}{\partial n^2}(\rho'-\rho), \tag{12}$$

and from Fig. 2 and the energy conservation we have

$$\cos \varphi=1-\frac{q^2}{2 \rho^2}\left(1 \mp \frac{h \nu_q}{q(\partial E / \partial n)}\right) . \tag{13}$$

Therefore, the first term of (11) becomes

$$\left(\frac{\partial E}{\partial k_x}\right)_{\mathbf{k}+\mathbf{q}}=\frac{\partial E}{\partial n} \cos \theta\left[1 \pm \frac{\partial^2 E / \partial n^2}{(\partial E / \partial n)^2} h \nu_q-\frac{q^2}{2 \rho^2}\left\{1 \pm\left(\frac{\partial^2 E / \partial n^2}{(\partial E / \partial n)^2}-\frac{1}{\rho(\partial E / \partial n)}\right) h \nu_q\right\}\right] . \tag{14}$$

Putting (9), (10) and (14) into (2) and integrating with respect to $\tilde{\omega}$ and ϑ , we have

$$\begin{aligned} \left(\frac{\partial f}{\partial t}\right)_{\text{coll}} &= -\frac{1}{\hbar A}\left(\frac{T}{\Theta}\right)^3 \frac{\partial E / \partial k_x}{\partial E / \partial n} \frac{\partial f_0}{\partial E} \int_{-\Theta / T}^{\Theta / T}\left[\left\{1+\frac{(\overline{1 / \rho})}{\partial E / \partial n} \kappa T z-\left(\frac{1}{\rho^2}\right) q_0^2\left(\frac{T}{\Theta}\right)^2 z^2\right\} c(\eta+z)\right. \\ &\quad \left.-\left\{1-\frac{\partial^2 E / \partial n^2-(\overline{1 / \rho}) \cdot \partial E / \partial n}{(\partial E / \partial n)^2} \kappa T z\right\} c(\eta)\right] \frac{e^{\eta}+1}{e^{\eta+z}+1} \frac{z^2 d z}{|1-e^{-z}|}=-\frac{1}{\hbar} \frac{\partial E}{\partial k_x} \mathcal{L}(c), \end{aligned} \tag{15}$$

where $A^{-1} \equiv C^2 \Delta h q_0^3 / (8 \pi^2 M u_0)$, $z \equiv h \nu_q / \kappa T$, Θ the Debye temperature, q_0 the maximum wave number of phonons, u_0 the sound velocity, and $(\overline{1 / \rho})$ and $(\overline{1 / \rho^2})$ are the average of $(1 / \rho)$ and $(1 / \rho^2)$ with respect to $\tilde{\omega}$. If we put

$$c(\eta)=\left(e F+T \frac{\partial}{\partial x} \frac{\xi}{T}\right) c^{(1)}(\eta)+\frac{1}{T} \frac{\partial T}{\partial x} c^{(2)}(\eta),$$

the Boltzmann equation separates into two integral equations

$$E^{n-1} \frac{\partial f_0}{\partial E} = \mathcal{L}(c^{(n)}), \quad n=1, 2. \quad (16)$$

Now, if the Fermi surface does not touch to the zone boundary, the effect of Umklapp processes may become negligibly small at low temperatures. But if the Fermi surfaces touches the boundary, we must not neglect, even at low temperatures, the Umklapp processes which are associated with the phonons of small wave numbers and transfer the states of the electrons near the zone boundary to the states near the same zone boundary in the adjacent zone (or the states near opposite boundary in the reduced zone scheme). We note here that in our calculation the Umklapp processes of this type are perfectly taken into account automatically.

§ 3. Solution of the Boltzmann Equation

The variation principle used first by Kohler¹⁰ states that the solution ϕ of the Boltzmann equation is such as to make the integral

$$-\int \phi \left(\frac{\partial f}{\partial t} \right)_{\text{coll}} dk \quad (17)$$

a maximum, subject to a certain subsidiary condition. In the present approximation, by putting (4) and (15) into (17), the integral (17) is replaced by

$$(c^{(n)}, c^{(n)}) = \kappa T \iint \frac{(\partial E / \partial k_x)^2}{\partial E / \partial n} c^{(n)} \mathcal{L}(c^{(n)}) dS d\eta, \quad (18)$$

which is made a maximum, subject to the subsidiary condition

$$\kappa T \iint \frac{(\partial E / \partial k_x)^2}{\partial E / \partial n} c^{(n)} \mathcal{L}(c^{(n)}) dS d\eta = \iint E^{n-1} \frac{(\partial E / \partial k_x)^2}{\partial E / \partial n} \frac{\partial f_0}{\partial \eta} c^{(n)} dS d\eta, \quad (19)$$

where dS is the surface element on the constant energy surface. Now if we put the trial function $c^{(n)}(\eta)$ in the form

$$c^{(n)}(\eta) = c_0^{(n)} + c_1^{(n)} \eta, \quad (20)$$

after the usual manipulation of the variational method, (See § 2 in I) we obtain the electrical conductivity σ , the thermal conductivity κ_T and the thermoelectric power S as follows;

$$\sigma = \frac{e^2}{4\pi^3 \hbar} \frac{(\alpha_0^{(1)})^2}{d_{00}}, \quad (21)$$

$$\kappa_T = \frac{1}{4\pi^3 \hbar T} \frac{(\alpha_0^{(1)} \alpha_1^{(2)} - \alpha_1^{(1)} \alpha_0^{(2)})^2}{(\alpha_0^{(1)})^2 d_{11}}, \quad (22)$$

$$S = -\frac{\kappa}{e} \frac{\alpha_1^{(1)} \alpha_2^{(1)} d_{00} - \alpha_0^{(1)} \alpha_2^{(1)} d_{01} + \alpha_0^{(1)} \alpha_1^{(1)} d_{11}}{(\alpha_0^{(1)})^2 d_{11}}, \quad (23)$$

where

$$\alpha_r^{(n)} = \iint E^{n-1} \frac{(\partial E / \partial k_x)^2}{\partial E / \partial n} \frac{\partial f_0}{\partial \eta} \eta^r dS d\eta, \quad (24)$$

and

$$d_{rs} = \kappa T \iint \frac{(\partial E / \partial k_x)^2}{\partial E / \partial n} \eta^r \mathcal{L}(\eta^s) dS d\eta. \quad (25)$$

The calculations of $\alpha_r^{(n)}$ and d_{rs} are given in the appendix. Putting (24) and (25) into (21), (22) and (23), we have the final results:

$$\frac{1}{\sigma} = \frac{2\pi^2\hbar}{e^2A} \left(\frac{T}{\Theta}\right)^5 q_0^2 \frac{f_3}{f_1^2} J_5\left(\frac{\Theta}{T}\right), \tag{26}$$

$$\frac{1}{\kappa_T} = \frac{18\hbar T^2}{A\pi^2\kappa^2\Theta^3} \left\{ 1 + q_0^2 \left(\frac{T}{\Theta}\right)^2 \frac{f_3}{f_2} \frac{\pi^2}{3} \right\} \frac{f_2}{f_1^2} J_5\left(\frac{\Theta}{T}\right), \tag{27}$$

$$S = - \frac{\pi^2\kappa^2T}{3e} \frac{(f_2(df_1/dE) - f_1f_4) + (\pi^2/3)q_0^2(T/\Theta)^2\{2f_3(df_1/dE) - f_1(df_3/dE)\}}{f_1f_2\{1 + (\pi^2/3)q_0^2(T/\Theta)^2 \cdot f_3/f_2\}}, \tag{28}$$

where

$$J_n\left(\frac{\Theta}{T}\right) = \int_0^{\Theta/T} \frac{z^n dz}{(e^z - 1)(1 - e^{-z})},$$

and

$$\left. \begin{aligned} f_1 &= \int \frac{(\partial E/\partial k_x)^2}{\partial E/\partial n} dS, & f_2 &= \int \frac{(\partial E/\partial k_x)^2}{(\partial E/\partial n)^2} dS, \\ f_3 &= \int \frac{(\partial E/\partial k_x)^2}{(\partial E/\partial n)^2} \left(\frac{1}{\rho^2}\right) dS, & f_4 &= \int \frac{(\partial E/\partial k_x)^2}{(\partial E/\partial n)^4} \frac{\partial^2 E/\partial n^2}{dS}, \end{aligned} \right\} \tag{29}$$

in which the integrations are taken on the constant energy surface in the first Brillouin zone. In Eqs. (26), (27) and (28), f_n ($n=1, 2, \cdots, 4$) and df_n/dE denote their values on the Fermi surface.

For the crystals which have cubic symmetry, (29) can be rewritten in simpler forms

$$\left. \begin{aligned} f_1 &= \frac{1}{3} \int \frac{\partial E}{\partial n} dS, & f_2 &= \frac{1}{3} \int dS, & f_3 &= \frac{1}{3} \int \left(\frac{1}{\rho^2}\right) dS, & f_4 &= \frac{1}{3} \int \frac{\partial^2 E/\partial n^2}{(\partial E/\partial n)^2} dS. \end{aligned} \right\} \tag{30}$$

§ 4. Discussion

If the energy band is spherical, (30) becomes

$$f_1 = \frac{4\pi}{3} k^2 \frac{dE}{dk}, \quad f_2 = \frac{4\pi}{3} k^2, \quad f_3 = \frac{4\pi}{3}, \quad f_4 = \frac{4\pi}{3} k^2 \frac{d^2E/dk^2}{(dE/dk)^2}, \tag{31}$$

and so (26), (27) and (28) become

$$\frac{1}{\sigma} = \frac{3\pi\hbar q_0^2}{2e^2Ak_0^4\alpha^2} \left(\frac{T}{\Theta}\right)^5 J_5\left(\frac{\Theta}{T}\right), \tag{32}$$

$$\frac{1}{\kappa_T} = \frac{27\hbar T^2}{2\pi^3\kappa^2k_0^2\alpha^2\Theta^3} \left\{ 1 + \frac{\pi^2}{3} \frac{q_0^2}{k_0^2} \left(\frac{T}{\Theta}\right)^2 \right\} J_5\left(\frac{\Theta}{T}\right), \tag{33}$$

$$S = - \frac{\pi^2\kappa^2T}{3e} \frac{2/\alpha k_0 + \pi^2/3(4/\alpha k_0 + 2\beta/\alpha_2)(q_0^2/k_0^2)(T/\Theta)^2}{1 + (\pi^2/3)(q_0^2/k_0^2)(T/\Theta)^2}, \tag{34}$$

$$(\text{where } \alpha \equiv (dE/dk)_{E=\zeta} \text{ and } \beta \equiv (d^2E/dk^2)_{E=\zeta})$$

These results agree with Eqs. (29), (32) and (35) given in I. (Wilson's Eqs. (10.63.1) and (10.63.2) for σ and κ_T reduce to the right forms in the free electron model, but not in the general spherical band model.)

Now our results have been derived under the assumption that the temperature is much lower than the Debye characteristic temperature. But our results give the correct expression in the case of the spherical energy band and the model of the spherical energy band is ap-

proximately good at high temperatures at least semiquantitatively. Therefore, Eqs. (26), (27) and (28) may be regarded as an interpolation formulae which are valid at all temperatures at least semi-quantitatively. (There is a weak point, however, that these equations do not involve the effect of the Umklapp processes of usual type which are important at high temperatures and considered in I.)

From (26) and (27), it is seen that the temperature dependences of the electrical and thermal conductivities of the anisotropic media are not altered from those of isotropic media. This provides a justification of the usual approximation of spherical band model or the free electron model in the derivation of the temperature dependence of the electrical and thermal conductivities. The ratio of the electrical to thermal conductivities at low temperatures is given by

$$\frac{\sigma T^3}{\kappa_T} = \frac{9e^2}{\pi^4 \kappa^2} \frac{\Theta^2}{q_0^2} \frac{f_2}{f_3}. \quad (35)$$

For the case of the spherical energy surface, the ratio f_2/f_3 becomes $(3\pi^2 n)^{2/3}$ where n is the number density of electrons. Klemens¹⁰⁾ has shown that the experimental values of $\sigma T^3/\kappa_T$ for monovalent metals are generally smaller than the theoretical values calculated by the assumption of the spherical energy band, and especially for noble metals, the experimental values are several times smaller than the theoretical values, and thus he has concluded that the Fermi surface of noble metals touches the zone boundary. These facts may be interpreted from our results as follows.

From (30), the ratio f_2/f_3 is given by

$$\frac{f_2}{f_3} = \int dS / \int \left(\frac{1}{\rho^2} \right) dS$$

Now, in the region near the zone boundary, the Fermi surface may bulge outwards to the boundary, and the mean curvature should become larger than the curvature of the sphere of equal volume. Therefore, the value of the ratio f_2/f_3 would become smaller than the value expected for the spherical energy surface. Especially, if the Fermi surface touches the zone boundary, the absolute values of the principal curvatures $1/\rho_1$ and $1/\rho_2$ (one of which is negative) at the region near the zone boundary become very large, and so the value of the ratio f_2/f_3 would become very smaller than the value for the case of the spherical energy band.

The thermoelectric power of pure metals at low temperatures is given by

$$S = -\frac{\pi^2 \kappa^2 T}{3e} \frac{f_2(df_1/dE) - f_1 f_4}{f_1 f_2}, \quad (37)$$

and, since f_1 and f_2 are positive, the sign of S is determined by the sign of $f_2(df_1/dE) - f_1 f_4$. To calculate df_1/dE , we use the approximation of concentricity shown in Fig. 2, and, in (30), we expand $\partial E/\partial n$ and the surface element dS at the Fermi surface. Then $f_1(E)$ becomes

$$f_1(E) = \frac{1}{3} \int_{E=\zeta} \left[\frac{\partial E}{\partial n} + \left\{ \frac{\partial^2 E}{\partial n^2} \left(\frac{\partial E}{\partial n} \right)^{-1} + 2 \left(\frac{1}{\rho} \right) \right\} (E - \zeta) \right] dS_0,$$

where dS_0 is the surface element on the Fermi surface. Therefore, we have

$$\left(\frac{df_1}{dE} \right)_{E=\zeta} = \frac{1}{3} \int_{E=\zeta} \left\{ \frac{\partial^2 E}{\partial n^2} \left(\frac{\partial E}{\partial n} \right)^{-1} + 2 \left(\frac{1}{\rho} \right) \right\} dS_0, \quad (38)$$

and

$$9 \left(f_2 \frac{df_1}{dE} - f_1 f_4 \right) = \int dS \int \frac{\partial^2 E}{\partial E \partial n} dS + 2 \int dS \left[\left(\frac{1}{\rho} \right) dS - \frac{\partial E}{\partial n} dS \int \frac{\partial^2 E}{(\partial E / \partial n)^2} dS. \quad (39)$$

For the spherical energy band, (29) reduces to

$$2 \int dS \int \frac{1}{k_0} dS = 2(4\pi)^2 k_0^3$$

and thus the thermoelectric power becomes negative as shown in I. Therefore, it must be the anisotropy of the band structure that gives the positive thermoelectric power for the pure noble metals at low temperatures.

For the anisotropic energy band, since the first and the third terms of the right side of (39) are of the same order of magnitude and of opposite signs, if the second term has large negative value, the thermoelectric power would become negative. (For the positive hole model, ρ (=constant) is negative and (39) becomes negative agreeing with the usual results.) Since, at present, the detailed behavior of the band structure is unknown, we can not calculate the right hand side of (39) with necessary accuracy. However, there might be a possibility of positive thermoelectric power if on the certain regions on the Fermi surface the mean curvature $(1/\rho)$ has very large negative value. As Klemens has shown, if the Fermi surface of noble metals touches to the zone boundary, the Fermi surface near the zone boundary must have a saddle type shape ($1/(\rho_1\rho_2)$ is negative), and the absolute value of the negative principal curvature would be larger than the positive principal curvature, and so $(1/\rho)$ would become negative.

However, since our results are only approximate solutions which may be good when the anisotropy is not so remarkable, further investigations must be required to obtain a decisive conclusion.

§ 5. Relation with the Spherical Band Approximation

Our method described in § 3 may be applicable approximately to the lattice scattering at high temperatures and the impurity scattering, if the anisotropy is not so remarkable. Therefore, by comparison of the results in these case with the results obtained in I based on the spherical band approximation, we can clarify the meanings of the parameters α and β appeared in I, where α and β have been defined based on the averaged spherical energy band which, however, have not clearly defined.

For the impurity scattering, the time of relaxation τ exists and it may be regarded approximately to be dependent of the energy of the $\mathbf{k}$ state only³⁾. Therefore, the change of the distribution function due to the impurity scatterings can be written in the form,

$$\left(\frac{\partial f}{\partial t}\right)_i = -\frac{f-f_0}{\tau} = \frac{1}{\tau} \frac{\partial E}{\partial k_x} \frac{\partial f_0}{\partial E} c(\eta). \quad (40)$$

This term gives to the electrical and thermal resistivities additional residual parts

$$\frac{1}{\sigma_i} = \rho_i = \frac{4\pi^3 \hbar^2}{e^2 f_1 \tau} \quad (41)$$

and

$$\frac{1}{\kappa_i} = \frac{12\pi \hbar^2}{\kappa^2 f_1 T \tau} \quad (42)$$

respectively. Eqs. (41) and (42) coincide with more general expressions¹¹⁾

$$\sigma = \frac{e^2}{12\pi^3} \int \frac{\tau v^2 dS}{|\text{grad}_{\mathbf{k}} E|} \quad (43)$$

$$\kappa_T = \frac{\kappa^2 T}{36\pi} \int \frac{\tau v^2 dS}{|\text{grad}_{\mathbf{k}} E|} \quad (44)$$

if we assume that τ depends only on the energy of electrons. If we use the spherical band

approximation, (41) and (42) agree with (28) and (31) in I. If we write (28) and (31) in I in the form

$$\frac{1}{\sigma_i} = \frac{3\pi^2 \hbar^2}{e^2 k_0^2 \alpha \tau}, \quad (45)$$

and

$$\frac{1}{\kappa_i} = \frac{9\hbar^2}{\kappa^2 T k_0^2 \alpha \tau}, \quad (46)$$

and compare (45) and (46) with (41) and (42), we see that the parameter α appeared in I corresponds to

$$\alpha = \left\langle \frac{\partial E}{\partial n} \right\rangle, \quad (47)$$

where $\langle \rangle$ denotes the average on the Fermi surface.

For the thermoelectric power of impure metals, we easily obtain

$$S = -\frac{\pi^2 \kappa^2 T}{3e} \left[\rho_i \left(\frac{1}{f_1} \frac{df_1}{dE} + \frac{1}{\tau} \frac{d\tau}{dE} \right) + \rho_0 \left\{ \left(2 \frac{1}{f_1} \frac{df_1}{dE} - \frac{1}{f_3} \frac{df_3}{dE} \right) + \left(\frac{\Theta}{T} \right)^2 \frac{3}{\pi^2 q_0^2} \left(\frac{f_2(df_1/dE) - f_1 f_4}{f_1 f_3} \right) \right\} \right] \\ \left/ \left[\rho_i + \rho_0 \left\{ 1 + \frac{3}{\pi^2 q_0^2} \left(\frac{\Theta}{T} \right)^2 \frac{f_2}{f_3} \right\} \right] \right., \quad (48)$$

In (48), if we use the spherical band approximation to the term due to the impurity scatterings and the term which survive at high temperatures, we have

$$S = -\frac{\pi^2 \kappa^2 T}{3e} \left[\rho_i \left(\frac{2}{\alpha k_0} + \frac{\beta}{\alpha^2} + \frac{1}{\tau} \frac{d\tau}{dE} \right) + \rho_0 \left\{ \left(\frac{2\beta}{\alpha^2} + \frac{4}{\alpha k_0} \right) + \frac{3}{\pi^2 q_0^2} \left(\frac{\Theta}{T} \right)^2 \left(\frac{f_2(df_1/dE) - f_1 f_4}{f_1 f_3} \right) \right\} \right] \\ \left/ \left[\rho_i + \rho_0 \left\{ 1 + \frac{3}{\pi^2 q_0^2} \left(\frac{\Theta}{T} \right)^2 \frac{f_2}{f_3} \right\} \right] \right., \quad (49)$$

and, therefore, we see that the parameter β appeared in I corresponds to

$$\beta \simeq \left\langle \frac{\partial E}{\partial n} \right\rangle \left\langle \frac{\partial^2 E / \partial n^2}{\partial E / \partial n} \right\rangle. \quad (50)$$

From (47) and (50), the meanings of α and β have become clearer than those given in I. The exact expression of the parameter β in the case of complicated Fermi surface will not be written in such a simple form as (50). However, if we regard β as a phenomenological parameter which has the order of magnitude of the right hand side of (50), the calculations given in I would not lose general validity in the case of rather complicated band structure.

Appendix

Calculation of $\alpha_r^{(n)}$ and d_{rs}

The calculation of $\alpha_r^{(n)}$ is straightforward, and the results are as follows;

$$\alpha_0^{(1)} = -f_1, \quad \alpha_0^{(2)} = -\zeta f_1, \quad \alpha_1^{(1)} = -\frac{\pi^2}{3} \kappa T \frac{df_1}{dE}, \\ \alpha_1^{(2)} = -\frac{\pi^2}{3} \kappa T \left(\zeta \frac{df_1}{dE} + f_1 \right), \quad \alpha_2^{(1)} = -\frac{\pi^2}{3} f_1. \quad (A-1)$$

The calculation of d_{00} and d_{11} is also straightforward, and we have

$$d_{00} = A^{-1} \left(\frac{T}{\Theta} \right)^5 q_0^2 f_3 J_5 \left(\frac{\Theta}{T} \right), \quad (A-2)$$

$$d_{11} = A^{-1} \left(\frac{T}{\Theta} \right)^3 f_2 \left\{ 1 + \frac{\pi^2}{3} q_0^2 \left(\frac{T}{\Theta} \right)^2 \frac{f_3}{f_2} \right\} J_5 \left(\frac{\Theta}{T} \right). \quad (\text{A-3})$$

We have neglected in d_{11} a term which has J_7 , since this term gives numerically only a small contribution to d_{11} and is beyond our approximation.

d_{10} is given by

$$\begin{aligned} d_{10} &= -A^{-1} \left(\frac{T}{\Theta} \right)^3 \int_{-\infty}^{\infty} d\eta \int_{-\Theta/T}^{\Theta/T} dz \int_{\eta=\text{const}} dS \frac{(\partial E / \partial k_x)^2}{(\partial E / \partial n)^2} \\ &\quad \cdot \left\{ \frac{\partial^2 E / \partial n^2}{(\partial E / \partial n)^2} \kappa T z - \left(\frac{1}{\rho^2} \right) \frac{q_0^2}{2} \left(\frac{T}{\Theta} \right)^2 z^2 \right\} \frac{\eta}{(e^\eta + 1)(e^{-\eta} + e^z)} \frac{z^2}{|1 - e^{-z}|} \\ &= A^{-1} \left(\frac{T}{\Theta} \right)^3 \kappa T f_4 J_5 \left(\frac{\Theta}{T} \right) + A^{-1} \left(\frac{T}{\Theta} \right)^5 \frac{q_0^2}{2} \iint \frac{f_3(E) \eta}{(e^\eta + 1)(e^{-\eta} + e^z)} \frac{z^4}{|1 - e^{-z}|} dz d\eta \\ &= A^{-1} \left(\frac{T}{\Theta} \right)^3 \kappa T f_4 J_5 \left(\frac{\Theta}{T} \right) + A^{-1} \left(\frac{T}{\Theta} \right)^5 \frac{\pi^2}{3} \kappa T q_0^2 \frac{df_3}{dE} J_5 \left(\frac{\Theta}{T} \right). \end{aligned} \quad (\text{A-4})$$

Here we have neglected also the term of J_7 arising from the integration which includes $f_3(E)$. d_{01} is given by

$$\begin{aligned} d_{01} &= d_{10} + A^{-1} \left(\frac{T}{\Theta} \right)^3 \iint \left[\frac{(\partial E / \partial k_x)^2}{(\partial E / \partial n)^2} \left\{ 1 + \left(\frac{1}{\rho} \right) \left(\frac{\partial E}{\partial n} \right)^{-1} \kappa T z \right\} dS \right] \frac{-z}{(e^\eta + 1)(e^{-\eta} + e^z)} \frac{z^2 dz d\eta}{|1 - e^{-z}|} \\ &\quad - A^{-1} \left(\frac{T}{\Theta} \right)^5 \frac{q_0^2}{2} \iint \left[\frac{(\partial E / \partial k_x)^2}{(\partial E / \partial n)^2} \left(\frac{1}{\rho^2} \right) dS \right] \frac{-z^3}{(e^\eta + 1)(e^{-\eta} + e^z)} \frac{z^2 dz d\eta}{|1 - e^{-z}|}. \end{aligned} \quad (\text{A-5})$$

The second term of the right side of (A-5) vanishes, if we expand dS as

$$dS = dS_0 \left\{ 1 + 2 \left(\frac{1}{\rho} \right) \left(\frac{\partial E}{\partial n} \right)^{-1} \kappa T \eta \right\},$$

and the third term gives a small term including J_7 which is neglected in our approximation. Thus we have

$$d_{01} = d_{10}, \quad (\text{A-6})$$

from which Onsager's reciprocal relation can be derived easily.

An Order-Disorder Transformation Phenomenon in the $\text{FeTiO}_3\text{-Fe}_2\text{O}_3$ Solid Solution Series

By Yoshikazu ISHIKAWA*

Institute for Solid State Physics, University of Tokyo, Tokyo

(Received May 8, 1958)

The effects of heat treatments on the magnetic properties of the synthesized solid solution $x\text{FeTiO}_3\text{-(1-x)Fe}_2\text{O}_3$ of ilmenite and hematite were examined in detail for compositions x around 0.5. It was confirmed that a transformation from an ordered state (ferrimagnetic one) into a disordered state (antiferromagnetic one) takes place cooperatively at a distinct transition point. This transformation temperature is lowered with decrease in the ilmenite content from 1100°C for $x=0.65$ to 600°C for $x=0.45$. The completely disordered specimens could not be obtained for the composition $x \geq 0.6$ by the quench method while the completely ordered state could not be attained in the specimens with $x \leq 0.5$ because of decrease of the transformation temperature for these specimens and a reduction of the rate of ion diffusion at such low temperatures. The results obtained were discussed by using the Bragg-Williams approximation. It was noted briefly that the reverse thermo-remanent magnetism found in this system is closely related to the order-disorder transformation phenomenon which exists in this system.

§ 1. Introduction

The order-disorder transformation phenomenon which was first observed in a Cu-Au alloy¹⁾ has been found in many substitutional binary alloys and investigations of this phenomenon have been carried out both experimentally and theoretically by many investigators. The results obtained have been reviewed in literatures²⁾.

On the other hand, such a transformation phenomenon has been observed very rarely in ionic compounds. This may be due to the situation that in the ionic compounds a change in the arrangement of cations usually increases the electrostatic energy greatly.

There are many magnetic oxides whose magnetic properties are greatly affected by the heat treatment. For example, in magnesium ferrite, MgFe_2O_4 , which has a nearly inverse spinel structure and has the saturation moment of $1.1 \mu_B$ when prepared by cooling slowly, the intensity of magnetization increases when it is quenched from high temperatures. This phenomenon is interpreted as a result of an increase in the magnesium content on the tetrahedral sites in the quenched specimen. Pauthenet and Bochirol have reported³⁾ that the value of x varies with

temperature according to a Boltzmann distribution law given by Néel⁴⁾:

$$x(1+x)/(1-x)^2 = \exp(-E/T),$$

where E is an energy involved in an interchange of a Mg ion on an octahedral site and a Fe ion on a tetrahedral site and is 1200°K for MgFe_2O_4 . We can see by this equation that the change in the distribution of cations in this specimen does not take place cooperatively because for a cooperative phenomenon E must depend on x .

On the other hand, a change in the distribution of Li ions on the octahedral sites in LiFe_2O_4 ⁵⁾ or a change in the arrangement of holes in FeS_x ⁶⁾ has been reported to take place cooperatively, but detailed investigations of such cooperative phenomena have not yet been made.

We have reported in previous paper that the magnetic properties of the solid solution of FeTiO_3 and Fe_2O_3 : $x\text{FeTiO}_3\text{-(1-x)Fe}_2\text{O}_3$ are greatly affected by the heat treatment. For example, the specimen with x around 0.5 which is feebly ferromagnetic when it is quenched from 1200°C can be changed to strongly ferrimagnetic by an appropriate heat treatment⁷⁾. Such a change in the magnetic properties by the heat treatment makes the magnetic properties of this series very complicated. It is, therefore, necessary to examine

* Present address; Department of Applied Physics, Faculty of Engineering, Tokyo University, Tokyo.

more carefully how these properties are affected by various heat treatments.

In the course of these experiments, we have found the change in the magnetic properties takes place cooperatively having a distinct transition point for the specimens with x around 0.5. As we have expected in the previous papers^{7),8)} that the ferrimagnetism and feeble ferromagnetism in this series are correlated with the crystal symmetries $R\bar{3}$ and $R\bar{3}C$ respectively, this phenomenon may be explained as a kind of order-disorder transformation phenomenon where Ti and Fe ions are distributed at random in the feebly ferromagnetic specimen, while are arranged in order in the ferrimagnetic one. Hence it may be worthwhile to examine whether such a transformation phenomenon in the ionic compound can be explained by the theories which have been successfully applied to the order-disorder transformation phenomena observed in many alloys.

§ 2. Experimental Procedure

In order to investigate the order-disorder transformation phenomenon in the solid solution series, it must be necessary, first of all, to recognize what physical quantity is most affected by the heat treatment. We have reported in the previous paper that the electrical conductivity and Seebeck voltage have little correlation with the change of crystal symmetry⁹⁾. On the other hand, as the order-disorder transformation temperature lies far above the Curie temperature of the specimen and the magnetic susceptibility at such a high temperature was found to be little affected by the heat treatment⁸⁾, the change in the ordering can not be observed directly at the temperature where such a change really occurs even by the magnetic method. Hence we detected the degree of order at a desired temperature of the specimen by measuring the intensity of magnetization at room temperature of the specimen quenched from that temperature where it had been left in thermal equilibrium.

The experiments were carried out by using six specimens having the composition x around 0.5, which had been prepared in advance by the method described in the previous paper^{8)*}.

* This paper will be referred to as I hereafter in this paper.

Each specimen was sealed into a quartz capsule which was carefully evacuated to an approximated oxygen pressure so as not to reduce or oxidize the specimen or not to precipitate the spinel phase during the heat treatment. Then, the specimen was placed in a furnace and after having been annealed at a constant temperature until its equilibrium state it was quenched into water. It was confirmed that it required more than twenty four hours to attain the equilibrium state at low temperatures (400~500°C), only one hour at high temperatures ($>700^\circ\text{C}$). The variation of the intensity of magnetization of the quenched specimen with temperature was measured in a field strength of 8500 Oe in order to find the Curie temperature of the specimen. This procedure can be carried out without disturbing the arrangement of cations because the Curie temperatures of all specimens used in this experiment are below 300°C and a rearrangement of cations can hardly take place at such low temperatures. By repeating the same procedure for the specimen quenched from each temperature on both heating and cooling processes we obtained the variation of the intensity of magnetization at room temperature with the quenching temperature for each specimen. The quenching temperature was limited below 1250°C, above which the oxygen ions might flow into the quartz capsule through its wall.

§ 3. Experimental Results

The results obtained by the above procedure were shown in Figs. 1-6. (a) of these figures show the variation of the magnetization at room temperature with the quenching temperature and (b) the thermomagnetic curves of the specimen when it was quenched from the temperature attached to each curve. In Fig. 1, a case for $x=0.51$ is given, where we found the magnetization at room temperature decreases with the quenching temperature and disappears sharply at 790°C. As we shall show in the latter section the magnetization at room temperature is approximately proportional to the long range order parameter S introduced by Bragg and Williams, hence we can consider this curve indicates the variation of the long range order with temperature. From this figure we can understand that the change in the magnetization or the crystal

Fig. 1 (a). The variation of magnetization at room temperature of a specimen with $x=0.51$ vs. quenching temperature. (b). The thermomagnetic curves of the specimen quenched from temperatures attached to each curve. The magnetization is measured in a field strength of 8500 Oe.

Fig. 2 (a). The variation of magnetization at room temperature of a specimen with $x=0.56$ vs. quenching temperature. (b). The thermomagnetic curves of the specimen quenched from temperature attached to each curve.

symmetry takes place cooperatively at a definite transition temperature. Furthermore we found the magnetizations measured on both heating and cooling processes accord well and no temperature hysteresis was observed

at the critical temperature. It may, therefore, be concluded that this transition is of the second order. We found from Fig. 1(b) that when the specimen was quenched from higher temperatures and hence the magneti-

zation at room temperature was decreased, the Curie temperature was shifted to the low temperature side. Such a tendency has already been reported in I, where we showed only two extreme values in the perfectly ordered and the perfectly disordered states.

In Fig. 2(a) the variation of the magnetization at room temperature of the specimen for $x=0.56$ with the quenching temperature was shown. The magnetizations measured on both heating and cooling processes were also found to accord with one another. This curve is

Fig. 3 (a). The variation of magnetization at room temperature of a specimen with $x=0.61$ vs. quenching temperature. (b). The thermomagnetic curves of the specimen quenched from temperature attached to each curve.

Fig. 4 (a). The variation of magnetization at room temperature of a specimen with $x=0.68$ vs. quenching temperature. (b). The thermomagnetic curves of the specimen quenched from temperature attached to each curve.

very similar to the one found in Fig. 1(a), but the transition temperature is raised up to 890°C in this case. Furthermore it must be noticed in the figure that when the specimen was quenched from a temperature higher than the critical temperature the magnetization at room temperature was rather increased. This strange phenomenon was observed in all specimens with x greater than 0.56. From Fig. 2(b) we find the variation of the Curie temperature with the quenching temperature is similar to the case for $x=0.51$. In Fig. 3(a) a case for $x=0.61$ is shown. We find from the figure the situation is very different from the two former cases. In this case the decrease of magnetization began rather sharply

at 960°C attaining to a minimum value at 1000°C. When the quenching temperature was higher than 1000°C the magnetization at room temperature was increased and the feebly ferromagnetic specimen or perfectly disordered one could not be obtained for this composition. In Fig. 4(a) a case for $x=0.68$ is shown, where we find the decrease in the magnetization at room temperature began to take place at the quenching temperature 1050°C, but the decrease is very small. It must be noticed, as we showed in the figure by an upward arrow, that when the specimen was quenched from 1150°C and the magnetization of the quenched specimen was measured soon after the quenching it took the value

Fig. 5 (a). The variation of magnetization at room temperature of a specimen with $x=0.48$ vs. quenching temperature. (b). The thermomagnetic curves of the specimens quenched from temperatures attached to each curve.

Fig. 6 (a). The variation of magnetization at room temperature of a specimen with $x=0.465$ vs. quenching temperature. (b). The thermomagnetic curves of the specimens quenched from temperatures attached to each curve.

18.6 e.m.u./gr at room temperature, but it was found to be increased up to 20.5 e.m.u./gr after keeping it at room temperature for a day, which means a recovery process can take place even at room temperature for this specimen. The decrease of the Curie temperature with the decrease in the magnetization at room temperature was also observed in both cases of $x=0.61$ and 0.68 as Figs. 3(b) and 4(b) show. It must be noticed in Fig. 3(b) that the thermomagnetic curves of the specimens quenched from 1210°C and 970°C accord well with one another, which suggests that the phenomenon of the reincrease of the magnetization at room temperature above the critical temperature is not due to a different ordering mechanism but is due to a recovery of the ordering during a short period of the quenching which may be longer when the quenching temperature is higher. It is also expected that when the quenching temperature is higher the crystal imperfection is increased in the specimen, which may promote the rate of ordering in the recovery process as has been reported in the case of Cu_3Au alloy^{10,11}. The situation that the short range order might not be destroyed completely at about 1200°C in the specimen of the higher ilmenite content may also contribute to this phenomenon. It was thus found that the disordered state can not be established in the specimens for $x \geq 0.6$.

On the other hand, in cases of $x=0.48$ and $x=0.465$, we can also find the critical temperature as are shown in Figs. 5(a) and 6(a), but the maximum values of the magnetization at room temperature are considerably smaller compared with those of the specimens with $x \geq 0.5$, indicating the perfect ordering can not be established in these specimens at any cost. This situation may be explained by a fact that the transition temperatures were lowered to $700\sim 600^\circ\text{C}$ in these specimens. As the rate of diffusion of cations is greatly reduced when the annealing temperature is lowered below 500°C , the establishment of the ordered state becomes very difficult in these specimens. By carefully comparing Fig. 1(a) with Fig. 2(a), we may expect even in the specimen with $x=0.51$ the perfect ordering is not established. We have thus understood the situation that when the content of Fe_2O_3 exceeds 50 molpercent the saturation value

of magnetization of the annealed specimen decreases sharply as has been reported in I. In every cases the magnetizations measured on both heating and cooling processes accord well each other and so the transition is expected to be that of the second order.

Through these results we have confirmed

Fig. 7. The phase diagram of the $\text{FeTiO}_3\text{-Fe}_2\text{O}_3$ system. Cross marks indicate transition points determined experimentally, while a broken line is calculated by using the Bragg-Williams approximation.

Fig. 8. The variation of the Curie temperature with the magnetization at room temperature or with the long range order parameter. Numerals attached to each curve indicate the FeTiO_3 mol. per cent.

that though the magnetization of all specimens used in this experiment is affected by the heat treatment, the transition from the perfectly ordered state to the perfectly disordered state is observed only in the specimen with $x=0.56$.

The critical temperatures of these specimens thus obtained are plotted in Fig. 7 against the composition. The liquidus-solidus lines drawn in the figure were estimated from the melting points of FeTiO_3 and Fe_2O_3 . We can estimate from the figure that the critical temperature of the specimen with $x=0.4$ is about 550°C , hence the increase in the magnetization by annealing can not be expected in the specimen with x less than 0.4. In Fig. 8 we showed the variation of the Curie temperature with the magnetization at room temperature or with the degree of long range order. As this figure shows all curves have the same characteristics that the rate of decrease in the Curie temperature is large for a slight decrease in the degree of order from the perfectly ordered state but its rate is decreased for a further decrease in the degree of order.

§ 4. Discussion

We have investigated in the above section the effect of the heat treatment on the magnetic properties and expected that the transformation from the ferrimagnetic state to the antiferromagnetic state corresponds to the transformation of the arrangement of cations from the ordered state to the disordered state. In order to confirm this expectation a neutron diffraction analysis was conducted by G. Shirane *et al* in both quenched and annealed specimens of $x=0.5$ and found that diffraction lines indexed by (100) and (111) were intensified greatly in the annealed specimen¹²⁾. This fact indicates that the ordering of Ti and Fe ions was established by the annealing process, while patterns in the quenched specimen can be interpreted by assuming the disordering of Fe and Ti ions. We have, thus, confirmed that the phenomenon which we observed in the solid solution is a kind of order-disorder transformation, hence in this section we shall try to discuss this phenomenon by using the Bragg-Williams approximation.

In order to simplify the problem we neglect the difference between Fe^{+2} and Fe^{+3} ions. Such a simplification may be permissible be-

cause the interchange of the positions of Fe^{+2} and Fe^{+3} ions can take place merely through the electron transfer and therefore the required energy for an interchange of Fe^{+2} and Fe^{+3} ions is negligible compared with that of Ti and Fe ions. Hence the order-disorder transformation phenomenon in the solid solution $x\text{FeTiO}_3 \cdot (1-x)\text{Fe}_2\text{O}_3$ is reduced to that in a binary alloy of $\text{Fe}_{2-x}\text{Ti}_x$. Since, as we have showed in I, the cation sites can be divided into four sublattices A_1 , A_2 , B_1 and B_2 in the rhombohedral structure, two types of superstructures among these four sublattices are possible in the Fe-Ti system. One is at FeTi and the other at Fe_3Ti . The former corresponds to pure ilmenite and the latter to the solid solution of $0.5\text{FeTiO}_3 \cdot 0.5\text{Fe}_2\text{O}_3$. Though the former is really observed in pure ilmenite¹³⁾, the latter is not expected to exist because the critical temperature does not show any anomalous change for x around 0.5 in Fig. 7. Accordingly, we can neglect the difference between A_1 and A_2 or B_1 and B_2 in this system as we did in I. Then, the problem is reduced to a case where two kinds of cations Fe and Ti are distributed among two sublattices A and B. Let the total number of cations in one mol be, N . If f_{Fe} denotes the fraction of Fe ions, $f_{\text{Ti}}=1-f_{\text{Fe}}$ denotes that of Ti ions. As the fraction of A sites r_A does not generally agree with f_{Fe} in this system we put $f_{\text{Fe}}=r_A+\delta$, where $\delta \geq 0$ in our case. Accordingly f_{Ti} is given by $f_{\text{Ti}}=1-r_A-\delta$. Next we shall describe the fraction of A sites occupied by Fe ions by P_A which takes the value 1 in the perfectly ordered state and $r_A+\delta$ in the disordered state. We shall define the long range order parameter S as

$$S = \frac{P_A - r_A - \delta}{1 - r_A} \quad (1)$$

in this paper which takes the maximum value

$$S_m = 1 - \frac{\delta}{1 - r_A} \quad (2)$$

in the perfectly ordered state and is zero in the disordered state. The numbers of Fe ions on A sites $[\text{Fe}/A]$ and on B sites $[\text{Fe}/B]$ are expressed by using the above quantities as

$$[\text{Fe}/A] = P_A r_A N,$$

$$[\text{Fe}/B] = (r_A + \delta)N - [\text{Fe}/A] = (r_A + \delta - P_A r_A)N. \quad (3)$$

If we assume the magnetic moments of one kind of sublattice are aligned in the same direction, coupling antiferromagnetically with those of another kind of sublattice, the resultant magnetization per mol J_s at 0°K is given by

$$J_s = J_{\text{Fe}}[\text{Fe}/\text{A}] - J_{\text{Fe}}[\text{Fe}/\text{B}] = J_{\text{Fe}}N(2P_A r_A - r_A - \delta) \\ = J_{\text{Fe}}N[2(1-r_A)r_A S + (2r_A - 1)(r_A + \delta)], \quad (4)$$

where J_{Fe} is the magnetic moment of a Fe ion. In case of $\text{Fe}_{2-x}\text{Ti}_x$ Eq. (4) is reduced to

$$J_s = J_{\text{Fe}} S, \quad (5)$$

since $N = 2N_a$, $r_A = \frac{1}{2}$ and $\delta = \frac{1}{2}(1-x)$, where N_a is the Avogadro number. This equation means that the resultant magnetization at 0°K is proportional to the long range order parameter S . In the actual case, the measurement is carried out at room temperature and the magnetization on the A sublattice is expected not to be saturated. The ordinates in Figs. 1-6(a), therefore, are not necessarily proportional to S in a strict meaning, but we can approximately say that these curves express the change in the degree of order with the temperature. In the perfectly ordered state, J_s is given as

$$J_s = J_{\text{Fe}}[1 - (1-x)] = xJ_{\text{Fe}} = 4x. \quad (6)$$

The long range order parameter S can be calculated by the Bragg-Williams method and is found to be

$$S = 1 - 2 \frac{\{(e^y + \delta^2(e^y - 1)^2)\}^{1/2} - 1}{e^y - 1} \quad (7)$$

in which $y = V/RT$ and the ordering energy V is assume to be

$$V = V_0 S \quad (8)$$

following the Bragg-Williams assumption¹⁴⁾. The transition temperature T_c obtained from Eqs. (7) and (8) is

$$T_c = (V_0/4K)(1 - 4\delta^2) = (V_0/4K)x(2-x). \quad (9)$$

In Fig. 9 we showed by the solid line the behavior of $S(T)$ obtained from Eqs. (7) and (8) by a graphical method in case of $x = 0.56$ for which composition the most typical order-disorder transformation phenomenon could be observed. The broken line in the figure indicated the experimental results for $x = 0.56$. Considering the roughness of the theory and the simplification made in the calculation, the agreement is rather well and the theoretical curve would approach to the experimental

values if the short range order were taken into account. The variation of critical temperature with the composition x was also calculated from Eq. (9) by assuming $(V_0/4K) = 1300^\circ\text{K}$ and the result was drawn by the broken line in Fig. 7. We found from the

Fig. 9. The dependence of the long range order parameter $S(T)$ calculated in a case of $x = 0.56$ upon temperature. Hollow marks indicate the experimental results.

figure our theory explains well a tendency of the decrease of critical temperature with the composition. The deviation of the theoretical curve from the experimental result may be due to an effect of the short range order. We have thus found the order-disorder transformation phenomenon observed in the $\text{FeTiO}_3\text{-Fe}_2\text{O}_3$ solid solution series could be fairly well explained by the Bragg-Williams approximation.

On the other hand, the decrease in the Curie temperature with the decrease in the degree of order must be attributed to the situation that the number of pairs between Fe^{+2} and Fe^{+3} ions decreases and that between Fe^{+2} and Fe^{+2} ions increase with the decrease in the degree of order as we discussed in detail in I. It is, therefore, very difficult to obtain the dependence of the Curie temperature on the long range order parameter S because for this purpose we must distinguish Fe^{+2} from Fe^{+3} which difference has been neglected in our theory.

§ 5. The Reverse Thermo-Remanent Magnetism

The queer phenomenon of the reverse thermo-remanent magnetism* or shortly reverse TRM, was first discovered for certain ferromagnetic oxide minerals containing the ilmenite-hematite solid solution by T. Nagata S. Uyeda and S. Akimoto¹⁶⁾. Uyeda has conducted a series of detailed studies on the mechanism of this phenomenon^{16), 17)}. Main results of his study will be summarized as follows:

(1) The phenomenon of reverse TRM, being found not only in natural but also in synthesized solid solution series $x\text{FeTiO}_3-(1-x)\text{Fe}_2\text{O}_3$, is an intrinsic property of the solid solution series.

(2) Among the solid solution members, only

Fig. 10. The intensity of thermo-remanent magnetization at room temperature vs. composition: TRM plotted are the total TRM produced by field cooling in $H=2.0$ Oe.

○ Specimens quenched from 1200°C .

× Onnealed specimens.

(after Uyeda¹⁷⁾)

* The reverse TRM is a phenomenon that the residual magnetization which a ferromagnetic specimen acquires when it is cooled through the Curie point in a magnetic field is oppositely directed to that of the applied field.

those with $0.7 > x \geq 0.45$ show the reverse TRM whereas those with different x values show only normally directed TRM as is shown in Fig. 10: the reverse TRM is a peculiar property of the specimens which show the order-disorder transformation dealt with in the present paper.

(3) As for the specimens showing the order-disorder transition, the TRM is normally directed in the disordered state and the reverse TRM develops with the increase of the degree of order. The reverse TRM seems to be preserved in the specimen which have seemingly been attained to the completely ordered state by prolonged heat treatment.

(4) When the composition and the degree of order of a specimen is properly chosen, the reverse TRM occurs even when the magnetic field applied during cooling is as intense as 2×10^4 Oe. Consequently, the origin of the phenomenon is considered to be related with a superexchange interaction and not with macroscopic magneto-static one, such as demagnetizing field.

Uyeda's study has further indicated the existence of weakly ferromagnetic second phase in the specimen having the reverse TRM and the Curie point of the second phase should be higher by $30 \sim 50^\circ\text{C}$ than that of the bulk. Based upon these results, he considered the origin of the phenomenon as follows¹⁷⁾. In the specimens with $0.70 > x \geq 0.45$ of $x\text{FeTiO}_3-(1-x)\text{Fe}_2\text{O}_3$, a parasitically ferromagnetic disordered phase (A-phase) coexists with a ferrimagnetic ordered phase (B-phase), where $T_{cA} > T_{cB}$, the boundaries between them being in a good registry. The spins in the two phase are coupled in a way that their spontaneous magnetizations (J_s) are directed antiparallelly by some unknown mechanism related to the superexchange force over their boundaries. If such is the case, when the specimen undergoes a field cooling from above T_{cA} , the spins of the parasitically ferromagnetic phase are aligned in the direction of the field first, and then the spins of the ferrimagnetic phase are directed reversely. In order to explain the fact that the reverse TRM property is preserved even after the ordering has apparently completed, Uyeda pointed out that it would be necessary to assume some mechanism of "fossilization" of the disordered phase in the ordered matrix. However, ac-

cording to our study reported in this paper, the Curie point was found to rise considerably with the increase of the degree of order. Therefore, it seems unlikely that the second phase (A-phase) is the residual part left disordered during the process of formation of the order. We should rather like to assume that the second phase (A-phase) may be something related with the surface structure of the ordered domain which develops in the disordered matrix. One expectation is that the A phase may be a ferrimagnetic thin layer on the surface of the ordered domain, whose composition and Curie point are slightly different from those within the domain. The existence of such a thin layer has ordinarily been expected in the development of the ordered domain¹⁸⁾. By such an assumption for A-phase, we can interpret more reasonably the experimental fact that the reverse TRM is preserved even in the completely ordered specimen, because such a surface structure of the domain can be left undisappeared on the boundary of the domain even after these domains come to contact closely with each other.

As a concluding remark of this section we would like to note that the detailed investigation of the reverse TRM will give us some light on the minute structure of the ordered domain in the process of the formation of order in these oxide specimens. A further study of the detailed mechanism of the reverse TRM is now under progress in cooperation with S. Uyeda.

Acknowledgement

The author wishes to express his hearty thanks to Prof. Shozo Sawada for his kind encouragement and guidance throughout this experiment. His thanks are also due to Dr. Akimoto for his X-ray analysis and Dr G. Shi-

rane for his neutron analysis. The section of the reverse TRM is entirely indebted to Dr. S. Uyeda.

Diffusion of Cadmium into Single Crystals of Copper*

Tokutaro HIRONE, Nobuhiko KUNITOMI,** Masanobu SAKAMOTO**
and Hideo YAMAKI***

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Received May 9, 1958)

The diffusivity of cadmium into single crystals of copper has been measured in the temperature range from 725°C to 950°C using radioactive isotope Cd^{115} as a tracer. The results indicate that $D_0 = 0.935 \text{ cm}^2/\text{sec}$ and $H = 45,700 \text{ cal/mol}$. These values are compared with the corresponding values for the diffusion of zinc into copper in order to investigate the effect of the difference in atomic radii.

§ 1 Introduction

In order to study the effect of excess valency on the activation energy of solute diffusion, the diffusion coefficients of several kinds of atoms into monovalent noble metals have been investigated experimentally and theoretically.^{1), 2), 3), 4), 5), 6)} However, the effect of the atomic size in the diffusion process has not yet been investigated sufficiently. Although this effect has been considered to contribute to the activation energy of the diffusion,^{7), 8)} the experimental evidences have revealed less effect than expected.^{9), 10)}

Since cadmium and zinc have different ionic radii and the same valence the comparison of the diffusivities of both atoms will give an information on the effect of atomic size. The purpose of the present paper is to measure the activation energy of cadmium diffusion into copper single crystals and to compare it with that of zinc which has been obtained by Hino, Tomizuka and Wert.¹¹⁾

§ 2 Experiment

Single crystals of copper (99.98% pure) were grown by the Bridgeman technique. The specimens were formed from these crystals into drum shaped piecess. In order to obtain the specimen possibly free from the mosaic structure, the diffusion surface of the crystals was carefully cut with a jeweler's saw, ground with fine emery, whetted with a stone and

etched carefully with dilute HNO_3 solution. The estimated thickness of the plated layers ranged below 200Å.

The specimens were then placed in pairs with active surfaces together, in quartz tube filled with argon gas of about a half atmospheric pressure at room temperature. In some specimens which were annealed near melting point, a thin mica plate was used as the separator between two active surfaces in order to avoid the cohesion of both crystals. The temperature control was kept within $\pm 2^\circ\text{C}$ for every diffusion anneal.

After the diffusion anneal, the side surface layer of the specimen was removed by the Boley watchmaker's lathe to eliminate the effect of surface diffusion. The sections, 0.003 cm to 0.010 cm thick, were then removed by using this precision lathe, and the activity of each section was determined with a thin mica end-window Geiger-Müller counter tube in a standard scaling unit. Each cut was weighed to check their thickness and compared with the value obtained from the reading of the gauge. For the counting, two methods were actually used; the first was to measure the sample in a circular dish of the same geometry and the second was to measure by solving the sample in dilute HNO_3 solution in circular metaaclyle vessel. In our case, the accuracy of the counting was almost unchanged for two cases except less counting efficiency for the latter.

§ 3 Results

Diffusion runs were made at temperature in the range from 950°C to 725°C for periods ranging from 3 hours to slightly more than 4 days. As is shown in Fig. 1, a linear curve

* This work is supported partly by the Grant-in-Aid for the Scientific Research from the Ministry of Education.

*** Now at Hitachi Research Institute, Hitachi Co., Hitachi, Ibaragi.

was obtained for every sample, when the logarithm of the concentration of radioactive cadmium was plotted against the square of the penetration distance indicating a little effect of imperfections in the crystals. The linear lines in this figure fitted for the meas-

Fig. 1. Penetration curves for diffusion of cadmium into single crystals of copper.

ured points were obtained by the aid of the least square method, which allows the diffusion coefficient to be determined directly.

The Table I summarizes the results of individual samples and Fig. 2 gives the loga-

Table I. Diffusion Data of Cadmium into Copper

Curve	Temperature (deg. C)	Time (sec)	Diffusion Coeff. (cm ² /sec)
1	950	9.87×10^3	8.74×10^{-11}
2	900	9.90×10^3	1.46×10^{-10}
3	850	7.56×10^4	2.88×10^{-10}
4	825	6.50×10^4	5.19×10^{-10}
5	800	8.64×10^4	9.51×10^{-10}
6	775	8.84×10^4	1.43×10^{-9}
7	750	8.64×10^4	2.45×10^{-9}
8	725	2.89×10^5	6.12×10^{-9}

rithm of diffusion coefficient as a function of the reciprocal absolute temperature. It was found that the measured values were expressed by the Arrhenius equation $D = D_0 \exp(-H/RT)$. And the frequency factor D_0 and the activation enthalpy H were calculated by means of the least square method.

The values thus calculated are

$$D^0 = 0.935 \pm 0.271 \text{ cm}^2/\text{sec},$$

$$H = 45,700 \pm 900 \text{ cal/mol}.$$

§ 4 Discussion

Since the primary purpose of this work is to investigate the effect of atomic size of the solute atom, it is interesting to compare the obtained results with those for zinc into copper and with the theoretical value. The diffusion of zinc into single crystals of copper has been measured by Hino and others¹¹⁾ and their results are represented by

$$D_0 = 0.34 \text{ cm}^2/\text{sec},$$

and

$$H = 45,600 \text{ cal/mol}.$$

It should be noticed by comparing their results with ours that the activation enthalpy H is nearly the same for both cases, while the frequency factor is a little larger in our case.

From a theoretical consideration some difference of the activation enthalpy is expected due to the difference of ionic radii of zinc and cadmium. Firstly, it should have an influence upon the coulomb contribution to the formation vacancy. According to Blatt,¹²⁾ the redistribution of screened electrons near the impure

Fig. 2. Diffusion coefficients plotted as $\log D$ versus $1/T$.

atom with positive excess valency should cause the larger formation energy of vacancy at the neighboring site of a larger impure atom, since the apparent excess valency becomes smaller than that of smaller impure atom. The more accurate theory of Fujiwara,¹³⁾ in which the exchange interaction of the core electrons has been taken into account, also indicates the less screening effect of cadmium atom than zinc in copper. This effect should cause the larger formation enthalpy of vacancy for cadmium than for zinc. Secondly, the migration enthalpy of the impure atom also increases in the case of cadmium diffusion because it has larger ionic radius. Therefore, the theoretical consideration should result the larger activation enthalpy of cadmium diffusion than that of zinc diffusion in any case. Thus the theoretical expectation contradicts with the experimental results of the present authors and Sawatzky.

However, these conclusions are very tentative and more work should be carried out

for the measurement of the diffusion of solute atoms which have different atomic size and the same atomic valence.

Diffusion of Cobalt into Iron-Cobalt Alloy**

Tokutaro HIRONE, Nobuhiko KUNITOMI* and Masanobu SAKAMOTO*

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Received May 9, 1958)

The diffusivities of Co⁶⁰ into 50-50 atomic percent iron-cobalt alloy were measured by means of the lathe sectioning method for the temperature range including f.c.c. to b.c.c. phase transformation. The experimental values were expressed by

$$D = 1.1 \times 10^{-4} \exp(-41800/RT) \quad \text{cm}^2/\text{sec} \quad \text{for f.c.c. structure,}$$

$$D = 2.6 \times 10^{-6} \exp(-27400/RT) \quad \text{cm}^2/\text{sec} \quad \text{for b.c.c. structure.}$$

The activation energies for diffusion in the b.c.c. and f.c.c. lattices were compared with the theoretical values calculated by the approximation of the closed shell repulsion with the Born-Mayer potential. And it is concluded that the vacancy mechanism is responsible for the diffusion in the body centered cubic metal in the same manner as in the face centered cubic metal.

§1. Introduction

The diffusion coefficient in solid solution

* Now at Japan Atomic Energy Research Institute, Tokai-mura, Ibaragi.

** This research was supported in part by Grant in Aid for Scientific Research by the Ministry of Education.

alloy is affected not only by the physical character of each constituent atom but also by the lattice structure of the alloy. Among these, the effect of the physical character of each atom, such as the atomic size or the atomic valence, has been investigated by

many researchers.^{1),2),3)} Few studies, however, have been carried out on the effect of lattice structure.⁴⁾

It has been considered in the crystal lattices of usual metals and alloys that the vacancy plays an important role for atomic diffusion.⁵⁾ Especially in metals with the face centered cubic lattice, such as in the case of monovalent noble metals, it has been definitely shown from the observation of Kirkendall effect⁶⁾ and the theoretical consideration⁷⁾ based on the accurate results obtained by the tracer method that the vacancy migration is most predominant.

In the body centred cubic lattice, on the other hand, the both interstitial and vacancy mechanisms are considered to be approvable, although the ring diffusion process proposed by Zener⁸⁾ and Le Claire⁹⁾ is disproved by the recent observation of Kirkendall effect.¹⁰⁾

The purpose of this paper is to determine the mechanism of diffusion in the body centered cubic lattice by measuring the change of activation energy during b.c.c. to f.c.c. phase transformation, and by comparing the results observed with the corresponding values expected theoretically. Based on this idea, the specimen material should have a lattice transformation from the body centered cubic lattice to the face centered cubic lattice at an appropriate temperature. Fortunately, the iron-cobalt 50-50 atomic percent alloy has a phase transformation of the required type f.c.c. to b.c.c., at about 980°C and forms an ordered structure of the Cs-Cl type below 760°C, and satisfied the condition mentioned above.

§ 2. Experimental Method

Purity 99 percent iron and purity 98 percent cobalt were cast into cylinders of 15 mm diameter by the vacuum melting method. After forging, they were cut and machined into the drum-shaped specimens, 10 mm in diameter and about 20 mm in length. One face of each specimen was polished mechanically and electroplated Co⁶⁰ for about 10 Å thickness. The plated specimens were sealed off in quartz tubes in which argon gas was filled, and placed in a furnace for diffusion anneals. The temperature was held constant within limits of $\pm 2^\circ\text{C}$ over the time of diffusion anneals which ranged from several hours to

three months, depending on the temperature, covering the range 840°C–1250°C.

The measurement was performed by means of the lathe sectioning method which was concluded to be most accurate to determine the diffusion coefficient by using the radioactive isotope.¹¹⁾ After the diffusion annealing, the sectioning, was done on the Boley's precision lathe. In order to eliminate the effect of surface diffusion, a thickness of approximately $6(Dt)^{1/2}$ was removed from the side before sectioning where D is the expected diffusion coefficient and t the time of anneal. In sectioning, the thickness of each cut varied from 1/100 mm to 5/100 mm, and the depth of penetration of each cut was measured by a dial gauge and corrected by means of the weighing of all cuts. The material from each cut was placed under the Geiger-Müller counter tube upon the same geometrical conditions to determine the amount of radioactive cobalt.

In the case of volume diffusion the specific activity c which depends linearly on the Co⁶⁰ concentration of each cut falls off exponentially with the square of the penetration depth x . That is

$$\ln c = -x^2/4Dt + \text{const.} \quad (1)$$

where D is the diffusion coefficient and t is the time of diffusion anneal.

§ 3. Experimental Results

The diffusion measurements were performed at the different ten temperatures over the range 840°C–1250°C. Results plotted in Fig. 1 show that the specific activity of each cut decreases exponentially with the square of penetration depth. This fact indicates that there is no observable effect of the grain boundary or surface diffusion. According to Eq. (1), the diffusion coefficients corresponding to the temperatures of anneal were calculated from the penetration curves with the aid of the least square method. In Fig. 2, the logarithms of the diffusion coefficients thus calculated are plotted against the reciprocal of the absolute temperature.

The diffusion coefficients for five temperatures over the range of 1000°C–1250°C where the specimen has the face centered cubic lattice and those for three temperatures over the range 840°C–925°C where it has the body

centered cubic lattice exhibit to satisfy the Arrhenius equation, respectively. The value at 950°C is anomalous since its diffusion was

carried out near the transition temperature. By means of the least square calculations, the temperature dependence of the diffusion coefficient in both structures is given by

$$D = 1.1 \times 10^{-4} \exp(-41800/RT) \quad \text{cm}^2/\text{sec} \quad \text{in f.c.c.}$$

$$D = 2.6 \times 10^{-8} \exp(-27400/RT) \quad \text{cm}^2/\text{sec} \quad \text{in b.c.c.}$$

where R is the gas constant and T is the absolute temperature. The probable errors of the activation energy and frequency factor are determined by the statistical analysis to be $\pm 4\%$, $\pm 70\%$ in the face centered cubic lattice and $\pm 3\%$, $\pm 40\%$ in the body centered cubic lattice, respectively.

Comparing both equations with each other, we find that the activation energy for diffusion in the body centered cubic lattice is by about 14.4 kcal/mol smaller than that in the face centered cubic lattice.

In recent years, Gerstricken and Dekhtyar reported very large values of the diffusion coefficients which was determined by the absorption method for the temperatures corresponding to the face centered cubic region of the same alloy.¹²⁾ This difference of diffusion coefficients is supposed to be due to the inevitable experimental inaccuracy of the absorption method.

§ 4. Discussion

It has been concluded from the observation of Kirkendall effect in the face centred cubic and body centered cubic metals that the diffusion mechanism in both lattices is attributed to the movement of lattice imperfections. There are, however, two fundamental mechanisms of atomic diffusion with lattice imperfections, namely diffusion by means of interstitial atom and of vacancy. The purpose of the following calculation is to determine the preferred mechanism in the body centered cubic structure. The activation energy for diffusion is mainly influenced by the cohesive character of metals which is consisted of two main factors, namely the coulomb and exchange interaction. Since the coulomb interaction is not appreciably affected by the change of the interatomic distance and it is more difficult to estimate theoretically, in this case the computation of activation energy has been restricted within the repulsion of closed shells.

Fig. 1. Penetration curves for the diffusion of cobalt into iron-cobalt alloy.

Fig. 2. Diffusion coefficients plotted as $\log D$ versus $1/T$.

The constants in this potential have been generally determined by the elastic moduli, but those for the iron-cobalt alloy have not yet been measured exactly. Therefore we employed the values derived by Huntington for copper¹³⁾ and corrected them by replacing the interatomic distances in the iron-cobalt alloy for each structure. The differences of atomic number among iron, cobalt and copper is very small and those have the atomic radii of the same order of magnitude. Hence it may not introduce any great error even if the constants for copper are used instead of those for iron and cobalt in Born-Mayer's potential. The expressions of potentials for this calculation are

$E_r=0.038 \exp 13.6(r_0-r/r_0)$ e.v. in f.c.c.
 $E_r=0.038 \exp 10.8(r_0-r/r_0)$ e.v. in b.c.c.

In the following paragraphs, the results of calculation for the differences of the free energies between the normal and saddle point configurations for the two processes will be given by using the above formulas as the repulsive force. And these configurations for the two diffusion mechanisms and the two lattice structures are shown in Fig. 3.

Fig. 3. Configurations involved in the vacancy and interstitial mechanism of diffusion. ● denotes an atom at an ordinary lattice site. ○ denotes vacancy. ⊕ denotes atom at a saddle point of migration.

1) Vacancy case

In Fig. 3a, the saddle configurations of vacancy mechanism for the face centered cubic and body centered cubic lattices are shown. In these configurations two atoms are taken off from adjointed positions in the

metallic lattice leaving two vacancies after them. And then one atom is placed on the saddle point which is the middle point between the two vacancies. In the case of the face centered cubic lattice, one of the atoms which are taken off from the interior, is put on the surface with a net decrease of 17 repulsive bonds and the other atom is placed at the saddle point which has the four nearest neighbour atoms. These four atoms are mutually adjacent and displaced to the both vacancies in order to make the repulsive energy minimum. Similarly in the case of body centered cubic lattice 11 ordinary repulsions decrease and 4 new bonds take places between the diffusing atom and its nearest neighbours which are displaced so as to minimize the repulsive energy.

2) Interstitial case

Fig. 3b shows the saddle point configurations of the interstitial mechanisms for the face centered cubic and body centered cubic lattices respectively. In both cases, one atom is taken

Experiment	1.74	1.15

from the surface and another atom from ordinary lattice point which leaves a vacancy in the interior. These two atoms are placed on the saddle points which are on either side of the vacancy. In the face centered cubic

lattice, therefore, the calculation is performed under the conditions that on the surface 6 ordinary bonds are broken and on saddle points 8 atoms are displaced. For the body centered cubic lattice, in the same way, the processes contain 4 ordinary bonds broken and 8 atoms displaced at the saddle configuration. Results of the calculations of the activation energies due to these mechanisms mentioned here are shown in the table II with the experimental results.

The calculated values indicate that the activation energy in the body centered cubic lattice is much smaller than that in the face centered cubic lattice and this behavior is in qualitative agreement with that observed. Since the above computation does not include the electronic contribution for the activation energy, the calculated values are expected to show smaller values than those in which the electronic contribution is taken into account. In fact the calculated values are greater than those observed, therefore it is to be concluded that the interstitial mechanism of diffusion is unreasonable for both lattices.

One of the remarkable results of the present experiment is the very small frequency factor compared with that observed in the usual self-diffusion experiment. For example, the frequency factor D_0 for copper self-diffusion is $0.47 \text{ cm}^2/\text{sec}$, while the present D_0 is $1.1 \times 10^{-4} \text{ cm}^2/\text{sec}$ in the face centered cubic lattice and $2.6 \times 10^{-6} \text{ cm}^2/\text{sec}$ in the body centered cubic lattice.

As well known, D_0 is expressed by

$$D_0 = \nu a^2 \gamma \exp(\Delta S/R) \text{ cm}^2/\text{sec}.$$

Where ν is the lattice vibrational frequency, a is the lattice parameter, γ is a geometrical parameter determined by the lattice structure and ΔS is the entropy of activation. According to the theoretical and experimental works published previously, the value of D_0 is small

in the grain-boundary diffusion, because the restricted diffusion path decreases the entropy of activation. And also for the case of iron-cobalt alloy it seems to be probably that the diffusion path of cobalt are restricted by the kind of neighbouring atoms in the disordered distribution of iron and cobalt atoms.

The iron-cobalt alloy with the composition of 50-50 atomic percent shows the ordered structure below 750°C . Experiments to measure the activation energy and frequency factor of diffusion in the ordered structure will be obviously interesting in the consideration of ordering and diffusion mechanisms. But, since it must be performed in relatively low temperature range, there will be a number of experimental difficulties, e.g., the effect of grain-boundary diffusion and the extremely long period of diffusions anneal which is necessary because of the decreasing of the diffusion coefficients.

Diffusion of Cobalt into Single Crystals of Copper**

By Masanobu SAKAMOTO*

*Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai*

(Received May 9, 1958)

The measurements of diffusion coefficient of cobalt into copper have been carried out in the temperature range from 950°C to 700°C using Co^{60} as tracer. The result indicates that the diffusion coefficient is given by the equation $D=5.7 \exp(-55200/RT) \text{ cm}^2/\text{sec}$ and, therefore, that the activation energy is appreciably larger than that of copper self-diffusion. From this experiment it has been definitely shown that, for the negative value of excess valency Z , the effect of screening on the solute diffusion in metals plays an effective role in the same manner as the effect observed for the positive value of Z .

§ 1. Introduction

The diffusion experiments of cadmium, indium, tin and antimony into single crystals of silver^{1),2)} have indicated that the activation energy for diffusion decreases with increasing excess valency Z , which is the difference of valence electrons between solute and solvent atoms. This fact has been successfully interpreted by Lazarus' theory³⁾ which is based upon Thomas-Fermi approximation on the screening potential around impurity atoms. After that, Alfred and March⁴⁾ have developed an improved theory in which they used corrected forms of screening potential. For positive values of Z , these theories have been proved to be fairly reasonable because the calculated values are in agreement with the experimental results, mentioned above.

On the other hand, for negative values of Z , experiments to examine the theory have not yet been performed. According to these theories, it will or may be expected that the activation energy has to be larger for the impurity atom diffusion with the negative value of Z than that of self-diffusion, in contrast with the prediction that the diffusion is accelerated by the local stress⁵⁾. The present report aims to be compared with the result for self-diffusion in copper and to confirm theoretical values of activation energy.

§ 2. Experimental Results

Cylindrical single crystals of copper were

* Now at Japan Atomic Energy Research Institute, Tokaimura, Ibaragi.

** This work is supported partly by the Grant in Aid for the Scientific Research from the Ministry of Education.

prepared by Bridgeman method, cut and machined to form drum-shaped specimens. The specimens were electro-plated with the layer of cobalt-60 of about 20Å thickness from CoCl_2 solution, sealed off in quartz tube with argon gas, and annealed in the furnace in which temperature was held constant to within $\pm 2^\circ\text{C}$, for periods of several hours to 20 days. Specimens which were annealed were sectioned on a precession lathe and analyzed by counting technique in the preceding paper⁶⁾.

Six diffusion runs were performed over the temperature range from 950°C to 700°C. The

Fig. 1.

penetration curves for all specimens are shown in Fig. 1 which indicate a strict proportionality between the logarithm of the specific activity and the square of the penetration depth. The logarithms of the diffusion coefficients, calculated from these data, are plotted against the reciprocal of the absolute temperature in Fig. 2 and a summary of the

Fig. 2. Diffusion coefficients plotted as $\log D$ versus $1/T$.

Table I. Diffusion of cobalt into copper.

Curve	Unit of (depth) ² (cm) ²	Temperature (deg C)	Time (sec)	Diffusion coeff. D (cm ² /sec.)
1	4.55×10^{-6}	950	7.20×10^4	7.05×10^{-10}
2	2.27×10^{-6}	900	4.14×10^4	3.42×10^{-10}
3	2.27×10^{-6}	860	4.32×10^5	1.42×10^{-10}
4	1.71×10^{-6}	800	2.43×10^5	3.88×10^{-11}
5	1.71×10^{-6}	750	6.62×10^5	9.27×10^{-12}
6	1.71×10^{-6}	700	1.90×10^6	2.31×10^{-12}

data are shown in Table I. The straight line obtained by a least-square method is given by the equation

$$D = 5.7 \exp(-55200/RT) \text{ cm}^2/\text{sec.}$$

Statistically estimated errors are $\pm 2\%$ for

activation energy and $\pm 6\%$ for frequency factor.

§ 3. Discussion

It is interesting to compare the activation energies calculated by Lazarus, Alfred and March substituting the value $Z = -2$ for cobalt in copper, with the result mentioned above and the experimental data of self-diffusion for copper according to Kuper, *et al.*⁷⁾ These values for activation energy are shown in Table II.

Table II.

	Co in Cu (exp.)	Cu self. (exp.)	Lazarus (theo.)	Alfred, March (theo.)
Activation energy (kcal/mol)	55.2	47.1	53.9	59.8

According to a classical consideration, the local strain around an impurity atom reduces the difficulty of the atomic jump from one equilibrium position to the other in the crystal lattice. Therefore, the activation energy of the diffusion should decrease by the introduction of impure atom. And, in addition, the main contribution of closed shell repulsion also reduces the activation energy because the ionic radius of cobalt is smaller than that of copper. However, in contrary, the result of this report exhibits a increase of activation energy for the diffusion of cobalt into copper. Thus as a sole propable mechanism, one must take into account the effects of screening of the solute atoms on the Fermi electrons of solvent lattice.

In conclusion, one of the most interesting aspects of the present results is that the activation energy obtained here is about 8 kcal/mol larger than that of self-diffusion for copper. This provides the strong support for the expectation of theories, though it is hard to say that the calculated values are in numerical agreement with the observed one.

Finally, if the activation energies are measured for other impurities with the different values of negative Z in the same solvent, it might seem possible to justify the theory for the effect of screening on solute diffusion in higher accuracy.

The author wishes to express his sincere thank to Prof. T. Hirone for his kind inten-

tions and encouragement throughout the course of the present study and publishing. His heartfelt thank is also due to Dr. N. Kunitomi for his valuable advices and his kind inspection of the manuscript.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 13, No. 8, AUGUST, 1958

The Theory of the Fine Structure of the X-ray Absorption Spectrum

By Toshio SHIRAIWA, Tsutomu ISHIMURA and Masao SAWADA

Faculty of Science, Osaka University

(Received April 21, 1958)

In the interpretation of the fine structure of the X-ray absorption spectrum in solids, the life time of the state of the electron ejected by absorption of a photon is considered. The life time is mainly determined by the inelastic collision cross section between the ejected electron and the atoms in the crystal. With the assumption that the inelastic cross section has a magnitude of the order of one square Angstrom, Kronig's method for the molecule is applied to the solid in order to obtain the variation of the transition probability. The wave function of the final state of the transition is obtained as the sum of the plane wave, whose amplitude decreases with increasing distance from the absorbing atom, and the waves scattered by the neighboring atoms. The calculated results for the *K*-absorption spectra of copper, nickel and iron agree well with experiments.

§ 1. Introduction

An acceptable theory of the fine structure of the X-ray absorption spectrum was first proposed by Kronig.¹⁾ According to his theory the origin of the fine structure is ascribed to the zone structure of the energy levels of the electrons in the crystal which is a result of the effect of the periodic field in the crystal. The X-rays are absorbed by the electrons which make transitions from the X-ray *K* levels to empty levels lying above the Fermi surface. These empty levels are grouped into zones and there exist forbidden and allowed bands. Because the absorption coefficient is proportional to the product of the transition probability and the state density, a fine structure occurs. In his theory the variation of the transition probability was neglected and the fine structure was explained mainly by

the variation of the electronic state density. His computation of the latter, in which an electron in a lattice was treated as nearly free and the field of the lattice as a perturbing potential, is very precise. But his calculation predicts much more fine structure than experiment reveals. So he suitably grouped anomalies in the density of states curve and, by such grouping, explained the position of absorption maxima and minima of the fine structure.

On the other hand, for the fine structure of a gas molecule he computed²⁾ the fluctuation of the absorption coefficient caused by the variation of the transition probability and, in order to calculate the state function of the final state of the transition, he adopted the following method. An ejected electron, which is treated as a plane wave, is scattered

by the partner atoms in the molecule and the final state is assumed as the sum of the plane wave and the scattered waves. This method has been applied by several other authors.²⁾

Hayashi³⁾ assumed that the wave of an ejected electron is reflected by atomic net planes and gives rise to a quasi-stationary standing wave around the atom which has ejected the electron, when the wavelength is such that the corresponding Bragg angle is equal to $\pi/2$. Since this standing wave has a large amplitude around the center atom, a strong absorption occurs. Among possible standing waves he took waves of p -type symmetry to consider the transition from the K level and calculated the positions of the absorption maxima, with considerable agreement with the results of experiments for Cu, Ni and Li. In his theory the net planes which cause the standing wave were chosen on the assumption that the reflecting power of the net planes is determined by the number of neighboring atoms and an atom must exist on the normal which is drawn from the center atom to the net plane. The neighboring atoms, then, play a major part in reflection. He suggested that the existence of this quasi-stationary state was due to the additional potential field caused by the missing K electron.

The following approximation has been proposed by Kostarev⁴⁾ to obtain the wave function of the ejected electron. The potential field of the neighboring atoms surrounding the absorbing atom is averaged to be spherically symmetrical. The ratio of the absorption coefficient of a solid to that of an isolated atom is given by the ratio of the transition probabilities which itself is given by the ratio of the squares of the amplitudes of the wave functions in the two cases. And in this calculation it is assumed that the both wave functions coincide at points distant from the absorbing atom.

The knowledge which has so far been obtained from experiments on the absorption spectrum of crystals is mainly as follows: The fine structure depends on the crystalline structure and for crystal lattices of the same structure the energy separation measured from the main edge is inversely proportional to the square of the lattice constant. These facts are explained qualitatively by Kronig's

theory. Experimental results also show that the fine structure depends on the kind of element and the positions of the neighboring atoms in the region of comparatively high energy.⁵⁾ Hayashi's theory and Kostarev's theory conveniently explain this fact.

Kronig's theory is based on the calculation of the stationary state in the crystal and is easily acceptable theoretically. But as regards the comparison with experimental results, he has only proposed a graphical representation and this does not coincide with the experiments quantitatively.* This is indicated in (f) of Figs. 2, 3, and 4 which show the positions of the anomalies of the absorption coefficient by vertical lines according to Kronig's method. The height of each line corresponds to the multiplicity of the equivalent lattice planes which cause the discontinuous zone of the energy.

If we try to interpret the experimental results quantitatively, we must consider the following points. In the Kronig computation only the variation of the state density is considered, whereas one should also include the variation of the transition probability. Secondly, it is necessary to calculate in a more precise way than Kronig did the wave functions of the eigenstates, because in his theory only the degeneracy of the two states is considered near the discontinuous plane in wave number space, whereas near the cross line or point of these planes higher degeneracy occurs. These cross lines or points increase rapidly in number in the higher energy region so that the form of the zone must be changed considerably. If we could take account of these features and of the spreading of the spectral bands⁷⁾ caused by the life time of the state of the ejected electron and that of the K -excited state,^{8),9)} a fairly perfect interpretation of the fine structure would be given.

It will be shown in the present paper that if one considers the life time of the ejected electron, which can be done through a simplified calculation, one can more readily interpret the fine structure quantitatively. In the process of the transition by absorption of the photon energy, the electron ejected from an inner K -level to a nearly free space makes

* A modified graphical representation has been proposed by Kurylenko.⁶⁾

a wave packet around the absorbing atom, corresponding to the uncertainty of the energy, and this wave packet spreads with the lapse of time. The wave function is the solution of the time dependent Schrödinger equation for the initial condition that the function is that of the K state, and the potential field which determines this wave function is the field within the wave packet. Then, in obtaining the transition probability, it may be possible to use wave functions which satisfy the time independent Schrödinger equation with a potential field that extends over the inside of the wave packet but not outside of it, instead of using the eigenfunctions in the whole crystal. The amplitude of the wave function of the ejected electron decreases with time, and if the life time is sufficiently small the transition problem in the crystal could be limited to a small space around the absorbing atom.

The life time is determined by the incoherent cross section of the collision of the ejected electron due to the thermal motion of atoms and by the cross section of the inelastic collision with atoms. At room temperature it will be determined mainly by the inelastic collision except in the case of ionic crystals. The cross section of the inelastic collision will have a value larger than one square Angstrom and, for this value, the ejected electron almost decreases on passing through a few atomic layers. Therefore we can calculate the transition probability according to the principle mentioned above.

To calculate the wave function of the ejected electron, the authors adopted the method which had been used by Kronig and Petersen²⁾ for a gas molecule, modified by introducing the decrease of the amplitude caused by scattering. The calculation was applied to the case of copper, nickel and iron with the approximation that the potential field of each atom is of a well type.

§ 2. Calculations

The wave function of the ejected electron:

As has been mentioned in § 1, we must obtain the wave function of the ejected electron, whose amplitude decreases with increasing distance from the absorbing atom. As the rough approximation, we may use the eigenfunction obtained in the potential field

of the neighboring atoms in the finite domain which we determine suitably by the life time. But when this problem is treated as the scattering problem, it will be possible to obtain a more proper solution.

The wave function of the ejected electron can be expressed by the sum of the wave for an isolated atom and the waves scattered by the neighboring atoms. In the first approximation, we have only to consider the primary scattered waves, but when we consider the multiply scattered waves the approximation will become better.

In the case of the isolated atom the ejected electron is expressed by a series of spherical waves and, at points distant from the absorbing atom where the field of the absorbing atom can be neglected, it can be replaced by a series of plane waves, $\exp(i\mathbf{k}\mathbf{r})$, where $\mathbf{k}/2\pi$ is the wave number vector. The effect of the neighboring atoms is to decrease the amplitude of the ejected electron in the scattering process. The ratio of the intensity of the scattered wave to that of the incident wave in a collision is $\sigma_t = \sigma_{el} + \sigma_{inel}$, where σ_{el} and σ_{inel} are the cross section of the elastic and the inelastic collision respectively. We assume that the amplitude of the ejected electron decreases as $\exp(-\mu/2r)$, where μ is $(\sigma_{el} + \sigma_{inel})/\rho$, ρ being the number of atoms per unit volume and r the distance from the absorbing atom. Now let the incident wave at the s -th atom at distant r_s from the absorbing atom, ψ_i , be equal to

$$\exp\left(-\frac{\mu}{2}r_s\right)\exp(i\mathbf{k}\mathbf{r}). \quad (1)$$

When σ_{inel} is zero or small and the decrease of the amplitude is due only to the elastic scattering, the total probability of existence of the electron does not change with collisions and therefore we must consider multiple scattering. In this case, the result gives the eigenfunction in the whole crystal and Kronig's method for solids is more suitable than the present method. When σ_{inel} is large, the scattered waves from the distant atoms and the multiply scattered waves decrease and the present method is suitable.

The elastic and inelastic cross sections for slow electrons in crystals has not been measured, but it has been suggested by Farnsworth that slow electrons can only

Table I. Values of the cross sections of several elements for the collision of an electron: Experimental values are quoted from the reference 13). Theoretical values are calculated by numerical integration of the scattered amplitudes, which are obtained from the atomic structure factors for X-rays, with respect to the scattering angles. In the calculation of the inelastic cross section, Morse's method is used. The structure factors which are calculated from the Thomas-Fermi distributions are referred to the same reference.

penetrate a few atomic laryers.¹⁰⁾ The values calculated by the present authors using the form factor and Morse's¹¹⁾ and Bethe's¹²⁾ methods seem to be too large, in comparison with the experimental data on gases. Measurements have been made for several elements, including rare gases, alkali metals, Zn and Hg.¹³⁾ These data are listed in Table I. We cannot use these values for the atoms in the crystal, but it is perhaps not too wrong to assume that the cross section for inelastic collision for a slow electron is larger than one square Angstrom. In the present paper the authors choose a few values of μ arbitrarily, and calculate the variation of the transition probability in each case. As will be shown in the result of the calculation, the small difference in the values does not affect the result.

The wave function ψ of the ejected electron is represented by

$$\psi=\psi_i+\sum_s\psi_s+\sum_{s,t}\psi_{s,t}+\sum_{s,t,u}\psi_{s,t,u}+\cdots, \quad (2)$$

where ψ_i is the incident wave and ψ_s is the wave scattered by the s -th atom for the incident wave ψ_i and $\psi_{s,t}$ is the wave scattered by the t -th atom for the ψ_s , that is, the secondary scattered wave, and so on. Each wave is as follows:

1) *Incident wave*; ψ_i .

This is represented by

$$\exp\left(-\frac{\mu}{2}r+i\mathbf{k}\mathbf{r}\right)$$

and near the nucleus of the absorbing atom situated at point A in Fig. 1, we put

$$\exp(i\mathbf{k}\mathbf{r}). \quad (3)$$

Fig. 1. Showing the relation between positions of the absorbing atom and the scattering atoms and the several vectors and angle used in the calculation. The absorbing atom is situated at A and the scattering atoms are situated at B and C. $k/2\pi$ is the wave number vector of the incident wave.

2) *The primary scattered wave*; ψ_s .

The incident wave to the s -th atom is given by Eq. (1), and its scattered wave is represented by

$$\frac{f(\theta_s)}{r_b}\exp(i\mathbf{k}\mathbf{r}_b)\exp\left\{i\mathbf{k}\mathbf{r}_s-\frac{\mu}{2}(\mathbf{r}_s+\mathbf{r}_b)\right\}, \quad (4)$$

where θ_s is the scattering angle and r_b the distance from the s -th atom situated at B. In order to obtain the transition probability from a 1s state, it is enough to calculate the wave function in the spase where the wave function of the 1s state exists, concentrated in the vicinity of the nucleus. Then the spherical wave Eq. (4) is replaced by the plane wave,

$$q_s\exp(i\mathbf{k}_{s0}\mathbf{r}), \quad (5)$$
$$q_s=\frac{f(\pi-\gamma_{0,s})}{r_s}\exp\{(i\mathbf{k}\mathbf{r}_s+i\mathbf{k}\mathbf{r}_s)-\mu\mathbf{r}_s\},$$

where $\gamma_{0,s}$ is the angle between $\mathbf{r}_s$ and $\mathbf{k}$, and $\mathbf{k}_{s0}/2\pi$ is the wave number vector in the direction from B to A .

3) The secondary scattered wave; $\psi_{s,t}$.

The wave scattered by the s -th atom is a spherical wave, but we approximate the incident wave to the t -th atom by the plane wave,

$$\frac{f(\gamma_{0,st})}{r_{st}} \exp \left\{ (i\mathbf{k}r_{st} + i\mathbf{k}\mathbf{r}_s) - \frac{\mu}{2}(r_s + r_{st}) \right\} \cdot \exp(i\mathbf{k}_{st}\mathbf{r}_0), \quad (6)$$

where $\gamma_{0,st}$ is the angle between $\mathbf{r}_{st}$ and $\mathbf{k}$, $\mathbf{r}_{st}$ the vector drawn from B to C , $\mathbf{r}_0$ the position vector from C , and $\mathbf{k}_{st}/2\pi$ is the wave number vector in the direction from B to C . The above approximation is not so good as the approximation of Eq. (4), but the secondary scattered wave is weak compared with the primary scattered wave, so that the above approximation should be permissible. The wave scattered by the t -th atom for the incident wave (6) becomes, near the point A ,

$$q_{s,t} \exp(i\mathbf{k}_{t0}\mathbf{r}), \quad (7)$$

where

$$q_{s,t} = \frac{f(\gamma_{0,st})}{r_{st}} \frac{f(\pi - \gamma_{t,st})}{r_t} \cdot \exp \left\{ (i\mathbf{k}r_{st} + i\mathbf{k}r_t + i\mathbf{k}\mathbf{r}_s) - \frac{\mu}{2}(r_s + r_{st} + r_t) \right\}.$$

In the above formulae $\mathbf{k}_{t0}/2\pi$ is the wave number vector in the direction from the t -th atom to the absorbing atom, and $\gamma_{t,st}$ is the angle between $\mathbf{r}_t$ and $\mathbf{r}_{st}$.

4) The third scattered wave; $\psi_{s,t,u}$.

In the same way, the third scattered wave $\psi_{s,t,u}$ is obtained and the formula in the vicinity of A is as follows.

$$q_{s,t,u} \exp(i\mathbf{k}_{u0}\mathbf{r}), \quad (8)$$

$$q_{s,t,u} = \frac{f(\gamma_{0,st})}{r_{st}} \frac{f(\gamma_{st,tu})}{r_{tu}} \frac{f(\pi - \gamma_{u,tu})}{r_u} \cdot \exp \left\{ (i\mathbf{k}r_{st} + i\mathbf{k}r_{tu} + i\mathbf{k}r_u + i\mathbf{k}\mathbf{r}_s) - \frac{\mu}{2}(r_s + r_{st} + r_{tu} + r_u) \right\},$$

where $\mathbf{r}_{tu}$ is the vector drawn from the t -th atom to the u -th atom. $\gamma_{st,tu}$ is the angle between $\mathbf{r}_{st}$ and $\mathbf{r}_{tu}$, $\gamma_{u,tu}$ is the angle between $\mathbf{r}_u$ and $\mathbf{r}_{tu}$, and $\mathbf{k}_{u0}/2\pi$ is the wave number

vector from the u -th atom to the absorbing atom.

The scattered waves of higher orders are obtained in the same way, but, as these terms are not taken into the actual calculation, they are not given here.

The total wave function of the ejected electron is given from Eqs. (2), (3), (5), (6), (7) and (8) by

$$\psi = \exp(i\mathbf{k}\mathbf{r}) + \sum_s Q_s \exp(i\mathbf{k}_{s0}\mathbf{r}), \quad (9)$$

where

$$Q_s = q_s + \sum_t q_{t,s} + \sum_{u,t} q_{u,t,s} + \dots$$

The transition probability from 1s state:

The transition probability from the 1s state to the state of which wave function is represented by Eq. (9) has been obtained by Kronig.²⁾ The transition probability is proportional to the quantity,

$$\sum_{x,y,z} \left| \int \psi_0^* x \psi d\tau \right|^2 = \left\{ 1 - \sum_s (Q_s^* + Q_s) \cos \gamma_{0,s} - \sum_{s,s'} Q_s^* Q_{s'} \cos \gamma_{s,s'} \right\} \left| \int \psi_0^* z \exp(ikz) d\tau \right|^2 \quad (10)$$

where ψ_0 is the wave function of the 1s state, $\gamma_{s,s'}$ is the angle between $\mathbf{r}_s$ and $\mathbf{r}_{s'}$, and

$$\left| \int \psi_0^* z \exp(ikz) d\tau \right|^2$$

corresponds to the transition probability in the case of the isolated atom. Then, by calculating the term of the braces in Eq. (10), it is possible to obtain the variation of the transition probability relative to that of the isolated atom. The simplicity of Eq. (10) is due to the symmetry of ψ_0 , and when the initial state is L , that is for an L absorption spectrum, the transition probability will have a more complicated formula.

When the incident ray is unpolarized and the absorber is an assembly of fine crystals, the transition probability represented by Eq. (10) is averaged over all directions of the vector $\mathbf{k}$. So the term which gives the difference of the transition probability from that of the isolated atom becomes

$$\frac{1}{4\pi} \left\{ - \sum_s (Q_s^* + Q_s) \cos \gamma_{0,s} - \sum_{s,s'} Q_s^* Q_{s'} \cos \gamma_{s,s'} \right\} d\Omega$$

$$= \frac{1}{4\pi} \left\{ - \sum_s (q_s^* + q_s) \cos \gamma_{0,s} \right.$$

$$-\sum_{s,s'} q_s^* q_{s'} \cos r_{s,s'} - \sum_{s,t} (q_{t,s}^* + q_{t,s}) \cos r_{0,s} \\ - \sum_{s,t,u} (q_{u,t,s}^* + q_{u,t,s}) \cos r_{0,s} + \dots \} d\Omega, \quad (11)$$

where $d\Omega$ is the solid angle regarding to the k vector.

We proceed with the evaluation of Eq. (11). In the calculation it is assumed that the potential of each atom is a well type potential hole of radius a and with a depth V_0 , and in order to obtain the scattered amplitude, $f(\theta)$, Born's approximation is used, that is,

$$f(\theta) = -\frac{2m}{\hbar^2} \int_0^\infty \frac{\sin(2kr \sin \theta/2)}{2kr \sin \theta/2} V(r) r^2 dr \\ = -\frac{2m}{\hbar^2} V_0 a^3 \left(\frac{\cos K}{K^2} - \frac{\sin K}{K^3} \right), \quad (12)$$

where

$$K = 2ka \sin \theta/2.$$

In Eq. (11) we carry out the integration before the summation. The integrated formula of each term of Eq. (11) becomes as follows.

$$\int_{-1}^1 \exp(ikr_s x) x F(x) dx = \frac{1}{ikr_s} \exp(ikr_s x) F(x) \Big|_{-1}^1 \\ - \frac{1}{(ikr_s)^2} \exp(ikr_s x) \frac{\partial}{\partial x} \{x F(x)\} \Big|_{-1}^1 + \frac{1}{(ikr_s)^3} \exp(ikr_s x) \frac{\partial^2}{\partial x^2} \{x F(x)\} \Big|_{-1}^1 \dots, \quad (14)$$

and

$$\int q_s \cos r_{0,s} d\Omega = 2\pi \left(-\frac{2m}{\hbar^2} V_0 a^3 \right) \exp(-\mu r_s) \\ \times \left[\frac{1}{ikr_s^2} \left[\exp(2ikr_s) \left\{ \frac{\cos 2ka}{(2ka)^2} - \frac{\sin 2ka}{(2ka)^3} \right\} - \frac{1}{3} \right] \right. \\ \left. + \frac{1}{k^2 r_s^3} \left[\exp(2ikr_s) \left\{ \frac{1}{4} \frac{\cos 2ka}{(2ka)^2} - \frac{1}{4} \left(\frac{1}{2ka} + \frac{1}{(2ka)^3} \right) \sin 2ka \right\} + \left(\frac{1}{3} + \frac{1}{15} k^2 a^2 \right) \right] + \dots \right]. \quad (15)$$

Then the integrated formula of the first term, taking only the first term in (15), becomes

$$\frac{1}{4\pi} \int (q_s^* + q_s) \cos r_{0,s} d\Omega \simeq \left(-\frac{2m}{\hbar^2} V_0 a^3 \right) \frac{\exp(-\mu r_s)}{kr_s^2} \sin 2kr_s \cdot M(K_0), \quad (16)$$

where

$$M(K_0) = \frac{\cos K_0}{K_0^2} - \frac{\sin K_0}{K_0^3}, \quad K_0 = 2ka.$$

2) *Integration of the second term:*

$$q_s^* q_{s'} = \frac{1}{r_s r_{s'}} f^*(\pi - r_{0,s}) f(\pi - r_{0,s'}) \exp \{ ik(r_{s'} - r_s) + ik(r_{s'} - r_s) - \mu(r_s + r_{s'}) \}.$$

The term which must be integrated with respect to $d\Omega$ appears below, and, in the same

1) *Integration of the first term:*
From (4)

$$\int q_s \cos r_{0,s} d\Omega \\ = \frac{2\pi}{r_s} \exp(-\mu r_s + ikr_s) \int_{-1}^1 \exp(ikr_s x) x F(x) dx, \quad (13)$$

where

$$x = \cos r_{0,s}, \quad F(x) = f(\pi - r_{0,s}).$$

In Eq. (13) ka is small compared with kr_s , and kr_s has a comparative large value; for example, when the energy of the electron is 20 eV. and r_s is the distance to the nearest neighbor in Cu, the value of kr_s is 5.9 and k becomes larger as the energy of the electron increases. In the present paper the authors do not consider the fine structure in the vicinity of the main absorption edge, so the integration of Eq. (13) is expanded into a series whose n -th term includes the n -th power of $1/kr_s$ by partial integration:

manner as in 1) directly above, the authors use the partial integration method and take the first term alone.

$$\begin{aligned}
 & \int f^*(\pi - \gamma_{0,s}) f(\pi - \gamma_{0,s'}) \exp \{ik(r_{s'} - r_s)\} d\Omega \\
 &= \int_0^\pi \exp(ikr_{ss'} \cos \gamma_{0,ss'}) \sin \gamma_{0,ss'} d\gamma_{0,ss'} \int_0^{2\pi} f^*(\pi - \gamma_{0,s}) f(\pi - \gamma_{0,s'}) d\varphi \\
 &= -\frac{1}{ikr_{ss'}} \exp(ikr_{ss'} \cos \gamma_{0,ss'}) \int_0^{2\pi} f^*(\pi - \gamma_{0,s}) f(\pi - \gamma_{0,s'}) d\varphi \Big|_{\gamma_{0,ss'}=0}^\pi \\
 &\quad + \frac{1}{ikr_{ss'}} \int_0^\pi \exp(ikr_{ss'} \cos \gamma_{0,ss'}) d\gamma_{0,ss'} \int_0^{2\pi} \frac{\partial}{\partial \gamma_{0,ss'}} \{f^*(\pi - \gamma_{0,s}) f(\pi - \gamma_{0,s'})\} d\varphi \\
 &\simeq \left(-\frac{2m}{\hbar^2} V_0 a^3 \right)^2 \frac{2\pi}{ikr_{ss'}} [\exp(ikr_{ss'}) M\{K_+(\gamma_{s,ss'})\} - \exp(-ikr_{ss'}) M\{K_-(\gamma_{s,ss'})\}].
 \end{aligned}$$

Where M is the same function as in Eq. (16),

where

$$K_+(\gamma_{s,ss'}) = ka\sqrt{2(1 + \cos \gamma_{s,ss'})},$$

$$K_-(\gamma_{s,ss'}) = ka\sqrt{2(1 - \cos \gamma_{s,ss'})},$$

and

$$\begin{aligned}
 & \frac{1}{4\pi} \sum_{\substack{s,s' \\ s \neq s'}} \int q_s^* q_{s'} \cos \gamma_{s,s'} d\Omega = \frac{1}{8\pi} \sum_{\substack{s,s' \\ s \neq s'}} \int (q_s^* q_{s'} + q_s q_{s'}^*) \cos \gamma_{s,s'} d\Omega \\
 &= \frac{1}{2} \left(-\frac{2m}{\hbar^2} V_0 a^3 \right)^2 \sum_{\substack{s,s' \\ s \neq s'}} \frac{\exp\{-\mu(r_s + r_{s'})\}}{kr_s r_{ss'} r_{s'}} \cos \gamma_{s,s'} [\sin k(-r_s + r_{ss'} + r_{s'}) M\{K_+(\gamma_{s,ss'})\} \\
 &\quad \times M\{K_+(\gamma_{s',ss'})\} - \sin k(-r_s - r_{ss'} + r_{s'}) M\{K_-(\gamma_{s,ss'})\} M\{K_-(\gamma_{s',ss'})\}]. \quad (17)
 \end{aligned}$$

When $r_s = r_{s'}$

$$\frac{1}{4\pi} \sum_s \int q_s^* q_s \cos \gamma_{s,s} d\Omega = \frac{1}{4\pi} \sum_s \frac{\exp(-\mu r_s)}{r_s^3} \int |f(\theta)|^2 d\Omega.$$

The above term changes slowly with k , so that it is excluded from the calculation.

3) Integration of the third term:

In the same way we obtain the integrated formula of the third term.

$$\begin{aligned}
 & \frac{1}{4\pi} \int (q_{t,s}^* + q_{t,s}) \cos \gamma_{0,s} d\Omega = \left(-\frac{2m}{\hbar^2} V_0 a^3 \right)^2 \frac{\exp\{-\mu/2 \cdot (r_t + r_{ts} + r_s)\}}{kr_t r_{ts} r_s} \cos \gamma_{s,t} \\
 &\quad \times [\sin k(r_t + r_{ts} + r_s) M\{K_-(\gamma_{t,ts})\} + \sin k(-r_t + r_{ts} + r_s) M\{K_+(\gamma_{t,ts})\}] M\{K_+(\gamma_{s,ts})\}. \quad (18)
 \end{aligned}$$

4) Integration of the fourth term:

The fourth and other terms can be calculated in the same way; for example, the fourth term becomes

$$\begin{aligned}
 & \frac{1}{4\pi} \int (q_{u,t,s}^* + q_{u,t,s}) \cos \gamma_{0,s} d\Omega = \left(-\frac{2m}{\hbar^2} V_0 a^3 \right)^3 \frac{\exp\{-\mu/2 \cdot (r_u + r_{ut} + r_{ts} + r_s)\}}{kr_u r_{ut} r_{ts} r_s} \cos \gamma_{s,u} \\
 &\quad \times [\sin k(r_u + r_{ut} + r_{ts} + r_s) M\{K_-(\gamma_{u,tu})\} + \sin k(-r_u + r_{ut} + r_{ts} + r_s) M\{K_+(\gamma_{u,tu})\}] \\
 &\quad \times M\{K_-(\gamma_{ut,ts})\} M\{K_+(\gamma_{s,ts})\}. \quad (19)
 \end{aligned}$$

§ 3. Application to Actual Crystals

The calculation was applied to copper, nickel and iron. The values of total cross section shown in Table II were chosen. The ejected electron decreases to 1/e as it moves

a distance 1/2, 1 or 2 times the lattice constant, respectively.

In Eq. (11), the first term is the largest and the second and the third term follow it, and we have only to consider the first term,

Table II. The values of the total cross sections used in the calculation.

Element	Cu			Ni			Fe		
μ , in the lattice constant unit.	0.5	1	2	0.5	1	2	0.5	1	2
μ , in $\text{\AA}^{-1}$	0.069	0.138	0.277	0.071	0.142	0.284	0.087	0.174	0.349
σ_t , in $\text{\AA}^{-2}$	1.63	3.27	6.53	1.55	3.11	6.21	2.06	4.11	8.22

as long as the cross section of the elastic collision is not large compared with that of the inelastic collision. From Eq. (16) the difference between the absorption coefficient* for solid and that for an isolated atom is proportional to the following term, if one assumes that

$$\left| \int \phi_0 z \exp(ikz) d\tau \right|^2$$

is constant:

$$-\sum_s \left(-\frac{2m}{\hbar^2} V_0 a^3 \right) \frac{N_s}{r_s^2} \cdot \exp(-\mu r_s) \sin 2kr_s \left\{ \frac{\cos 2ka}{(2ka)^2} - \frac{\sin 2ka}{(2ka)^3} \right\}, \quad (20)$$

where N_s is the number of atoms which are at equal distances from the absorbing atom and the summation extends all over the different r_s . The value of a is small compared with r_s , so that the term in braces in Eq. (20) is a modulating factor for $\sin 2kr_s$. The value of the summation is determined mainly by the terms of small r_s , even if the value of μ is small.

This follows from the consideration of several factors:

- (1) For large r_s the terms $\sin 2kr_s$ have short periods with respect to k ;
- (2) the amplitude N_s/r_s^2 decreases with increasing r_s ;
- (3) the intervals between successive shells of neighboring atoms become smaller with increasing r_s .

* The absorption coefficient is given by the product of the transition probability and the state density, and in deriving Eq. (20), it is assumed that the state density is proportional to k as in the case of the isolated atom. Of course the state density will fluctuate in the solid, but the magnitude of the fluctuation is small compared with the fluctuation of the absorption coefficient.

Then the small difference in the value of μ and the domain of the summation do not affect the total summed value. Table III shows the values of N_s/r_s^2 for f.c.c. and b.c.c. crystals.

Table III. Distances from the absorbing atom to the neighboring shells and values of N_s/r_s^2 where N_s is the number of the atoms in each shell, in f.c.c. and b.c.c. crystals. r_s is expressed in unit of lattice constant.

(d) Calculated value for the second term (17) and the third (18), for $\mu=0.174 \text{ \AA}^{-1}$. The summation is extended over the same values of s, s' and s, t in (c).

- (f) Positions of the anomalies of the absorption coefficient by Kronig's method for solid.

cal line, which shows the position of the anomaly, corresponds to the multiplicity of the corresponding discontinuous plane of energy in the Brillouin zone diagram. In the calculations of (b), (c) and (d), the radius of potential hole a was taken to give the best-fit results with experiments. Considering that its value is the order of one tenth that of the lattice constant, these were found to be

$$a=0.42 \text{ \AA} \quad \text{for copper,}$$

$$a=0.42 \text{ \AA} \quad \text{for nickel,}$$

$$a=0.60 \text{ \AA} \quad \text{for iron.}$$

In order to estimate the above values the following facts were taken into consideration. In Eq. (20), the term modulating the amplitude changes its sign at the value of k which satisfies the

$$\cos 2ka - \frac{\sin 2ka}{2ka} = 0,$$

hence

$$k = \frac{2\pi}{a} \times 0.355.$$

Experimental curves in the same figures are referred to Hayashi³⁾ for Cu and to our own data for Ni and Fe, photographed with a Johann type spectrograph, 25 cm radius of the Rowland circle and by reflection from the (130) planes of quartz. With this spectrograph the half width of Cu $K\alpha_1$ line is 0.6 x.u., with 7 mm opening of the crystal surface, and it may be assumed that the crystal is bent with a considerably high accuracy. The experimental curve obtained by Hayashi is the density curve itself but ours give the logarithm of the X-ray intensity.

The abscissa in these figures is the value of energy of the free electron corresponding to the wave number $k/2\pi$, and retains, of course, the wave packet uncertainty. The value of $(-2m/\hbar^2 \cdot V_0 a^3)$ is not necessary in Eq. (20); however, it does become necessary when one considers the terms Eqs. (17) and (18). The ordinate is the value for the case that the cross section for elastic collision is 25% of the total cross section, at 46.5 eV. in copper, 48 eV. in nickel, and 41 eV. in Fe. The relation between $(-2m/\hbar^2 \cdot V_0 a^3)$ and the cross section of the elastic collision is given by the equation,

$$\sigma_{el} = \left(\frac{2m}{\hbar^2} V_0 a^3 \right)^2 \frac{2\pi}{(ka)^2} \left[\frac{1}{4} - \frac{1}{4} \frac{1}{(2ka)^2} \right]$$

$$+ \frac{1}{4} \frac{1}{(2ka)^3} \sin 2ka - \frac{1}{8} \frac{1}{(2ka)^4} (1 - \cos 4ka) \Big]. \quad (21)$$

In order to make clear the effect of the second term, and the third, these terms were calculated over a few neighboring shells; the results are shown by the dashed curves in the same figures. In iron the ratio of these terms to the first term is large compared with that for f.c.c. crystals. This is due to the b.c.c. structure, that is, to the fact that the value of N_s/r_s^2 for a b.c.c. structure is small compared with that for a f.c.c. crystal and the amplitude of the first term in Eq. (11) becomes correspondingly small. Thus the second and the third terms affect the result, when σ_{el} is not small. In the calculation of these terms the main part arises from those pairs of atoms for which $r_{t,ts}$ or $r_{s,s's}$ is small, this result being due to the character of the Born scattering.

§ 4. Discussion

Calculated results shown in Figs. 2, 3 and 4 are in fairly good agreement with experimental curves in the energy region of 50–250 eV.. In the energy region below 50 eV. the magnitudes of the fluctuations in the calculated curves are greater than those of the experiments. Perhaps this is a consequence of the assumption that the total cross section is independent of k , and also that Born's approximation becomes poor in the low energy region. When the second term and the third are taken into consideration better results are obtained for copper and nickel, but it is not so for iron. There are questions about the choice of the parameter a and about the effects of the terms neglected in the present calculation, but it will be meaningless to discuss these points further so long as a well type potential hole is assumed and Born's approximation is used.

The authors have calculated the variation of the transition probability on the assumption that the magnitude of the total cross section of the atom in a crystal is of the order of one square Angstrom and the inelastic part of the cross section is not small, and in this way good results have been obtained, although, to a rough approximation, the simple form of the potential hole and Born's

approximation were adopted. That our results are so good, may be due to the validity of the assumptions. If the assumption for the inelastic cross section is proper, the fine structure of the absorption spectrum will be related only to atoms in the neighborhood of the absorbing atom; consequently the present method allows one to obtain a clearer picture of the relation between the structure of the substance and the spectral fine structure, since one can treat the problem for various substances, from molecules to crystals, with a unified method.

In order to modify the present calculation, it is necessary to consider the following points. One must calculate accurately the scattered amplitude for the actual potential field and consider the additive potential field due to the missing K -electron. This is particularly important for calculations on insulators. Also the departure from the free electron approximation, which is adopted in the present calculation, must be considered. These are important in low energy region. In addition, the variation of the cross section with respect to k should be obtained in the whole energy region. The thermal motion of the atoms has not been considered in the present calculation but its effect can be obtained by averaging the calculated result with respect to the positions of the atoms.

In conclusion, the authors wish to express their sincere thanks to Prof. T. Nagamiya for his kind comment and advice, to Asst. Prof. T. Nishiyama and Asst. Prof. Y. Toyozawa of Kyoto University for useful suggestions, and to Mr. S. Yomosa and Dr. J. Kanamori for valuable discussions. They also express their gratitude to Profs. C. H. Shaw, J. Korrington and E. L. Jossem of Ohio State University for reading the manuscript and giving them kind remarks.

Nuclear Quadrupole Spectra of Boron Trichloride and Tribromide

By Takehiko CHIBA

*Department of Chemistry, Faculty of Science
University of Tokyo, Tokyo*

(Received March 28, 1958)

The pure quadrupole resonance spectra were observed on Cl^{35} and Cl^{37} in BCl_3 and Br^{79} and Br^{81} in BBr_3 at several temperatures. The spectrum of each nucleus consists of characteristic doublet (ν_{I} and ν_{II}) with the intensity ratio of ca. 3 to 5. The Zeeman study with a single crystal of BBr_3 was also carried out at liquid nitrogen temperature (77°K), to determine the asymmetry parameter η . The results are as follows:

	Cl^{35}	Cl^{37}	Br^{79}	Br^{81}
ν_{I}	21.582 ± 0.001	17.008 ± 0.002	175.293 ± 0.002	146.434 ± 0.002 Mc,
ν_{II}	21.578 ± 0.001	17.004 ± 0.002	175.264 ± 0.002	146.411 ± 0.002 Mc.
$\nu_{\text{I}} - \nu_{\text{II}}$	3.68 ± 0.10 kc	—	26.1 ± 0.5 kc	21.6 ± 0.5 kc
η	—	—	0.45 ± 0.05	—
eQq	42.9 Mc	—	340 Mc	—

The ionic character and the double bond character were estimated to be $i=0.42$ and $f=0.11$, respectively for the B-Br bond from the above results. In BCl_3 , $f=0.06$ was obtained by assuming $i=0.50$. The double bond characters of these compounds are fairly smaller than usually assumed.

The doublet separation cannot be explained by direct nuclear dipole-dipole interaction. A reasonable explanation was made by taking into account the effect of the intramolecular vibration: the isotopes of boron B^{10} and B^{11} provide different mean square amplitudes to the bending vibrations of BX_3 , which in turn produce a difference of q for B^{10}X_3 and B^{11}X_3 molecules. The effect was calculated by use of the normal frequencies of BCl_3 and BBr_3 . A fair agreement was obtained between the observed separation of the doublet and the calculated one. The observed intensity is also compatible with the assumption.

§ 1. Introduction

In nuclear quadrupole resonance spectrum the frequency of the absorption line is determined by the coupling of the quadrupole moment of a nucleus with the electric field gradient at the nucleus. In molecular crystals the field gradient is mainly fixed by the distribution of valence shell electrons in bonding and nonbonding orbitals, but a minor contribution of intermolecular field cannot be neglected because of high resolution of this spectroscopy, and, in fact, even a slight nonequivalence of the positions of atoms in the crystal can be detected by a difference of absorption frequencies. Thus the number of absorption lines corresponds to the number of nonequivalent positions of the nuclei in the crystal, though accidental coincidence of the absorption lines often takes place. This ex-

pectation has been well established by a number of studies¹⁾ for substances whose structures were determined by the X-ray analysis.

In his early work Livingston²⁾ reported two lines separated by five kilocycles for Cl^{35} nuclear quadrupole resonance spectrum of BCl_3 . On the other hand Rollier and Riva³⁾ found by the X-ray diffraction that all the chlorine atoms are equivalent in BCl_3 crystal. Hence from the relation mentioned above only a single line is expected for Cl^{35} nuclear quadrupole resonance spectrum of BCl_3 , and doublet actually observed has to be attributed to another effect. The main purpose of the present study is to make clear the origin of the doublet by the measurement of the resonance lines of BCl_3 and BBr_3 , the latter compound being known as isomorphous to the

former³⁾. In connection with this, the nature of B-halogen bond will be discussed from the observed coupling constants and the asymmetry parameters obtained from the observation of the Zeeman effect. Two accounts are taken into consideration in the present work: a) dipole-dipole interaction between the neighboring nuclei and b) boron isotope effect on the mean amplitudes of molecular vibration. It is confirmed that the latter is the cause of the doublet.

After this study had been finished, the present author noticed that Douglass⁴⁾ also made a study on boron trichloride with similar intention and his conclusion was quite close to the present one, though the effect a) was not definitely excluded because his measurement was carried out only on boron trichloride.

§ 2. Experimental

A. *Preparation of Materials.* Boron trichloride was prepared by passing dried chlorine gas on metallic boron at 400°C. The product obtained was purified twice by vacuum distillation.

Boron tribromide was prepared by heating a mixture of potassium borofluoride and aluminium bromide. As the raw product contained some partially fluorinated compounds, probably BFBr_2 , it was fractionally distilled to get a fraction boiling at 91°C.

B. *Measurement of Frequency.* Two radio-frequency spectrographs of superregenerative type were used: one for chlorine resonance and the other for bromine. The oscillator-detector circuit of the former was similar to that used by Dean⁵⁾, and that of the latter was almost the same as that by Kojima⁶⁾. The frequency ranges of the circuits were 15 to 45 Mc/s and 110 to 300 Mc/s respectively. The absorption signals were displayed on an oscilloscope screen or recorded on a pen-recorder through a lock-in amplifier and a phase-sensitive detector. For the accurate measurement of the frequency of an absorption line a signal generator was first adjusted to the absorption signal with the aid of an oscilloscope, then frequency of the signal generator was mixed with harmonics of 1000 kc which was generated by a 1 Mc crystal oscillator calibrated within the order of 10^{-5} by JJY frequency standard. The beat signal in the range of 500 to 1000 kc was picked up

and the beat frequency was measured with the precision of 0.3 kc by a frequency-calibrated heterodyne receiver. Small separation between the doublet lines was measured by the comparison with a quenching frequency on a recorder chart.

C. *Observation of Zeeman Effect of a Single Crystal.* The magnetic field used for the Zeeman effect of quadrupole resonance line was furnished by a Helmholtz coil of inner diameter of 16 cm, the field strength being 108 oersted/amp. A single crystal of BBr_3 was prepared by use of the apparatus shown in Fig. 1. An ampule, 1.5 cm in diameter

Fig. 1. Apparatus for the preparation of a single crystal.

and 5 cm in length containing ca. 10 g of BBr_3 , was lowered slowly (5–6 mm/hr) into a copper tube (3 mm thick, 2.5 cm in diameter, and 13 cm in length) which was cooled by liquid air. The single crystal thus prepared was annealed by storing it for a few days in a Dewar vessel filled with dry ice.

§ 3. Results

A. *Resonance Lines without Magnetic Field.* The measurement of the spectrum was made at the temperatures of liquid nitrogen and

oxygen for BCl_3 , and of liquid nitrogen and oxygen and dry ice for BBr_3 . Signals of high signal-to-noise ratio were observed both for BCl_3 and BBr_3 . In the case of bromide, however, no signal was observed at first. It was found to be attributed to the broadening effect of q by the random neighbor configuration which was caused by the contamination of a small amount of fluorine compounds. A similar broadening effect has been found in the case of solid solutions of *p*-dihalogenobenzenes⁷⁾.

The absorption pattern of the two compounds displayed a similar shape of closely lying doublet lines: the stronger one, ν_I , on the high frequency side and the weaker one, ν_{II} , on the low. The typical recording curve of Br^{81} in BBr_3 is shown in Fig. 2. The frequencies measured at various temperatures are given in Table I. The frequencies of Cl^{35} at the liquid nitrogen temperature are in good

Fig. 2. Resonance line of Br^{81} in BBr_3 at 77°K recorded as a derivative curve.

Table I. Observed frequencies of the pure quadrupole resonance spectra of boron trichloride and tribromide (in Mc).

		77°K	90°K	196°K

				26.1 ± 0.5 kc 21.6 ± 0.5 kc

Values in the parentheses are the band widths.

agreement with those reported by Livingston²⁾. By integrating the differential curve taken on the recorder, the intensity ratio was estimated to be 3 to 5. More accurate value of the ratio was not obtained not only because it depends on the base line assumed somewhat arbitrarily, but also because superregenerative detection is known to be less reliable for the shape of the absorption line. For bromide the absorption was also recorded by autodyne operation. The curve was almost similar to

that by superregenerative one. The line widths were fairly large, rough estimate of them being given in Table I. The separation of the lines was measured at the liquid nitrogen temperature. The results are also listed in Table I.

B. Zeeman Effect The main purpose of the observation of Zeeman effect of BBr_3 is to obtain asymmetry parameter of the halogen atoms. On account of the low melting point of the compound (-46°C), a great difficulty

was imposed to study the Zeeman effect of this substance. Furthermore the doublet structure of the original line made it more complicated. Thus the analysis was made to the step which was sufficient to obtain η with the aid of knowledge of crystal structure by the X-ray diffraction.

Now the frequencies of the Zeeman components are given in the case of $I=3/2$ by the following expression which is exact in η and is approximate to the first order in the applied magnetic field H

$$\nu = \nu_0 \pm \begin{Bmatrix} s_1 \\ s_2 \end{Bmatrix} \quad (1)$$

$$\begin{Bmatrix} s_1 \\ s_2 \end{Bmatrix} = \frac{\mu}{3h\xi} [\{ (2\xi-1)(2\xi+\eta+1)H_x^2 + 2(\xi-1)(2\xi-\eta+1)H_y^2 + (\xi+2)^2H_z^2 \}^{1/2} \pm \{ 2(\xi+1)(2\xi-\eta-1)H_x^2 + 2(\xi+1)(2\xi+\eta-1)H_y^2 + (\xi-2)^2H_z^2 \}^{1/2}], \quad (2)$$

where

$$\xi = \left(1 + \frac{1}{3} \eta^2 \right)^{1/2}. \quad (3)$$

μ is the magnetic moment of the nucleus, and H_x , H_y and H_z are the components of the applied magnetic field in the direction of three principal axes of the q tensor ($|q_{xx}| < |q_{yy}| < |q_{zz}|$). Thus a single line splits in general into four. According to the results of electron diffraction⁸, infrared spectrum, and the Raman effect⁹, BBr_3 molecule has three B-Br bonds in the directions of 120° with each other, all lying on the same plane. Crystal analysis give the same structure^{3,10}. Therefore, a magnetic field will in general give rise to a pattern of twelve-component lines, which may be too complicated to analyse directly. The analysis was made first by determining the direction in which the Zeeman pattern has a component line at its center ($s_2=0$ in Eq. (1)). The relation between the splitting pattern and the direction of the applied field is conveniently understood by a sphere shown in Fig. 3, in which the molecule is put at the center of the sphere and on the equatorial plane with a B-Br bond in the x-direction. A point on the surface of the sphere corresponds to a direction of the magnetic field relative to the molecule. The circles drawn on the surface of the sphere show the directions in which central lines are

to be observed. The curve is circle when $\eta=0$, but becomes elongate towards the z -direction as η grows up. In order to get the direction of a bond, first the area is located where two lines BCD and EFG run nearly parallel (actually about twenty degrees apart),

Fig. 3. Sphere showing angular relation of Zeeman patterns.

and then the point A is determined by measuring the split patterns on the bisecting line of the two parallel lines. The arc CAF provides a measure of η . The point C (or F) is the direction making an angle of $60^\circ - CAF/2$ with the bond direction. This angle is given from Eq. (2) by letting $s_2=0$ and $H_x=0$:

$$\tan \left(60^\circ - \frac{CAF}{2} \right) = \frac{H_y}{H_z} = \sqrt{\frac{2}{1+\eta}}. \quad (4)$$

From the length of the arc CF, $21 \pm 1^\circ$, η was calculated to be 0.45 ± 0.05 .

C. Temperature Dependence of Resonance Lines. The variation of the resonance lines with temperature was found to be normal in bromide. Since the lattice frequencies of the crystal are not known, exact resonance frequency free from the effect of the lattice vibration is not obtained. Therefore, the value extrapolated to $0^\circ K$, 175.9 Mc/s, is tentatively taken as ν_0 for Br^{79} of BBr_3 . This frequency, with the value of η obtained at $77^\circ K$, was used to calculate the coupling constant:

$$(eQq)^{79} = 2\nu_0 / \left(1 + \frac{1}{3} \eta^2 \right)^{1/2} = 340 \text{ Mc/s}. \quad (5)$$

For BCl_3 , η was not measured and, accordingly, taken $\eta=0.24$ as estimated in the discussion described later, eQq was found to be 42.9 Mc/s.

§ 4. Discussion

A. *Boron-Halogen Bonds in Boron Halide Molecules.* The B-X bond of boron trihalide molecules may be represented by the resonance among the following three structures:

If the scheme is assumed, the amount of unbalanced p-electrons which is directly connected to the field gradient can be calculated by a procedure similar to that used by Kojima¹¹. The z-axis is taken to be parallel to a B-Br bond, the x-axis to be perpendicular to the molecular plane, and the y-axis to be in the plane and perpendicular to the bond. The double bond in the configuration II involves a π -orbit in addition to the σ -orbit. The s-hybridization of a p_σ -bond in I or in II is assumed to be 15%¹². The factor ϵ , the increase of q by a positive nuclear charge at the halogen nucleus in the configuration II, is assumed to be +0.15 as given by Townes¹². In the configuration I the contribution to the field gradient q at the bromine nucleus comes from $(1-s)q_\sigma$ of the bonding electrons in p_σ plus s orbit, $2sq_\sigma$ of the nonbonding electrons in s plus p_σ orbit, and $2q_x$ and $2q_y$ of the nonbonding electrons in p_π orbits. In the configuration II q comes from $(1-s)q_\sigma(1+\epsilon)$ of the bonding electrons in p_σ plus s orbit, $2sq_\sigma(1+\epsilon)$ of the nonbonding electrons in π -orbit, and $q_x(1+\epsilon)$ of the bonding electrons in π orbit of the double bond. The configuration III contributed nothing to q because in the first approximation X-ion has a spherically symmetric distribution of electrons.

Now if the double bond character of the B-X bond (the fraction of the configuration II in the resonance structure) and its ionic character (that of III) are designated by f and i respectively, then it can be easily shown that the total field gradients in the x-, y- and z-directions are given by

$$q_{xx} = (0.425 - 0.425i - 1.086f)q,$$

$$q_{yy} = (0.425 - 0.425i + 0.639f)q,$$

and

$$q_{zz} = (-0.85 + 0.85i + 0.447f)q,$$

where q denotes the q -value of a pure $4p_\sigma$ orbit electron of a bromine atom in the bond direction, that, is q_{410} . Thus the amount of the unbalanced p electrons of the halogen atom in the bond direction U_p , is

$$U_p = -q_{zz}/q = +0.85 - 0.85i - 0.447f, \quad (6)$$

and the asymmetry parameter is

$$\eta = (q_{xx} - q_{yy})/q_{zz} = 1.725f/U_p. \quad (7)$$

The observed values of $\eta=0.45$ and of $U_p = (eQq)_{\text{obs}}/(eQq)_{\text{atom}} = 340/769.8 = 0.442$ provide the results of $f=0.12$ and $i=0.42$. The s-curve relation between ionicity and electronegativity proposed by Dailey and Townes¹³ gave $i=0.35$ for B-Br. Judging from the fact that in BX_3 three halogen atoms are attached to the same boron atom, the ionicity of the halogen atom should be fairly reduced and the ionicity of 0.42 obtained above seems unreasonable. However, it is hardly attributed to the neglect of the effect of intermolecular partial bond which is seen in some compounds such as iodine¹⁴ and bromine¹⁵. A recent result of the X-ray reinvestigation by Atoji and Lipscomb¹⁰ shows that the bond length of B-Cl is not quite different from that in the vapor state and the nearest intermolecular $\text{Cl} \cdots \text{Cl}$ distances have regular Van der Waals' values, which indicates that the bonds are essentially confined in the molecules but not shared between two molecules. The situation must be similar in BBr_3 , and it is also consistent with the normal temperature variation of the resonance frequencies in BBr_3 .

If U_p of B-Br bonds in other molecules could be explained by taking ionicity of Townes' value 0.35, the large apparent ionicity obtained in BBr_3 might be due to the effect such as intermolecular bonding or large crystalline field. However, U_p of $\text{B}_2\text{H}_5\text{Br}$ is 0.39*, which is consistent with ionicity of at

* The coupling constant of Br^{79} in $\text{B}_2\text{H}_5\text{Br}$ measured in the microwave spectroscopy is 294 Mc/s in the a-axis direction (C. D. Cornwell, J. Phys., **18** (1950) 1118). By transforming the q tensor using the molecular geometry, the coupling constant along the direction of the B-Br bond is estimated to be 298.4 Mc. Unknown asymmetry parameter in this case does not appreciably affect the transformation, since the a-axis is closely parallel to the B-Br bond.

least 50%. The decrease of ionicity from B_2H_5Br to BBr_3 is normal and an ionicity higher than Dailey and Townes' value is necessary to fit to the U_p of both of the two compounds. Therefore, it is hardly probable that large intermolecular effects exist in BBr_3 .

Although no asymmetry parameter was measured for BCl_3 , the situation must be quite similar. Thus by assuming 50% ionic character for B-Cl bond, $f=0.06$ is obtained from $U_p=42.9/109.7=0.392$. Hence by use of Eq. (6) η is calculated to be 0.24**. Contrary to this result, Gordy¹⁶⁾ estimated $f=0.29$ and $i=0.46$ for B-Cl bond in this compound. These values provide an abnormal result that the maximum q does not lie in the B-Cl bond direction but in the y-axis, and the value of $\eta=0.90$ obtained seems to be unreasonably large. From a relation of bond distance to the bond character Pauling¹⁹⁾ estimated that configuration II is the dominant one, and, accordingly, B-X bond has about 1/3 double bond character and about 2/3 single bond character. Though the present treatment utilizes some simplifying assumptions, it may be noted that the double bond character is found to be appreciably lower than Pauling's estimate in both of the two compounds. A similar situation was also met in the case of p-dichlorobenzene^{16), 17)}: the double bond character derived from quadrupole resonance data was far less than that formerly estimated from the bond distance.

B. Origin of Doublet Structure. As described above, the doublet lines are not expected from the crystal structure. It is another evidence of nonstructural origin of the doubling that the two lines showed similar behavior in the temperature dependence of the frequencies and in the Zeeman effect.

The doublet separation of the Cl^{35} resonance line, about 4 kc, is of the order of spin-spin interaction. The largest spin-spin coupling acts between the pair of boron and halogen atoms which form the direct bond, for it is the shortest inter-atomic distance in the boron halide crystal. The B-Cl distance of 1.75A

from the X-ray analysis and the spin moment of 2.7 nuclear magnetons of B^{11} (the abundance ratio of B^{11} being 81%) give the splitting of the order of 2.1 kc in case when $\eta=0$. It should be noted that Douglass calculated the splitting due to the same spin-spin interaction for B-Cl in case of $\eta=\pm 1$. Change in η gives different patterns but the total splitting is of the same order. Similarly the splitting is found to be 4.5 kc for bromine by assuming B-Br distance to be 1.87A and $\eta=0$. The calculated value for Cl^{35} is almost the same order as the observed one, 4 kc, but for Br^{79} it is too small to explain the observed separation 26 kc. It clearly indicates that the spin-spin interaction is not the main origin of the doublet. Each line of the doublet is remarkably broad, the width being almost 2 kc for BCl_3 and 10 kc for BBr_3 , which may be attributed to the spin-spin interaction discussed above.

A reasonable explanation of the doublet structure can be found in the difference of the mean square amplitudes of molecular vibrations in $B^{10}X_3$ and in $B^{11}X_3$ molecules as Douglass pointed out. When a bond with q of axial symmetry oscillates about a space-fixed axis, the q decreases to $q_0\left(1-\frac{2}{3}\langle\theta^2\rangle\right)$, where q_0 is its original value and $\langle\theta^2\rangle$ denotes the mean square amplitude of the angle of oscillation¹⁸⁾. In crystals the oscillation may be either lattice mode or intramolecular vibration, so that the difference in $\langle\theta^2\rangle$ caused by boron isotopes will reflect on a change in resonance frequency, and thus produces a doublet. Douglass calculated this effect and concluded that, though the agreement between the observed and the calculated is not very good, this is more likely to be the origin of the doubling.

In the present paper a similar calculation is also made for both BCl_3 and BBr_3 . The procedure and the values used in the calculation are somewhat different from Douglass' ones a) in the formula of temperature dependence of vibration in the presence of η , and b) in the frequencies of the normal vibrations and force constants.

Wang¹⁹⁾ derived a formula for the effect of molecular torsional motions on the shift of the quadrupole frequency of a nucleus with spin 3/2 in a field gradient without axial

** At the first glance it seems unreasonable for estimating η to use the value 42.9 Mc/s of the eQq which was obtained by assuming $\eta=0.24$. The assumed value of η was used to make a small correction for the asymmetry factor which is often neglected. In fact the correction is only 1%.

symmetry.

His final formula is

$$h\nu = q' \left(1 + \frac{1}{3} \eta'^2 \right)^{1/2} \quad (8)$$

where

$$q' = q \left[1 - \frac{3}{2} (\langle \theta_x^2 \rangle + \langle \theta_y^2 \rangle) + \frac{1}{2} \eta (\langle \theta_y^2 \rangle - \langle \theta_x^2 \rangle) + \frac{1}{2} (3 - \eta) \langle \theta_x^2 \rangle \langle \theta_y^2 \rangle \right], \quad (9)$$

and

$$\eta' = (q/q') \left[\eta + \frac{3}{2} (\langle \theta_y^2 \rangle - \langle \theta_x^2 \rangle) - \frac{1}{2} \eta (\langle \theta_y^2 \rangle + \langle \theta_x^2 \rangle) + \frac{1}{2} (3 - \eta) \langle \theta_x^2 \rangle \langle \theta_y^2 \rangle \right], \quad (10)$$

and $\langle \theta_x^2 \rangle$ and $\langle \theta_y^2 \rangle$ are the mean amplitudes of oscillations about the x and y axis, q and η are referred to the molecule at rest. Substituting Eqs. (9) and (10) into Eq. (8) and expanding it in the power series of $\langle \theta^2 \rangle$,

$$h\nu = h\nu_0 (1 - \alpha \langle \theta_x^2 \rangle - \beta \langle \theta_y^2 \rangle), \quad (11)$$

where

$$h\nu_0 = \frac{1}{2} e Q q \left(1 + \frac{1}{3} \eta^2 \right)^{1/2}, \quad (12)$$

and

$$\left. \begin{aligned} \alpha &= \left(3 + 2\eta + \frac{1}{3} \eta^2 \right) / 2 \left(1 + \frac{1}{3} \eta^2 \right), \\ \beta &= \left(3 - 2\eta + \frac{1}{3} \eta^2 \right) / 2 \left(1 + \frac{1}{3} \eta^2 \right). \end{aligned} \right\} \quad (13)$$

Eq. (13) is more appropriate than that used by Douglass, since the latter is lacking in the terms arising from $(m, m \pm 2)$ th energy matrix elements which have a significance of the first order.

In this calculation, the procedure of computing the mean square amplitudes about a space-fixed direction by use of a relation of Cartesian displacements to the normal vibrations is applied. This is convenient for treating complicated molecules. The Cartesian displacements $\mathbf{X}$ are related to the normal coordinates $\mathbf{Q}$ by the well-known matrix expression of $\mathbf{X} = \mathbf{A}\mathbf{Q}$, where $\mathbf{A} = \mathbf{M}^{-1} \mathbf{B}' \mathbf{U}' \times (\mathbf{L}^{-1})^{20}$. Therefore θ_j can easily be expressed by the normal coordinates:

$$\theta_j = \sum_i D_{ij} Q_i. \quad (j=x, y \text{ or } z) \quad (14)$$

Thus by taking time-average,

$$\langle \theta_j^2 \rangle = \sum_i D_{ij}^2 \langle Q_i^2 \rangle. \quad (15)$$

and

$$\langle Q_i^2 \rangle = \frac{h}{8\pi^2 \nu_i} \coth \frac{h\nu_i}{2kT}. \quad (16)$$

Normal frequencies used in the present calculation were those determined recently by Lindeman and Wilson²¹. From these normal frequencies generalized force constants, one for out-of-plane and three for in-plane degenerate modes were obtained. Then $\langle \theta^2 \rangle$'s were obtained by the method described above. The difference in the mean amplitudes due to boron isotopes gave different values of $B^{10}X_3$ and $B^{11}X_3$. The calculated values of the splitting were compared with the observed ones in the form of a fraction to the resonance frequency, that is,

$$\frac{\Delta\nu}{\nu} = \alpha (\langle \theta_x^2 \rangle_{B^{10}} - \langle \theta_x^2 \rangle_{B^{11}}) + \beta (\langle \theta_y^2 \rangle_{B^{10}} - \langle \theta_y^2 \rangle_{B^{11}}). \quad (17)$$

The results are shown in Tables II and III.

Table II. Calculated difference of mean square amplitudes ($\langle \theta^2 \rangle_{B^{10}} - \langle \theta^2 \rangle_{B^{11}}$) between $B^{10}X_3$ and $B^{11}X_3$ at 77°K (in 10^{-4}).

vibrational mode	BCl_3	BBr_3
ν_2	0.577	0.577
ν_3	0.329	0.294
ν_4	-0.010	-0.004

Table III. Calculated and observed splitting given in the fraction to the original frequency, $\Delta\nu/\nu \times 10^4$.

	$(\Delta\nu/\nu)_{\text{calcd}}$			$(\Delta\nu/\nu)_{\text{obsd}}$
	out-of-plane	in-plane	total	
BCl_3	0.716	0.549	1.265	1.70
BBr_3	0.586	0.540	1.126	1.49

A fair agreement between the observed and the calculated values is seen in the Table. It is noted that the out-of-plane mode makes larger contribution than the in-plane ones. The mean square amplitude of $B^{11}X_3$ is smaller than that of $B^{10}X_3$ and, therefore, the resonance line due to the former lies on the higher frequency side than that of the latter. As pointed out by Douglass, it is in good accord with the intensity ratio of the two lines; the line of higher frequency is stronger than that of lower frequency, which is expected from the abundance ratio of boron isotopes.

Several accounts will be considered with regards to the small discrepancy between the calculated and the observed values.

1. *The use of force constants obtained in the gaseous state instead of those in the solid state.* Since the normal modes in the solid state are not known, the mean amplitudes were calculated by use of the data in the gaseous state. In the molecular crystal, however, it cannot be considered to be very serious.

2. *The neglect of the stretching effect.* The dependence of q on the stretching coordinate of the bond was neglected in the calculation. Actually for some compounds, a small change of eQq associated with the stretching of a bond was found from the microwave spectroscopy²²⁾. The change is associated with the increase in the mean bond distance by the anharmonic part of stretching vibration. Unfortunately, there is no way of estimating the effect for the present case.

3. *Bond orbital following effect.* In the above calculation, the direction of the principal axis of the maximum q is considered to lie on the line connecting the boron to the halogen nuclei. However, if the bonding orbital does not follow exactly to the direction, the bending angle of q is not equal to that of B-X. Then, the mean amplitude $\langle\theta^2\rangle$ is likely to be larger than that in the above calculation. Similar effect was found in the case of ICN by the microwave spectroscopy²²⁾, where the change of eQq from the ground vibrational state to an excited state of the bending mode was slightly larger than that calculated from the mean amplitude.

From the above discussion, it is easily understood that the agreement given in Table III is quite good. At any rate it is safe to conclude that the origin of the doubling is the isotope effect of the mean amplitude. In the present study fine structure was not detected both in BCl_3 and in BBr_3 . Judging from the close resemblance of the line shape in BCl_3 and BBr_3 , the doubling mechanism must be the same for both cases.

A definite evidence which excludes both direct and indirect spin-spin effect* from be-

* The latter effect is referred to in the book by Das and Hahn as being cited from Douglass' conclusion. This is, however, far from the contents of his thesis. The author is grateful to Professor S. Kojima for pointing out this misquotation.

ing the origin of doublet is presented by the following observation. If the spin-coupling is the main origin of the doubling, the ratio of the doublet separation of Br^{79} and Br^{81} must be proportional to $\mu^{79}/\mu^{81}=0.927$, since the spin-coupling is proportional to the product of the magnetic moments of boron and halogen nuclei. On the other hand, if the doublet is due to the isotope effect of molecular vibration, the separation is proportional to $Q^{79}/Q^{81}=1.197$, since the observed separation should be $\frac{1}{2}eQ(\Delta q)$, where Δq is the same for Br^{79} and Br^{81} . The doublet separation was carefully measured both for Br^{79} and Br^{81} lines and the result was $26.1/21.6=1.21$, which agreed with the latter prediction. Therefore, it is sure that the origin of the doubling is the isotope effect of boron on molecular vibration and the spin-spin coupling, thought it is present, may be only effective within each line of the doublet. In fact, ν_{I} line is appreciably broader than ν_{II} in both compounds, which may be associated with the magnetic moment of B^{10} and B^{11} nuclei. In BCl_3 similar consideration cannot provide a conclusive evidence since $Q^{35}/Q^{37}=1.27$ is close to $\mu^{35}/\mu^{37}=1.20$.

The lattice vibration might be effective in the similar sense to the splitting of the resonance line, since the difference of the masses of isotopes of Cl^{35} and Cl^{37} or Br^{79} and Br^{81} cannot be overlooked. If one of the lattice mode, for example, a torsional oscillation about the figure axis, is considered, the splitting due to the isotope effect similar to that described above will occur in BCl_3^{35} , $\text{BCl}_2^{35}\text{Cl}^{37}$, $\text{BCl}^{35}\text{Cl}_2^{37}$ and BCl_3^{37} . However, lattice frequencies are considered to be so low that the condition $h\nu < kT$ is fulfilled. As seen in the Appendix, the effect of isotopic mass does not enter so long as the force constant remains unchanged. Thus the vibrations which are effective in the isotope splitting are only those having $h\nu > kT$ and, consequently, it is sufficient to consider only intermolecular vibrations.

Acknowledgment

The author wishes to express his gratitude to Professor Y. Morino for his kind guidance and encouragement throughout the course of this work. The author is also grateful to Professor S. Kojima and Dr. A. Shimauchi,

Tokyo University of Education, for their kind advice and discussions. He is also indebted to Mr. H. Shimizu for a help in the preparation of the samples. The expenses of the work were defrayed from the Scientific Research Encouragement Grant of the ministry of Education, to which the author's thanks are also due.

Appendix

Effect of Isotopic Mass on the Mean Amplitude. The magnitude of a change of a mean amplitude caused by mass difference depends on $h\nu/kT$. It is illustrated by a simplified one-dimensional model.

The mean amplitude of a vibration of frequency is given by

$$\langle A^2 \rangle = \frac{h}{8\pi^2\nu} \coth \frac{h\nu}{2kT} = \frac{h\nu}{f} \left(\frac{1}{2} + \frac{1}{e^{h\nu/kT} - 1} \right), \quad (\text{A.1})$$

where

$$\nu = \frac{1}{2\pi} \sqrt{\frac{f}{m}}, \quad (\text{A.2})$$

and f and m denote respectively a force constant and an effective mass of the vibration. The fractional change of the mean amplitude $\frac{\Delta \langle A^2 \rangle}{\langle A^2 \rangle}$ caused by a fractional change of the mass $\Delta m/m$ is, therefore, given by

$$\frac{\Delta \langle A^2 \rangle}{\langle A^2 \rangle} / \frac{\Delta m}{m} = \frac{xe^x}{e^{2x} - 1} - \frac{1}{2}, \quad (\text{A.3})$$

where

Fig. 4.

$$x = h\nu/kT.$$

The value is plotted against x in Fig. 4. From the curve it can be seen that the isotopic mass difference has a negligible effect when $h\nu \lesssim kT$, provided the force constant remains unchanged.

Zeeman Effect of Nuclear Quadrupole Resonance Spectrum in Cyanuryl Chloride

By Yonezo MORINO, Takehiko CHIBA, Takashi SHIMOZAWA,
and Masaharu TOYAMA

*Department of Chemistry, Faculty of Science
University of Tokyo, Tokyo*

(Received April 7, 1958)

A study on the Zeeman effect of Cl^{35} nuclear quadrupole resonance spectrum was carried out on a single crystal of cyanuryl chloride. Three distinct q -tensors were found in this crystal, two of them being equivalent. The directions of the principal axes were determined within the accuracy of 1° . It was concluded that in the crystal all molecules are disposed parallel (or antiparallel) to one another and three C-Cl bonds of a molecule are on a plane, making an angle 120° with one another, one of them being not equivalent to the other two. A large asymmetry parameter, 0.26, was obtained. From the coupling constant and the asymmetry parameter, the double bond character and the ionic character of C-Cl bonds were estimated to be 10% and 17%, respectively. The large double bond character was considered to be associated with the large electronegativity of nitrogen atoms in the ring.

§ 1. Introduction

The first study on the Zeeman effect of nuclear quadrupole resonance spectrum in a single crystal was accomplished by Dehmelt¹⁾ for the iodine nuclei in tin tetraiodide. Livingston and Zeldes²⁾ made a study on the iodine nuclei in iodic acid and showed an evidence of extra Zeeman components resulted from proton interaction. Dean³⁾ made a study on the chlorine nuclei in *p*-dichlorobenzene. Meal⁴⁾ applied the Zeeman study on the chlorine nuclei in *p*-chloroaniline to the crystal analysis. Kojima et al.^{5), 6)} made comprehensive studies on the Zeeman splitting of nuclear quadrupole resonance lines of single crystals of bromine and *p*-dibromobenzene, obtaining accurate values of asymmetry parameters.

Two valuable informations are obtained from the Zeeman studies. One is the spatial orientation of the principal axes of the electric field gradient tensor (q_{ij}) at the nucleus. As the principal axis of the q -tensor is considered to lie on the bond direction at such a nucleus as chlorine in the C-Cl bond, the Zeeman effect is useful for the study of the crystalline structure or of the molecular structure in the solid state. The other information is the asymmetry parameter η of the q -tensor. Although in the case of $I=1$ or $I \geq 2$ it can be obtained from the nuclear quadrupole resonance spectrum in the absence of a magnetic

field, in the case of $I=3/2$ as chlorine nucleus it can only be obtained by the Zeeman study. The most important contribution to η in such a case as chlorine in the C-Cl bond is considered to come from the double bond character of the bond, since a single σ -bond provides no asymmetry to the q -tensor. Hence the measurement of the asymmetry parameter gives a unique method for estimating contribution of π -bond. Thus the Zeeman effect is valuable for the study on the nature of a bond.

The molecular structure of cyanuryl chloride was studied by Akimoto⁷⁾ by use of the electron diffraction by gaseous molecules, but the crystalline structure is not completely known; only its space group was reported to be C_{2h}^6 by Hoppe *et al.*⁸⁾ The nuclear quadrupole resonance spectrum of the chlorine nuclei in cyanuryl chloride without the applied magnetic field was recently reported by Negita *et al.*^{9), 10)}, whose results are in good agreement with those of the present work.

§ 2. Theory

The Zeeman effect of nuclear quadrupole resonance spectrum was first solved by Krüger¹¹⁾ in the case of axially symmetric q -tensor. Bersohn¹²⁾ expanded it to the atoms with asymmetric q -tensors and nuclear spin quantum number of half integers and calcu-

lated the energy levels to the first order in the magnetic field H and to the second order in the asymmetry parameter η .

The principal axes of a q -tensor are defined as the x , y and z -axes, the z -axis representing the direction of the largest component and the x -axis that of the smallest one. Then

$$0 \leq \eta \leq 1,$$

where

$$\eta = (q_{xx} - q_{yy})/q_{zz}. \quad (1)$$

In the absence of a magnetic field, the energy levels of $m = \pm 3/2$ or $\pm 1/2$ of quadrupole coupling for a nucleus with a spin quantum number $I = 3/2$ are degenerate, so that only one resonance line is observed corresponding to the transition between the two levels. By applying a magnetic field, each doubly degenerate level splits into two mixed levels and the resonance line splits into four lines corresponding to four transitions as shown in Fig. 1. Although the transition be-

Fig. 1. Splitting of the energy levels for $I = 3/2$ by the Zeeman effect.

tween two mixed levels of $m = \pm 1/2$ is also possible from the selection rule $\Delta m = \pm 1$, its resonance line exists at a region of so low frequency that it is not observed in the usual work, when the applied magnetic field is small.

By an approximate calculation to the first order in H the frequencies ν_1 , ν_1' , ν_2 and ν_2' of four splitting lines are given by

$$\left. \begin{aligned} \nu_1, \nu_1' &= \nu_0 \pm s \\ \nu_2, \nu_2' &= \nu_0 \pm t \end{aligned} \right\} \quad (2)$$

where ν_0 is the unperturbed resonance frequency given by

$$\nu_0 = \frac{eQq_{zz}}{2h} \xi; \quad \xi = \left(1 + \frac{1}{3}\eta^2\right)^{1/2} \quad (3)$$

and s and t are the splittings given by

$$\left. \begin{aligned} s \Big| \\ t \Big| \end{aligned} \right\} &= \frac{\mu}{3h\xi} \{ [(4\xi^2 - 2\xi - 2)H^2 - (3\xi^2 - 6\xi - 6)H_z^2 \\ &\quad + 2\eta(\xi - 1)(H_x^2 - H_y^2)]^{1/2} \\ &\quad \pm [(4\xi^2 + 2\xi - 2)H^2 - (3\xi^2 + 6\xi - 6)H_z^2 \\ &\quad - 2\eta(\xi + 1)(H_x^2 - H_y^2)]^{1/2} \} \quad (4)$$

where μ is the nuclear magnetic moment, H_x , H_y and H_z are the components of the applied magnetic field in the three principal axes of the q -tensor, and h is Planck's constant. Eqs. (2), (3) and (4) hold for any value of η . In the ordinary case where η is small compared to 1, Eq. (4) can be reduced to the following approximate formula of the second order in η^* :

$$\left. \begin{aligned} s \Big| \\ t \Big| \end{aligned} \right\} &= \frac{\mu}{3h} \{ [9H^2 + \eta^2(H^2 - 3H_z^2)]^{1/2} \\ &\quad \pm [(4H^2 - 3H_z^2) - 4\eta(H_x^2 - H_y^2) \\ &\quad + (1/3)\eta^2(H^2 - 3H_z^2)]^{1/2} \}. \quad (5)$$

The direction of the principal axes of the q -tensor at the nucleus under consideration can be obtained by comparing the observed splitting curves with the theoretical ones (Fig. 2).

Fig. 2. Angular dependence of the Zeeman effect.

The splitting frequencies, when the magnetic field is applied parallel to the principal axes⁸ are given by

$$\left. \begin{aligned} s_z &= s_0, & s_y &= s_0(1 + \eta), & s_x &= 2s_0, \\ t_z &= s_0(1 - \eta), & t_y &= s_0, & t_x &= s_0, \end{aligned} \right\} \quad (6)$$

* The coefficients of the η^2 -terms in Eq. (5) slightly differ from those of Bersohn's¹²⁾ and Kojima's^{5),6)} formula.

where

$$s_0 = \frac{2}{3} \cdot \frac{\mu H}{h}$$

It should be noted in the z -direction the outer splitting is twice as large as the inner one, and the latter is equal to the outer splitting in the x -direction as well as to the inner splitting in the y -direction. It provides a good clue for the determination of the principal axes, as shown later. The asymmetry parameter η is calculated from the splitting in the direction of the axis x or y as follows:

$$\eta = \frac{s_x - t_x}{s_x} = \frac{s_y - t_y}{t_y} \quad (7)$$

The parameter η can also be obtained by measuring the directions in which three-line patterns are observed. The directions of the three-line patterns are given by putting $t=0$ into Eq. (5); it is easily shown that

$$\eta = \{ -3(H_x^2 - H_y^2) \pm [9(H_x^2 - H_y^2)^2 + 6(H^2 - 3H_x^2)^2]^{1/2} \} / (H^2 - 3H_x^2), \quad (8)$$

where the $\pm$ signs must be taken as $\eta \geq 0$ by the definition.

§ 3. Resonance Spectrum in the Absence of Magnetic Field

The sample was purified by recrystallization of commercial cyanuryl chloride from benzene solution.

Without the applied magnetic field two resonance lines ν_I and ν_{II} with the intensities of $\nu_I: \nu_{II}=2:1$ were observed at room temperature for both nuclei Cl^{35} and Cl^{37} . The signal to noise ratio was very high. The lines were sharp, the line-widths being about 1 kc. Their frequencies are in good agreement with the observation by Negita *et al.*^{9),10)}

The resonance frequencies were measured at several temperatures as tabulated in Table I. The frequency changes with temperature are plotted in Fig. 3. It is noted that ν_{II} is higher than ν_I at 294°K (the room temperature), but they are reversed at 197°K (dry ice temperature) and coalesce to one line at 77°K

Table I. Pure quadrupole resonance frequencies in chlorine nuclei of cyanuryl chloride.

Temperature (°K)	ν_I^{35} (Mc)	ν_{II}^{35} (Mc)	$\nu_I^{35} - \nu_{II}^{35}$ (Mc)	ν_I^{37} (Mc)	ν_{II}^{37} (Mc)	$\nu_I^{37} - \nu_{II}^{37}$ (Kc)
294	36.2997	36.3172	-17.5	28.6078	28.6202	-12.4
197	36.5502	36.5446	+ 5.6			
77	36.7708	36.7708	0			

$$\nu_I^{35}/\nu_I^{37} = 1.26891 \pm 0.00002, \quad \nu_{II}^{35}/\nu_{II}^{37} = 1.26894 \pm 0.00002 \quad (\text{at } 294^\circ\text{K})$$

Fig. 3. Temperature dependence of the Cl^{35} resonance frequencies.

(liquid nitrogen temperature). This anomalous feature in temperature dependence suggests an existence of a transition point between

77°K and 197°K, but in order to confirm the existence it is necessary to detect abrupt change of the resonance frequencies at a specified temperature.

The mean frequency of the two lines at 0°K is estimated to be 36.83 Mc by extrapolation. The ratio ν_I^{35}/ν_I^{37} and $\nu_{II}^{35}/\nu_{II}^{37}$ are in good agreement with the ratio Q^{35}/Q^{37} of the quadrupole moments of the two nuclei.

§ 4. Zeeman Effect of the Resonance Lines for Cl^{35}

A). *Preparation of a Single Crystal.* A single crystal of cyanuryl chloride was prepared by the pointed-bottom-crucible method¹³⁾. The apparatus is schematically illustrated in Fig. 4. A diaphragm was put between the electric furnace and the cooler to keep a suitable temperature gradient. The sample contained in an ampule with a sharp-pointed

bottom was melted in the furnace and then lowered into the cooler to freeze into a single crystal. A good single crystal was obtained at the lowering rate of about 3 mm/hr under such a temperature gradient as shown in Fig. 5.

B). *Apparatus for Observation.* A super-regenerative spectrometer¹⁴⁾ was used. The splitting frequencies were measured by recording the resonance lines as derivative curves of the absorption.

The magnetic field was furnished by Helm-

holtz coil with a field strength of 108 gauss/ampere at the center (Fig. 6). The field actually used was about 10 gauss. The Helmholtz coil can be rotated in a whole range of angle about the vertical axis, but it cannot be inclined beyond 40° from the vertical axis

Fig. 4. Apparatus for preparation of single crystals.

Fig. 5. Temperature distribution in the apparatus shown in Fig. 4.

Fig. 6. Magnet for the Zeeman effect.

because of the contact of the lead-wire of the rf-coil with the edge of the Helmholtz coil. All the spherical angles were covered by carrying out several runs at different angular positions of the crystal mounting.

C). *Method of Observation.* The observation with the applied field showed that the line ν_I splits into eight lines in general and ν_{II} into four. Since a resonance line of a q -tensor splits into four lines by a magnetic field, the above result indicates that ν_{II} is due to one kind of q -tensor q_{II} , whereas ν_I is due to two kinds of q -tensors q_I and q_I' which are equivalent each other except the direction in the crystal. Any direction on the two planes which bisects the angles between the principal axes z_I and z_I' (the direction of the maximum q components of q_I and q_I') is equivalent for both q_I and q_I' . Hence the fields in these directions yield the same splitting lines for q_I and q_I' , so that ν_I splits into four lines. Such planes were first determined by searching the directions where the four-line patterns of ν_I were observed. These planes are called XZ - and YZ -planes. The

Z-axis, the intersection of the two planes XZ and YZ , is perpendicular to both z_I and z_I' . In other words, z_I and z_I' are on the plane XY thus determined. In order to determine the angle between z_I and z_I' on this plane and to locate the direction of the q_{II} referring to the axes X, Y and Z , the splittings by the magnetic field in the directions on the planes XY, YZ and ZX were observed. The splitting frequencies were measured by referring to the difference between the two resonance lines $\nu_{II}-\nu_I$, and were reduced to the values at a certain field strength by use of the value of electric currents in the Helmholtz coil.

D). *Results.* A good confirmation of the directions of the principal axes of the q -tensor

is provided by the consideration of the symmetry property; an axis is determined to be one of the principal axes, if symmetric splitting curves with respect to this axis are obtained in two planes involving it. The observed Zeeman splitting curves are plotted against the direction of the field in Fig. 7. The X, Y and Z axes, therefore, correspond to the three principal axes of the q_{II} -tensor; the X -axis is the principal z -axis, because in the X -direction the outer splitting s_{II} is twice as large as the inner splitting t_{II} , as required by Eq. (6). The Y - and Z -axes are the y - and x -principal axes, respectively, because the inner splitting t_{II} in the Y -direction is equal to the inner splitting t_{II} in the X -direction as well as to the outer splitting s_{II} in

Fig. 7. Angular dependence of the Zeeman effect of Cl^{35} resonance lines in cyanuryl chloride.

a) In the XZ plane

Fig. 7.
b) In the YZ plane

the Z-direction (compare Eq. (6)).

For the q -tensors, q_I and q_I' , the X -axis is also concluded to be one of the principal axes from the symmetrical shape of the splitting curves of ν_I in the XZ - and YZ -planes. Eight splitting curves of ν_I in the XY -plane are classified into two groups: one due to the q_I -tensor and the other due to the q_I' -tensor. Two inner splittings t_I and $-t_I$ which are symmetric with respect to ν_I are due to the same q -tensor, for instance, q_I , and similarly t_I' and $-t_I'$ which are symmetric with the formers with respect to the X - and Y -axes are due to the other, q_I' . The splitting curves due to the same q -tensor must have the same symmetrical dependence on the angles whether they are outer or inner. $\pm s_I$ and $\pm t_I$, there-

fore, compose a group of splitting curves due to q_I , and $\pm s_I'$ and $\pm t_I'$ compose a group due to q_I' . Since the Z -axis is one of the principal axes for both the q_I - and q_I' -tensors, the others must be on the XY -plane; they were found to lie in the directions $(X+30^\circ Y)$ and $(X-60^\circ Y)$ for the q_I -tensor and $(X-30^\circ Y)$ and $(X+60^\circ Y)$ for the q_I' -tensor, where $(X+30^\circ Y)$ designates the direction 30° far from the X -axis towards the Y -axis on the XY -plane. The principal axes x , y and z are assigned from the splittings in each directions as tabulated in Table II. It is noted that the principal x -axes are along the Z -axis for all q -tensors.

The values of the asymmetry parameters η are determined from the splittings in the

Fig. 7.
c) In the XY plane

Table II. The principal axes of the q -tensors.

	x -axis	y -axis	z -axis
q_I	Z	$X+30^\circ Y$	$X-60^\circ Y$

XY -plane	$X-8^\circ Y$ $X+69^\circ Y$	$X+8^\circ Y$ $X-69^\circ Y$	$X+51.5^\circ Y$
YZ -Plane	$Z+37.5^\circ Y$	$Z+37.5^\circ Y$	None
ZX -Plane	None	None	$Z+31^\circ X$

(the exp. error; $\pm 1^\circ$)

the angle 51.5° , the value of η is also calculated by Eq. (8) to be

$\eta = 0.26 \pm 0.08$.

This is in good agreement with the results from the splittings in the directions of the principal x - and y -axes.

The observed splitting curves are in good agreement with the theoretical ones which are calculated by putting into Eq. (5) the observed directions of the principal axes and the asymmetry parameters of the q -tensors (see Fig. 7). Slight discrepancies are found in the splitting of ν_{II} near the Z -axis.

The intensities of the outer splitting lines are weaker than those of the inner, and they increase by approaching to the x - and y -axes, whereas they decrease to the z -axis and then become unobservable at the z -axis, just as expected from the theory. But an unexpected feature appeared in a small range close to the x - and y -axes, where the intensities of the outer splitting lines decreased.

The pure quadrupole coupling constant is calculated by Eq. (3) by using the value of η together with that of the resonance frequency $\nu_0 = 36.83$ Mc which is extrapolated from the observed to 0°K ; the result is

$$(eQq)_{\text{Cl}^{35}} = 73.0 \text{ Mc.}$$

§ 5. Discussion

A). *Directions of the C-Cl bonds.* The chlorine atoms corresponding to the electric field gradient tensor q_I , q_I' and q_{II} are denoted by Cl_I , Cl_I' and Cl_{II} , respectively. Since in the C-Cl bond the principal z -axis of the q -tensor at the Cl nucleus is considered to agree with the direction of the bond, the principal z -axes z_I , z_I' and z_{II} of the above q -tensors represent the directions of the bonds C- Cl_I , C- Cl_I' and C- Cl_{II} . Hence there are three kinds of directions of the C-Cl bonds in the crystal. These three directions correspond to those of the three C-Cl bonds in a molecule, because one molecule of cyanuryl chloride contains three Cl atom whose bond directions are different from one another.

From the directions of the z -axes listed in Table II, the angles between the C-Cl bonds are obtained to be either 60° or 120° . Here are two values because of the quadratic nature of q -tensor, but it seems most plausible to prefer the latter such a molecule as cyanuryl chloride. The error of measurement of angles is about 2° . Thus

$$\widehat{\text{Cl}_I\text{Cl}_I'} = \widehat{\text{Cl}_I\text{Cl}_{II}} = \widehat{\text{Cl}_I'\text{Cl}_{II}} = 120^\circ \pm 2^\circ,$$

The angles can also be obtained from the directions in which three-line patterns were observed: that is,

$$\begin{aligned} \widehat{\text{Cl}_I\text{Cl}_I'} &= 119^\circ, \\ \widehat{\text{Cl}_I\text{Cl}_{II}} \text{ and } \widehat{\text{Cl}_I'\text{Cl}_{II}} &= 119.5 - 120.5^\circ, \end{aligned}$$

which agree with the value mentioned above within the range of experimental error.

The most probable structure of cyanuryl chloride molecules is thus concluded to be the planar structure as shown in Fig. 8,

Fig. 8. Disposition of cyanuryl chloride molecules in the crystal.

where all the constituting atoms are arranged on one plane and the angles between the C-Cl bonds are all $120^\circ \pm 2^\circ$. Although the Zeeman effect determines the angles between each pair of the three C-Cl bonds, it cannot give the relative positions of the bonds with the triazine ring. Therefore any configuration cannot be discarded in which the triazine ring inclines from the XY -plane, so long as the three bonds remain at the directions described above.

The nuclear quadrupole resonance spectrum obtained above gives informations on the crystalline structure too. As only two lines which corresponded to the three Cl nuclei in a molecule were observed, it is concluded that all the molecules occupy equivalent positions in the crystal with the molecular plane parallel to one another and with all the C-Cl bonds parallel or antiparallel to the corresponding bonds in the other molecules. The atoms Cl_I and Cl_I' are located at equivalent positions in the crystal, but not equivalent

to Cl_{II}. This fact, together with the result of the Zeeman effect that the angle $\widehat{\text{Cl}_{II}\text{Cl}_I}$ is equal to that of $\widehat{\text{Cl}_{II}\text{Cl}_I'}$, leads to the conclusion that the crystal has a plane of symmetry through the C-Cl_{II} bond and perpendicular to the XY-plane. The frequency shift between ν_I and ν_{II} must come from a slight difference of the environment of the chlorine nuclei in the crystal.

It was observed that by cooling the crystal cracks run parallel to the XY-plane through the crystal, that is, to the molecular planes in the crystal (see Fig. 8).

B). *Asymmetry parameter.* The asymmetry parameters of Cl atoms in cyanuril chloride were found to be remarkably large in comparison with those in chlorine derivatives of benzene. It may be attributed to the large double bond character of the C-Cl bonds in cyanuril chloride.

The ionic character i and the double bond character f of the C-Cl bonds are estimated from the values of η and the coupling constant $(eQq)_{\text{obs}}^{15), 16)}$ by the method used by Kojima *et al.* for *p*-dibromobenzene⁶⁾. According to them, the number of unbalanced p -electrons contributing to the q_z -component is given by

$$U_p = \frac{1}{2}(N_x + N_y) - N_z \\ = (1 - i - f)(1 - s) + \frac{1}{2}(1 + \epsilon)(1 - 2s') \quad (9)$$

if the resonance scheme shown in Fig. 9 is

Fig. 9.

assumed for the C-Cl bonds. The π -electrons consisting of the double bond in III are assumed to be supplied from the p_z -orbit of chlorine atom. s and s' denote the s -character of the σ -orbit due to the sp -hybridization in the configurations I and III*, and ϵ denote

* In their treatment of *p*-dibromobenzene, Kojima *et al.* neglected the s character of the σ -bond in the double bond: i.e. they assumed that $s'=0$. It may be reasonable to keep the term s' , as in the above argument.

the change in the screening effect by a positive formal charge at the chlorine atoms in III. Townes and Dailey^{15), 16)} estimated $s=0.15$ and $\epsilon=0.15$ for chlorine atom.

Since $U_p=1$ for a free atom, U_p is calculated by

$$U_p = (eQq)_{\text{obs}} / (eQq)_{\text{atom}}, \quad (10)$$

where $(eQq)_{\text{atom}}$ is the quadrupole coupling constant in a free chlorine atom, that is, 109.7 Mc¹⁷⁾, and $(eQq)_{\text{obs}}$ is the observed in the molecule, that is, 73.0 Mc. Hence $U_p=0.66$ for cyanuril chloride.

The asymmetry parameter η is given by

$$\eta = \frac{U_x - U_y}{U_z} = \frac{3}{2} \frac{f(1 + \epsilon)}{U_z}. \quad (11)$$

Thus the double bond character f is obtained to be 10% from $\eta=0.26$ and $U_p=0.66$ by use of Eq. (11), and from it the ionic character i is calculated to be 17% by Eq. (9). It should be noted that the double bond structure III is as important as the ionic structure II. This feature has already been pointed out by Negita *et al.*

The asymmetry parameter η , the double bond character f and ionic character i of the C-Cl bonds in cyanuril chloride are compared with those of benzene derivatives in Table

Table IV. Comparison of the nature of the carbon-halogen bonds in cyanuril chloride with those in benzene derivatives.

	η	f	i
<i>p</i> -dichlorobenzene ³⁾	0.08	3%	24%
<i>p</i> -dibromobenzene ⁶⁾	0.12	5	15
cyanuril chloride	0.26	10	17

IV. The C-Cl bonds in cyanuril chloride have smaller amount of ionic character and considerably larger amount of double bond character than those in *p*-dichlorobenzene. The C-Br bonds in *p*-dibromobenzene have an intermediate double bond character between them, and the same order of ionic character as cyanuril chloride. These features may be explained in terms of electronegativities of the constituting atoms; the electronegativity of nitrogen is 3.0 which is larger than that of carbon, 2.5, and comparable with that of chlorine, 3.0¹⁸⁾. In cyanuril chloride electrons are attracted towards both the chlorine atoms and triazine ring, and then the contributions

of the configuration III with the double bond should be comparable with that of the ionic configuration II and larger than that of the double bond structure in *p*-dichlorobenzene. The comparison with *p*-dibromobenzene is also established by considering the electronegativity of bromine 2.8 which is smaller than that of chlorine.

It may be interesting to compare the results with 1,3,5-trihalogenobenzenes which have the same symmetry as cyanuryl halides. The comparison of the nuclear quadrupole resonance frequencies was carried out by Negita et al., between cyanuryl chloride and 2-chloropyridine and between 1,3,5-trihalogenobenzene and monochlorobenzene and similar tendencies were concluded.

The x -directions of C-Cl bonds are concluded to be parallel to the Z -axis, that is, perpendicular to the molecular plane for all the Cl atoms. It is a definite evidence that electrons in the p -orbitals which are perpendicular to the plane of the molecule take part in forming the π -bonds.

C). *Temperature Dependence of the Resonance Frequencies.* Both of the resonance frequencies ν_I and ν_{II} decrease with the increase of temperature. This tendency may be explained by the torsional oscillation of molecule as stated by Dehmelt¹⁹⁾, Bayer²⁰⁾, and Wang²¹⁾. According to Bayer, the temperature coefficient of resonance frequency is expressed as a function of temperature as follows:

$$\frac{1}{\nu_0} \frac{d\nu}{dT} = -\frac{3}{2} \frac{h^2}{4\pi^2 k T^2} \sum_m \frac{e^{h\nu_m/kT}}{I_m(e^{h\nu_m/kT} - 1)^2} \quad (13)$$

where ν and ν_0 denote the resonance frequencies at $T^\circ\text{K}$ and 0°K respectively, and ν_m the torsional frequency corresponding to the moment of inertia I_m . When $h\nu_m/kT \ll 1$,

$$\frac{1}{\nu_0} \frac{d\nu}{dT} = -\frac{3k}{8\pi^2} \sum_m \frac{1}{I_m \nu_m^2} \quad (14)$$

Thus so long as the frequency of torsional oscillation is assumed to be independent of temperature, the temperature dependence is regarded as almost linear as shown by Dehmelt¹⁹⁾.

The temperature coefficient for each resonance line is obtained as follows:

$$\frac{1}{\nu_0} \frac{d\nu_I}{dT} = -0.703 \times 10^{-4} \text{ deg}^{-1},$$

$$\frac{1}{\nu_0} \frac{d\nu_{II}}{dT} = -0.637 \times 10^{-4} \text{ deg}^{-1},$$

where the extrapolated value 36.8 Mc was put in ν_0 . They are almost in the same value as those of ordinary organic compounds; for example, for *p*-dichlorobenzene, Wang²¹⁾ obtained $-0.916 \times 10^{-4} \text{ deg}^{-1}$ at 16.9°C and Kushida, Benedek, and Bloembergen²²⁾ $-0.60 \times 10^{-4} \text{ deg}^{-1}$ by correcting the volume change.

The difference of the temperature coefficients between ν_I and ν_{II} may be explained by the nonequivalence of the positions of Cl_{II} and the other two in the crystal. If the three Cl atoms were all equivalent in a crystal, all the modes of torsional oscillations with the axes in the molecular plane would be degenerate. The degeneracy is, however, removed in cyanuryl chloride by the anisotropy mentioned above, so that the frequency ν_{II} depends on two modes of rotations around Y and Z axes, but ν_I depends on all the modes. ν_I and ν_{II} have, therefore, different temperature coefficients, which are given by

$$\frac{1}{\nu_0} \frac{d\nu_{II}}{dT} = -\frac{3k}{8\pi^2} \left[\frac{1}{I_x \nu_x^2} + \frac{1}{I_y \nu_y^2} \right], \quad (15)$$

and

$$\frac{1}{\nu_0} \frac{d\nu_I}{dT} = -\frac{3k}{8\pi^2} \left[\frac{1}{I_x \nu_x^2} + \frac{1}{I_y \nu_y^2} \cos^2 \frac{\pi}{6} + \frac{1}{I_z \nu_z^2} \cos^2 \frac{\pi}{3} \right], \quad (16)$$

where I_x , I_y and I_z are the moments of inertia about the axes X , Y and Z , respectively, and ν_x , ν_y and ν_z are the corresponding torsional frequencies which have not yet been measured for cyanuryl chloride.

In the case of *p*-dichlorobenzene^{21)~23)}, it was found that the contribution of the Z -mode is twice as large as that of the Y -mode. If the same ratio is assumed for cyanuryl chloride, Eqs. (15) and (16) provide the ratio of

$$I_x \nu_x^2 : I_y \nu_y^2 : I_z \nu_z^2 = 1.4 : 2 : 1. \quad (17)$$

Since $I\nu^2$ is proportional to the force constant against the rotational motion, Eq. (17) indicates that the molecule can rotate more easily about the X -axis than about the Y -axis. It seems quite reasonable, because the X -axis is a symmetry axis, whereas the Y -axis is not.

§ 6. Conclusion

1). Cyanuryl chloride molecule has a planar

structure in the crystal, the angles between C-Cl bonds being all $120^\circ \pm 2^\circ$.

2). At room temperature each molecule occupies an equivalent position in a crystal, the corresponding C-Cl bonds being all parallel (or antiparallel) to one another. One of the C-Cl bonds is nonequivalent to the other two. Thus two resonance lines are observed with the relative intensity of $\nu_{II} : \nu_I = 1:2$.

3). Large asymmetry parameters in the Cl atoms, $\eta_I = 0.23$ and $\eta_{II} = 0.26$, were observed, from which the double bond character and the ionic character are estimated to be 10% and 17%, respectively. The large double bond character was explained as the result of large electronegativity of nitrogen atoms in the triazine ring. The electrons in the p -orbitals perpendicular to the molecular plane play a role of π -bond in conjugation with the ring.

4). The difference between the temperature coefficients of ν_I and ν_{II} was discussed by the anisotropy of the crystal field.

Acknowledgement

The authors wish to express our indebtedness to Mr. S. Morita, Research Laboratory of Mitsubishi Chemical Industry, Ltd., for the sample used in this research. The expenses of the work were defrayed from the Scientific Research Encouragement Grant of the Ministry of Education, to which the authors' thanks are also due.

Absorption Spectra of Cr^{3+} in Al_2O_3

Part A. Theoretical Studies of the Absorption Bands and Lines

By Satoru SUGANO

*Department of Physics, Faculty of Science,
University of Tokyo, Tokyo*

and Yukito TANABE

*Department of Applied Physics, Faculty of Engineering,
University of Tokyo, Tokyo*

(Received, April 5, 1958)

In the frame-work of the crystalline field theory, the excited states of Cr^{3+} in Al_2O_3 and the optical transitions to these states are studied taking into account the effect of trigonal field and spin-orbit interaction. Initial splittings and optical anisotropies of the broad band (transitions to quartet states) and the sharp lines (transitions to doublet states) are examined. For the sharp lines, the Zeeman effect is also examined and the Zeeman patterns are predicted. Comparing these theoretical results with those of the experimental ones given in Part B, the assignments of U , Y bands and R_1 , R_2 , B_1 , B_2 lines have been established. It is shown that the g -shifts of the excited doublets observed in the Zeeman patterns can also be explained under such assignments. It is also shown that the experimental data of the optical absorption can be reasonably connected to those of the paramagnetic resonance absorption.

§ 1. Introduction

In the last several years, it has been believed by many authors that the optical spectra of normal complex ions of the first transition-metal elements are reasonably explained by the crystal-field or the ligand-field theory of d -electrons¹⁾. It is true that the theory predicted the positions of the absorption bands and lines in agreement with the experiments and gave reasonable order of magnitudes for the intensities and widths. However, we still feel that a more definite evidence than those mentioned above is needed to confirm the theory because the number of the observed absorption bands in the individual complex is rather limited and the detailed analyses of the sharp absorption lines have not yet been made. The main purpose of this series of papers is to give a more sound foundation to the crystal field theory of optical absorption than that previously established by examining, both theoretically and experimentally, the details of the optical spectra of ruby.

The reason why we adopt ruby for this purpose is as follows:

Similarity of the spectra to those of Cr alum: A single crystal of ruby whose colour is, as well known, due to Cr^{3+} impurities in

Al_2O_3 crystal shows similar spectra to those of Cr alum; The spectra in the visible region consist of two bands (obs. max. at $\sim 18000\text{ cm}^{-1}$ and $\sim 25000\text{ cm}^{-1}$) and of several groups of lines situated at $\sim 14400\text{ cm}^{-1}$ and $\sim 21000\text{ cm}^{-1}$. From the knowledge of the crystal structure (§ 2), we can see that Cr^{3+} impurities which substitute Al^{3+} ion of Al_2O_3 are surrounded almost octahedrally by six nearest O^{2-} ions and are therefore subject to a strong cubic field just as in the case of Cr^{3+} ion in Cr alum. In addition to this cubic field, there is a relatively strong trigonal field whose axis is the optic axis C_3 . Thus we can safely assume that the same treatment will be applicable to both Cr alum and ruby to explain their optical spectra.

Contrast to Cr alum: It has a distinct optic axis and, as will be reported in a later paper, shows a remarkable optical anisotropy which is not observed in the case of Cr alum. It is stable both at high and low temperatures so that we can get much informations on the optical behaviours at these temperatures, while Cr alum is unstable at high temperature and shows phase-transition at low temperature which complicates the interpretation of the line spectra of Cr alum greatly. It shows a

relatively strong luminescence in the red region where the sharp line absorptions are observed. This luminescence is absent in Cr alum.

Thus ruby can provide us with more useful and definite informations than Cr alum that has been regarded as a representative material with its abundance of spectra, the elucidation of which has been the success of the crystal field theory.

Of course, ruby, as a diluted antiferromagnetic substance Cr_2O_3 , has many interesting problems in its own and thus the present study may also be interesting from another point of view.

Experimentally, we have a fairly abundant knowledge about ruby. Deutchbein²⁾ has examined many narrow spectra of both absorption and emission many years ago and Lehmann³⁾ has performed an elaborate experiment on the Zeeman effect of the characteristic doublet R_1 and R_2 observed at $\sim 14400\text{ cm}^{-1}$. There remain, however, some doubts with respect to the quantitative aspect of his experiment. In view of the importance of the Zeeman effect in the analysis of the line spectra, measurements of the Zeeman effect were made again under experimentally better conditions both for the line spectra of R_1 , R_2 and B_1 , B_2 . The absorption lines B_1 and B_2 are located at $\sim 21000\text{ cm}^{-1}$ and their Zeeman effects have not been observed yet. These will be reported in the second paper (Part B).

As for the broad bands, detailed quantitative measurements, especially on splittings and anisotropies, seem absent as far as we know although Thosar⁴⁾ has briefly reported the optical anisotropy of the first band (at the longer wave-length side). The results of experimental studies on these bands will be given in a later paper.

The knowledge about the ground state of ruby are provided by the recent experiments of paramagnetic resonance⁵⁾.

The present paper is devoted to the theoretical consideration which enables us to analyse the experimental facts already known and those to be reported later. Although details of the newly obtained experimental results will be given in later papers, the results that seem definite and important will be sometimes referred to, if necessary, in order to confirm the theory.

§ 2. The Crystal Structure

The crystal symmetry of ruby⁶⁾ is, as well known, rhombohedral with its unit cell containing two molecules of Al_2O_3 . Some of Al^{3+} ions are considered to be substituted by Cr^{3+} ions. Their nearest neighbours are six O^{2-} ions, which form a distorted octahedron around Al^{3+} or Cr^{3+} ion, which has neither inversion nor reflection symmetry (σ_v) as Fig.

Fig. 1. A portion of the Al_2O_3 arrangement projected upon a plane normal to the 3-fold axis C_3 and passing through the apex of a unit rhombohedron. Fractions give distances below the projection plane measured in terms of the height of the unit rhombohedron. Atoms of Al (or Cr) are small, the oxygens are large circles. (Wyckoff, 1948)

1 shows. The symmetry of this distorted octahedron is C_3 whose principal axis passes through the apexes of the unit rhombohedron. It may be noted that the four positions of Al^{3+} in the unit cell are energetically equivalent, since the four distorted octahedrons are transformed into one another by translation or both by translation and inversion at the central ion.

§ 3. The Hamiltonian for the Cr^{3+} Ion and Wave Functions for d -electrons

In our previous papers⁷⁾ on the octahedral complexes, the effect of spin-orbit interaction has been completely neglected. For the analyses of the line spectra of ruby, the spin-orbit interaction plays an essential role together with the trigonal field as we shall see later. Thus the Hamiltonian which we must take for the Cr^{3+} ion in ruby is

$$\left. \begin{aligned} \mathcal{H} &= \mathcal{H}_0 + \mathcal{H}' \\ \mathcal{H}' &= V_{\text{trig}} + V_{80} \end{aligned} \right\}, \quad (3.1)$$

where $\mathcal{H}_0$ is the Hamiltonian for the cubic case without spin-orbit interaction, V_{trig} the trigonal field and V_{so} the spin-orbit interaction. Judging from the similarity of the absorption spectra of ruby to those of Cr alum, we may suppose that the cubic part will be larger than the other two terms. $\mathcal{H}'$ will be treated as a small perturbation to the cubic system.

The eigen-functions of $\mathcal{H}_0$ for the chromophoric electrons are already known. They are given in (3.7) of I*, where the z axis was chosen in the direction of the fourfold axis of the octahedron. The principal axis of the trigonal field in ruby is, however, just one of the three fold axis of the octahedron, and it is

more convenient to take this axis as the axis of quantization in the present case. The cubic bases, namely, the unperturbed eigenfunctions are accordingly transformed so that they span the irreducible representations of both O_h and C_{3v}^{**} ,

$$\varphi(\Gamma M) = \sum_i \varphi(\Gamma \gamma)(\Gamma \gamma | \Gamma M), \quad (3.2)$$

where $\varphi(\Gamma \gamma)$ is the previous cubic base belonging to the γ component of the cubic representation Γ and is abbreviated as

$$\left. \begin{aligned} \varphi(E\gamma) &= (u, v) \\ \varphi(F_1\gamma) &= (\alpha, \beta, \gamma)^* \\ \varphi(F_2\gamma) &= (\xi, \eta, \zeta)^* \end{aligned} \right\}, \quad (3.3)$$

while $\varphi(\Gamma M)$ are abbreviated as follows:

$$\left. \begin{aligned} \varphi(E \pm 1) &= (u_+, u_-) && \text{irreducible representation } E \text{ of } C_{3v} \\ \varphi(F_1 \pm 1) &= (a_+, a_-) && E \\ \varphi(F_1 0) &= a_0 && A_2 \\ \varphi(F_2 \pm 1) &= (x_+, x_-) && E \\ \varphi(F_2 0) &= x_0 && A_1 \end{aligned} \right\}. \quad (3.4)$$

These are at the same time the trigonal bases which belong to the irreducible representation of C_{3v} as shown on the right column of the above table.

The matrix elements of the unitary transformation $(\Gamma \gamma | \Gamma M)$ are given by

$$\begin{array}{c} (E\gamma | EM) \\ \begin{array}{cc} u_+ & u_- \end{array} \\ \hline \begin{array}{cc} -1/\sqrt{2} & 1/\sqrt{2} \\ -i/\sqrt{2} & -i/\sqrt{2} \end{array} \end{array} \quad \begin{array}{c} \alpha(\xi) \\ \beta(\eta) \\ \gamma(\zeta) \end{array} \quad \begin{array}{c} (F_1\gamma | F_1M), (F_2\gamma | F_2M) \\ \begin{array}{ccc} a_+ & a_- & a_0 \\ (x_+) & (x_-) & (x_0) \end{array} \\ \hline \begin{array}{ccc} -\omega/\sqrt{3} & \bar{\omega}/\sqrt{3} & 1/\sqrt{3} \\ -\bar{\omega}/\sqrt{3} & \omega/\sqrt{3} & 1/\sqrt{3} \\ -1/\sqrt{3} & 1/\sqrt{3} & 1/\sqrt{3} \end{array} \end{array}, \quad (3.5)$$

where $\omega = e^{2\pi i/3}$ and $\bar{\omega} = \omega^2$.

Since almost all of the matrix elements of operators needed in this paper are already given in IV, we now proceed to the discussions of what follows from the theory.

§ 4. Optical Anisotropy and Splitting of the Absorption Bands

As pointed out in § 1, the similarity of the absorption spectra of ruby to those of Cr alum leads us to the expectation that the absorption band at $\sim 18000 \text{ cm}^{-1}$, which we call U band hereafter, corresponds to the transition $(f_2^3)^4 A_2 \rightarrow (f_2^2 e)^4 F_2$ in the cubic case and the band

at $\sim 25000 \text{ cm}^{-1}$ (called Y band) to the transition $(f_2^3)^4 A_2 \rightarrow (f_2^2 e)^4 F_1$. This expectation will be confirmed if this assignment could explain the experimental facts⁸⁾, namely the splitting and the optical anisotropy of these bands.

Let us denote by $U^\perp$ and $Y^\perp$ the absorptions of U and Y when the electric vector E of the incident light is perpendicular to the optic axis C_3 , and by $U^\parallel$ and $Y^\parallel$ those when E is parallel to C_3 . The outline of the observed splittings and anisotropies of the bands

* Although actual symmetry of the field which electrons subject to is C_3 , it is allowed to treat it as if C_{3v} when we deal with the crystal energy of d -electrons.

* As to the choice of phase of these bases, see § 2 of IV¹⁰⁾.

to be reported later is as follows: Each absorption peak of $U^{\parallel}$ and $Y^{\parallel}$ is found at the shorter wave-length side of the corresponding peak of $U^{\perp}$ and $Y^{\perp}$. The splitting amounts approximately to 500 cm^{-1} for both U and Y . The absorption intensity of $U^{\perp}$ is much higher than that of $U^{\parallel}$ (the ratio is more than 2), while the absorption intensity of $Y^{\perp}$ is fairly low compared to that of $Y^{\parallel}$ (the ratio is about $1/2$). The intensity of $U^{\perp}$ is comparable to that of $Y^{\perp}$.

These experimental facts, especially the marked optical anisotropies of U and Y offer, as we shall see, important evidences in favour of the above assignments. The study of the optical anisotropy in the present case is as powerful as the study of the optical rotatory power. The importance of the study of the rotatory power in making the assignment of ${}^4F_1$ and ${}^4F_2$ has been recently emphasized by Moffitt⁹⁾.

(a) The splitting

Strictly speaking, we must take the spin-orbit interaction into account as well as the trigonal field, in order to discuss the splitting of the bands. Let us, however, neglect the effect of the former for a while. Then group theory shows that ${}^4F_2$ level splits into two sublevels ${}^4E$ and ${}^4A_1$ of C_{3v} and ${}^4F_1$ into ${}^4E$ and ${}^4A_2$ under the action of the trigonal field. If we adopt the assumption of strong field limit (i.e. neglect of the configuration interaction among the cubic levels), the positions of these split components measured from the respective unperturbed positions of ${}^4F_2$ and ${}^4F_1$ are given by

$$\left. \begin{aligned} f_2^2 e^4 F_2 & \begin{cases} {}^4E \quad ({}^4F_2 x_{\pm} | V_{\text{trig}} | {}^4F_2 x_{\pm}) = K/2 \\ {}^4A_1 \quad ({}^4F_2 x_0 | V_{\text{trig}} | {}^4F_2 x_0) = -K \end{cases} \\ f_2^2 e^4 F_1 & \begin{cases} {}^4E \quad ({}^4F_1 a_{\pm} | V_{\text{trig}} | {}^4F_1 a_{\pm}) = K/2 \\ {}^4A_2 \quad ({}^4F_1 a_0 | V_{\text{trig}} | {}^4F_1 a_0) = -K \end{cases} \\ f_2^2 e^2 {}^4F_1 & \begin{cases} {}^4E \quad ({}^4F_1 a_{\pm} | V_{\text{trig}} | {}^4F_1 a_{\pm}) = K \\ {}^4A_2 \quad ({}^4F_1 a_0 | V_{\text{trig}} | {}^4F_1 a_0) = -2K \end{cases} \end{aligned} \right\}, \quad (4.1)$$

in terms of a parameter K which measures the strength of the trigonal field and is related to the splitting on one electron level f_2 :

$$(f_2 x_{\pm} | v_{\text{rig}} | f_2 x_{\pm}) = K, \quad (f_2 x_0 | v_{\text{trig}} | f_2 x_0) = -2K. \quad (4.2)$$

(The e level is not split by the action of trigonal field. Note also that the trigonal field as a tensor operator is of type F_2 and $V_{\text{trig}} = V_0(F_2)$ in the notation of IV¹⁰⁾).

Thus, as far as we neglect the interaction among the sublevels split from different cubic levels, the magnitudes of the splitting of $f_2^2 e^4 F_2$ and $f_2^2 e^4 F_1$ are both $3K/2$. ${}^4A_1$ and ${}^4A_2$ sublevels are on the shorter wave-length side of each ${}^4E$ sublevels, in case K is negative, and *vice versa*. As will be seen in the next subsection, the present case seems to be just the former one, and we have

$$K \sim -350\text{ cm}^{-1} \quad (4.3)$$

from the observed splitting. This value of K in turn justifies the neglect of the effect of spin-orbit interaction in discussing the splitting of ${}^4F_2$ and ${}^4F_1$, since the order of magnitude of the relevant matrix elements of V_{s_0} will be that of the spin orbit coupling parameter $\lambda = \zeta/3$ which will be at most as large as $\sim 90\text{ cm}^{-1}$ (see § 5).

(b) The optical anisotropy

In the case of octahedral complex ions, all electric dipole transitions between the multiplets $f_2^n e^n S\Gamma_g$ were forbidden at the equilibrium configuration of nuclei because of the presence of centre of symmetry and the observed intensities of the absorption bands of these ions have been explained by taking the vibrational distortion of the octahedron into account.

In contrast, the environment of Cr^{3+} ion in ruby has no centre of symmetry. The naturally unsymmetrical field (the hemihedral part of the trigonal field V_{hem}) will make the electric dipole transition slightly allowed even in the absence of vibrational distortion. Although the effect of the latter might not be quite negligible, we will discard it in the discussion of the optical anisotropy and concern ourselves only with the effect of the former. This is also somewhat justified by the experimental facts to be reported later that the dependence of the oscillator strength of the absorption bands on temperature is slight at relatively high temperatures and that the band shapes vary with temperature roughly in the same way as that of allowed transitions.

The dipole strength of the transition between the ground state ${}^4A_2$ and the component M of the excited state ${}^4T_g$ is the square of the absolute value of the following matrix element:

$$\begin{aligned} & ({}^4A_{2g} | \bar{P} | {}^4T_g M) \\ &= \sum_{\Gamma_u' M'} \frac{({}^4A_{2g} | P | {}^4T_u' M') ({}^4T_u' M' | V_{\text{hem}} | {}^4T_g M)}{W({}^4T_g) - W({}^4T_u')} \end{aligned}$$

$$+ \sum_{u'} \frac{({}^4A_{2g}|V_{\text{hem}}|{}^4\Gamma_u'M')({}^4\Gamma_u'M'|P|{}^4\Gamma_gM)}{W({}^4A_{2g}) - W({}^4\Gamma_u')}, \quad (4.4)$$

where ${}^4\Gamma_u'$ is the higher excited state with odd parity and $W({}^4\Gamma_u')$ is the energy of that state. $\mathbf{P}$ is the electric dipole moment vector $\sum e\mathbf{r}_i$ of the system, $\mathbf{P}=(P_x, P_y, P_z)$. It is more convenient to use the following linear combination of P_x and P_y corresponding to the present choice of bases,

$$\left. \begin{aligned} P_+ &= -\frac{1}{\sqrt{2}}(P_x + iP_y), \\ P_- &= \frac{1}{\sqrt{2}}(P_x - iP_y), \\ P_0 &= P_z, \end{aligned} \right\} \quad (4.5)$$

so that

$$\left. \begin{aligned} \mathbf{P} &= -P_+ \mathbf{k}^+ - P_- \mathbf{k}^- + P_0 \mathbf{k}^0, \\ \mathbf{k}^+ &= -\frac{1}{\sqrt{2}}(\mathbf{i} + \mathbf{j}), \\ \mathbf{k}^- &= \frac{1}{\sqrt{2}}(\mathbf{i} - \mathbf{j}), \\ \mathbf{k}^0 &= \mathbf{k}, \\ |\mathbf{k}^+|^2 &= |\mathbf{k}^-|^2 = \frac{1}{2}(\mathbf{i}^2 + \mathbf{j}^2), \end{aligned} \right\} \quad (4.6)$$

where $\mathbf{i}$, $\mathbf{j}$ and $\mathbf{k}$ are the unit vectors in the directions of x , y and z coordinate axes respectively.

V_{hem} must be invariant under the trigonal rotation, and changes sign under the inversion with respect to the origin. If it is expanded in powers of the coordinates of electrons, the first term which will be predominant is of the form $\kappa \sum_i z_i$. This term is of type F_{1u} as

an irreducible tensor operator and will be denoted as $V_0(F_{1u})$ in the following. If we assume $V_{\text{hem}} = V_0(F_{1u})$, the excited state ${}^4\Gamma_u'$ in (4.4) is restricted to ${}^4F_{2u}$, since $\mathbf{P}$ is also an operator of the type F_{1u} . Then we find

$$\left. \begin{aligned} \langle {}^4A_2 | \bar{\mathbf{P}} | {}^4F_{2x_{\pm}} \rangle &= \pm \frac{i}{\sqrt{2}} \cdot \alpha({}^4A_2 \rightarrow {}^4F_2) \cdot \mathbf{k}^{\pm}, \\ \langle {}^4A_2 | \bar{\mathbf{P}} | {}^4F_{2x_0} \rangle &= 0, \end{aligned} \right\} \quad (4.7)$$

$$\left. \begin{aligned} \langle {}^4A_2 | \bar{\mathbf{P}} | {}^4F_{1a_{\pm}} \rangle &= -\frac{1}{\sqrt{6}} \cdot \alpha({}^4A_2 \rightarrow {}^4F_1) \cdot \mathbf{k}^{\pm}, \\ \langle {}^4A_2 | \bar{\mathbf{P}} | {}^4F_{1a_0} \rangle &= \frac{\sqrt{2}}{\sqrt{3}} \cdot \alpha({}^4A_2 \rightarrow {}^4F_1) \cdot \mathbf{k}^0, \end{aligned} \right\} \quad (4.8)$$

where α 's are suitable proportionality factors

which can be evaluated from (4.4), and the corresponding dipole strengths are

$$\left. \begin{aligned} W({}^4A_2 \rightarrow {}^4F_2; {}^4E) &= \sum_{M=x_+, x_-} W({}^4A_2 \rightarrow {}^4F_2 M) \\ &\propto \frac{1}{2} |\alpha({}^4A_2 \rightarrow {}^4F_2)|^2 \cdot (\mathbf{i}^2 + \mathbf{j}^2), \\ W({}^4A_2 \rightarrow {}^4F_2; {}^4A_2) &= W({}^4A_2 \rightarrow {}^4F_2 x_0) = 0, \\ W({}^4A_2 \rightarrow {}^4F_1; {}^4E) &= \sum_{M=a_+, a_-} W({}^4A_2 \rightarrow {}^4F_1 M) \\ &\propto \frac{1}{6} |\alpha({}^4A_2 \rightarrow {}^4F_1)|^2 \cdot (\mathbf{i}^2 + \mathbf{j}^2), \\ W({}^4A_1 \rightarrow {}^4F_1; {}^4A_1) &= W({}^4A_2 \rightarrow {}^4F_1 a_0) \\ &\propto \frac{2}{3} |\alpha({}^4A_2 \rightarrow {}^4F_1)|^2 \mathbf{k}^2. \end{aligned} \right\} \quad (4.9)$$

The transition probabilities for the linearly polarized light $E//C_3$ are given by the coefficients of $\mathbf{k}^2$ and those the linearly polarized light $E \perp C_3$ by the coefficients of $\mathbf{i}^2$ or $\mathbf{j}^2$ in (4.9) and (4.10). Thus with the assignments:

$$\left. \begin{aligned} U//: f_2^3 {}^4A_{2g} &\rightarrow (f_2^2 e) {}^4F_{2g}; {}^4A_1 \\ U^{\perp}: &\rightarrow (f_2^2 e) {}^4F_{2g}; {}^4E \\ Y//: &\rightarrow (f_2^2 e) {}^4F_{1g}; {}^4A_2 \\ Y^{\perp}: &\rightarrow (f_2^2 e) {}^4F_{1g}; {}^4E \end{aligned} \right\} \quad (4.11)$$

we have the following ratios between the dipole strengths;

$$\left. \begin{aligned} \omega(U//): \omega(U^{\perp}) &= 0:1 \\ \omega(Y//): \omega(Y^{\perp}) &= 4:1 \end{aligned} \right\} \quad (4.12)$$

Although the result are not quite satisfactory, the present simple treatment seems to explain the qualitative feature of the observed optical anisotropy in each absorption band under a reasonable assumption. The causes of the discrepancy between the theory and experiment may be as follows; the assumption $V_{\text{hem}} = V_0(F_{1u})^*$ and the neglect of the vibrational effect. We need, however, more detailed knowledge of the trigonal field and the vibrations excited in the crystal in order to improve the results. These problems will be left for future investigations, together with the unexplained ratio of the absorption intensities of U to that of Y .

§ 5. Splitting and Optical Anisotropy of the Absorption Lines

For the absorption lines R_1 and R_2 of ruby,

* Note that (4.7) and (4.8) holds as long as we assume V_{hem} is of type F_{1u} . They were derived by consideration solely based on the transformation properties of operators and wave functions.

we expect the assignments $f_2^3 {}^4A_2 \rightarrow$ split components of $f_2^3 {}^2E$ or $f_2^3 {}^2F_1$, and for B_1 and B_2 $f_2^3 {}^4A_2 \rightarrow$ split components of $f_2^3 {}^2F_2$, just as in the case of Cr alum. In this section, we will discuss the splitting of $f_2^3 {}^2E$, ${}^2F_2$ and ${}^2F_1$ levels due to the action of the trigonal field and the spin-orbit interaction, and also the optical anisotropy of the absorption lines corresponding to the transition to these split components from the ground state.

(a) The splitting

As pointed out in IV, the splitting of ${}^2E$ is described by the effective Hamiltonian

$$\mathcal{H}_{\text{eff}} = \lambda S_z T(A_2), \quad (5.1)$$

where λ is a parameter to be determined empirically and $T(A_2)$ is an orbital operator whose matrix representation is

$$\begin{matrix} u_+ \\ u_- \end{matrix} \parallel \begin{matrix} 1 & \\ & -1 \end{matrix} \parallel. \quad (5.2)$$

The eigenvalues of the above Hamiltonian and the corresponding eigenfunctions are

$$W_1 = \frac{1}{2}\lambda \quad 2\bar{A}^* \left\{ \begin{matrix} \mathcal{Y}({}^2E, \frac{1}{2}, u_+)^{**} \\ \mathcal{Y}({}^2E, -\frac{1}{2}, u_-)^{**} \end{matrix} \right\} \quad (5.3)$$

$$W_2 = -\frac{1}{2}\lambda \quad \bar{E}^* \left\{ \begin{matrix} \mathcal{Y}({}^2E, -\frac{1}{2}, u_+) \\ \mathcal{Y}({}^2E, \frac{1}{2}, u_-) \end{matrix} \right\}. \quad (5.4)$$

It remains to express the parameter λ in terms of known matrix elements. This is easy if we confine ourselves to the second order perturbation in $\mathcal{H}'$. Since ${}^2E$ does not split by the sole action of the trigonal field or of the spin orbit interaction, but split only through the interplay of these two, it follows

$$\begin{aligned} & ({}^2E M_s M | \mathcal{H}_{\text{eff}} | {}^2E M_s M) \\ &= \sum_{{}^2\Gamma M'_s M'} \frac{1}{W({}^2E) - W({}^2\Gamma)} \\ & \times \{ ({}^2E M_s M | V_{\text{trig}} | {}^2\Gamma M'_s M') \\ & \cdot ({}^2\Gamma M'_s M' | V_{so} | {}^2E M_s M) \\ & + \text{complex conjugate} \}. \end{aligned} \quad (5.5)$$

If the intermediate states ${}^2\Gamma$ are restricted to those in configuration f_2^3 that makes a large contribution in the above summation, the summation reduces to a single term with ${}^2\Gamma = {}^2F_2$, since ${}^2E$ does not couple with ${}^2F_1$ either through the trigonal field or the spin-orbit interaction. To make the following discussion

clear, the coupling scheme among the doublets in configuration f_2^3 and the quartets in configuration $f_2^3 e$ are illustrated in Fig. 2. Eva-

Fig. 2. The coupling scheme among the doublets ${}^2E$, ${}^2F_2$ and ${}^2F_1$ in configuration f_2^3 and the quartets ${}^4A_2(f_2^3)$, ${}^4F_2(f_2^3 e)$ and ${}^4F_1(f_2^3 e)$.

luating the matrix elements in (5.5) with the aid of the tables given in the Appendix and comparing (5.5) with (5.1), we find

$$\lambda({}^2E) = 4K\zeta / \{ W({}^2E) - W({}^2F_2) \} \quad (5.6)$$

where ζ is defined by

$$\zeta = -2(f_2, \frac{1}{2}, x_+ | v_{so} | f_2, \frac{1}{2}, x_+), \quad (5.7)$$

while ζ' which appears in the following discussion is defined by

$$\zeta' = -\sqrt{2}(f_2, \frac{1}{2}, x_+ | v_{so} | e, \frac{1}{2}, u_+), \quad (5.8)$$

in which $v_{so} = \zeta s \cdot l$. In this section we assume that ζ and ζ' are isotropic. The second order terms which come from V_{trig}^2 and V_{so}^2 cause only a shift of ${}^2E$ as a whole.

The effective Hamiltonian for ${}^2F_2$ is of the form:

$$\mathcal{H}_{\text{eff}} = FV_0 + \lambda(S_x T_x + S_y T_y) + \lambda_0 S_z T_z, \quad (5.9)$$

where V_0 and T_x , T_y , T_z are the operators whose matrix representations are given respectively by

$$V_0: \begin{matrix} x_+ & x_- & x_0 \\ x_+ & \parallel & -1 & \parallel \\ x_- & \parallel & & -1 & \parallel \\ x_0 & \parallel & & & 2 & \parallel \end{matrix}$$

* These are the two-valued representations of C_3 .

** $\frac{1}{2}$ denotes the spin quantum number M_s .

$$\begin{array}{c}
 x_+ \quad x_- \quad x_0 \quad x \quad x_- \quad x_0 \quad x_+ \quad x_- \quad x_0 \\
 T_x: \begin{array}{c} x_+ \\ x_- \\ x_0 \end{array} \left\| \begin{array}{ccc} -1/\sqrt{2} & -1/\sqrt{2} & 0 \end{array} \right\| T_y: \begin{array}{c} x_+ \\ x_- \\ x_0 \end{array} \left\| \begin{array}{ccc} i/\sqrt{2} & -i/\sqrt{2} & 0 \end{array} \right\| T_z: \begin{array}{c} x_+ \\ x_- \\ x_0 \end{array} \left\| \begin{array}{ccc} -1 & 1 & 0 \end{array} \right\|
 \end{array} \quad (5.10)$$

The eigenvalues of (5.9) and the corresponding eigenfunctions are

$$W_0 = -F - \frac{\lambda_0}{2} \quad 2\bar{A} \begin{cases} \Psi(^2F_2, \frac{1}{2}, x_+) \\ \Psi(^2F_2, -\frac{1}{2}, x_-) \end{cases} \quad (5.11)$$

$$W_1 = -F + \frac{\lambda_0}{2} - \frac{\lambda}{\sqrt{2}} \tan \alpha \quad \bar{E}_a \begin{cases} \Psi(^2F_2, -\frac{1}{2}, x_+) \cos \alpha + \Psi(^2F_2, \frac{1}{2}, x_0) \sin \alpha \\ \Psi(^2F_2, \frac{1}{2}, x_-) \cos \alpha + \Psi(^2F_2, -\frac{1}{2}, x_0) \sin \alpha \end{cases} \quad (5.12)$$

$$W_2 = -F + \frac{\lambda_0}{2} + \frac{\lambda}{\sqrt{2}} \cot \alpha \quad \bar{E}_b \begin{cases} \Psi(^2F_2, \frac{1}{2}, x_0) \cos \alpha - \Psi(^2F_2, -\frac{1}{2}, x_+) \sin \alpha \\ \Psi(^2F_2, -\frac{1}{2}, x_0) \cos \alpha - \Psi(^2F_2, \frac{1}{2}, x_-) \sin \alpha \end{cases} \quad (5.13)$$

where

$$\tan 2\alpha = \sqrt{2} \lambda / \left(3F - \frac{\lambda_0}{2} \right), \quad 0 \leq \alpha \leq \frac{\pi}{2}. \quad (5.14)$$

F , λ and λ_0 can also be expressed in terms of K and ζ . Let us first consider F . Since $(f_2^3 {}^2F_2 M_s M | V_{\text{trig}} | f_2^3 {}^2F_2 M_s M)$ vanishes, trigonal field splits ${}^2F_2$ through the second order perturbation:

$${}^2\sum_{F'M'} \frac{1}{W(^2F_2) - W(^2F')} ({}^2F_2 M_s M | V_{\text{trig}} | {}^2F' M_s M') ({}^2F' M_s M' | V_{\text{trig}} | {}^2F_2 M_s M). \quad (5.15)$$

This, however, causes the shift of ${}^2F_2$ as a whole as well as the splitting. The magnitude of the shift is equal to the trace of the above expression divided by 6. Subtracting this from (5.15) and comparing suitable matrix element of the resulting expression with the corresponding element of the first term of (5.9), we find under the same assumption as before

$$F(^2F_2) = -2K^2 / \{ W(^2F_2) - W(^2E) \} - K^2 / \{ W(^2F_2) - W(^2F_1) \}. \quad (5.16)$$

$(f_2^3 {}^2F_2 M_s M | V_{s0} | f_2^3 {}^2F_2 M_s' M')$ also vanishes and the second and the third term in (5.9) come from the second order perturbation:

$${}^2\sum_{F''M''} \frac{1}{W(^2F_2) - W(^2F'')} \{ ({}^2F_2 M_s M | V_{\text{trig}} | {}^2F'' M_s M'') ({}^2F'' M_s M'' | V_{s0} | {}^2F_2 M_s' M') + \text{c.c.} \}. \quad (5.17)$$

Proceeding as before we obtain

$$\left. \begin{aligned} \lambda(^2F_2) &= 2K\zeta / \{ W(^2F_2) - W(^2E) \} + K\zeta / \{ W(^2F_2) - W(^2F_1) \}, \\ \lambda_0(^2F_2) &= -4K\zeta / \{ W(^2F_2) - W(^2E) \} - 2K\zeta / \{ W(^2F_2) - W(^2F_1) \}, \end{aligned} \right\} \quad (5.18)$$

where the contributions from the second order term V_{s0}^2 are neglected, since they are estimated to be negligible if we use the value of ζ to be determined later.

The effective Hamiltonian for ${}^2F_1$ is of the same form as that for ${}^2F_2$. The matrix elements of the operator T for F_1 state is just the opposite sign (negative) of the corresponding elements for F_2 though those of V_0 are same for both F_1 and F_2 . The eigen-values and the eigenfunctions for ${}^2F_1$ is thus written

down at once by changing the sign of λ , λ_0 and writing ${}^2F_1 a_+$ etc. for ${}^2F_2 x_+$ etc. in (5.11)~(5.14). F , λ and λ_0 in this case are expressed in terms of K and ζ in the following way:

$$F(^2F_1) = -K^2 / \{ W(^2F_1) - W(^2F_2) \}, \quad (5.19)$$

$$\left. \begin{aligned} \lambda(^2F_1) &= -K\zeta / \{ W(^2F_1) - W(^2F_2) \}, \\ \lambda_0(^2F_1) &= 2K\zeta / \{ W(^2F_1) - W(^2F_2) \}, \end{aligned} \right\} \quad (5.20)$$

in which the second order terms V_{s0}^2 are again neglected.

We will now discuss the splittings of the

doublets in greater detail.

${}^2E$ splits into two Kramers doublets $2\overline{A}({}^2E)$ and $\overline{E}({}^2E)$. Here $2\overline{A}$ lies on the shorter wave-length side if $\lambda({}^2E) > 0$. This is really the case since it was found in § 4 that K is negative. Further considerations on the anisotropy and the Zeeman effect of the characteristic doublet R_1 and R_2 establish the following assignments in agreement with this prediction:

$$\left. \begin{aligned} R_1(14418\text{ cm}^{-1}): {}^4A_2 \rightarrow \overline{E}({}^2E) \\ R_2(14447\text{ cm}^{-1}): {}^4A_2 \rightarrow 2\overline{A}({}^2E) \end{aligned} \right\} . \quad (5.21)$$

Using the observed splitting $\lambda({}^2E) \sim 30\text{ cm}^{-1}$ and taking $W({}^2E) - W({}^2F_2)$ to be $\sim -6500\text{ cm}^{-1}$, the magnitude of ζ is found to be $\sim 140\text{ cm}^{-1}$. This is fairly small compared to the free-ion value $\sim 270\text{ cm}^{-1}$ adopted by Owen¹¹⁾, but not unreasonably small in view of the fact that the value of ζ generally decreases in crystals.

With this value of ζ , the approximate values of F , λ and λ_0 can now be estimated for ${}^2F_2$ and ${}^2F_1$ using (5.16), (5.18) and (5.19), (5.20) respectively:

$$\left. \begin{aligned} F({}^2F_2) &\sim -60\text{ cm}^{-1} \\ \lambda_0({}^2F_2) &\sim +45\text{ cm}^{-1} \\ \lambda({}^2F_2) &\sim -22\text{ cm}^{-1} \end{aligned} \right\} , \quad (5.22)$$

$$\left. \begin{aligned} F({}^2F_1) &\sim +20\text{ cm}^{-1} \\ \lambda_0({}^2F_1) &\sim +15\text{ cm}^{-1} \\ \lambda({}^2F_1) &\sim -8\text{ cm}^{-1} \end{aligned} \right\} , \quad (5.23)$$

and for these values,

$$\alpha({}^2F_2) \sim 0, \quad \alpha({}^2F_1) \sim 0,$$

where it was assumed that $W({}^2F_2) - W({}^2E) \approx W({}^2F_2) - W({}^2F_1)$. The predicted arrangements of the split components of ${}^2F_2$ and ${}^2F_1$ are

Fig. 3. The splittings of ${}^2F_2$ and ${}^2F_1$.

given in Fig. 3. The lines that correspond to the transitions to the split components of ${}^2F_1$ are not yet identified. As to those of ${}^2F_2$ it is fairly certain, as will be seen in the following, that the following assignments can be made for B_1 and B_2 :

$$\left. \begin{aligned} B_1(20993\text{ cm}^{-1}): {}^4A_2 \rightarrow 2\overline{A}({}^2F_2) \\ B_2(21068\text{ cm}^{-1}): {}^4A_2 \rightarrow \overline{E}_a({}^2F_2) \end{aligned} \right\} . \quad (5.24)$$

If $\alpha({}^2F_2) \sim 0$, we have $\lambda_0 \sim 75\text{ cm}^{-1}$ from the observed separation of B_1 and B_2 .

As far as we are concerned with the split components $2\overline{A}$ and $\overline{E}_a$ the predicted arrangement is qualitatively good*, but quantitatively not quite satisfactory (compare the experimental value of λ_0 with λ_0 in (5.22)). This disagreement is perhaps partly due to the omission of the interaction between ${}^2F_2$ and any higher excited doublet which will be larger for ${}^2F_2$ than for the deeply lying ${}^2E$, and partly due to the assumption $W({}^2F_2) - W({}^2E) \approx W({}^2F_2) - W({}^2F_1)$. Though the position of ${}^2F_1$ has not been known yet, it is highly probable that ${}^2F_1$ has a higher energy than that of ${}^2E$ judging from the sign and the magnitude of the g -shifts of the split

components $2\overline{A}({}^2E)$ and $\overline{E}({}^2E)$ (§ 6 (e)). This will increase the theoretical value of $\lambda_0({}^2F_2)$.

(b) The optical anisotropy

We assume as in II that the intensities of the line absorption are borrowed from those of the absorption bands through the spin-orbit interaction, that is, the dipole strength for the transition from the component a of the ground state ${}^4A_2$ to the component b of the doublet ${}^2\Gamma$ is given by the square of the matrix element

$$\begin{aligned} &({}^4A_2 a | \overline{P} | {}^2\Gamma b) \\ &= \sum ({}^4A_2 a | \overline{P} | {}^4\Gamma' c) ({}^4\Gamma' c | V_{so} | {}^2\Gamma b) \\ &\quad / \{ W({}^2\Gamma) - W({}^4\Gamma') \} , \end{aligned} \quad (5.25)$$

where c is the components of the excited quartets ${}^4F_2$ and ${}^4F_1$. This means that the contamination of the doublet states to the

* Though the arrangement of $2\overline{A}({}^2F_2)$ and $\overline{E}_a({}^2F_2)$ is qualitatively good, we cannot observe any absorption line at the long wave-length side of them. Somewhat broad line can be observed at the shorter wave-length side (21357 cm^{-1} at 78°K)²⁾. Thus, our theory might be wrong even qualitatively with respect to the predicted position of $\overline{E}_b({}^2F_2)$.

ground quartet is neglected*.

Using the tables of the Appendix, the dipole strengths evaluated by the formula (5.25) are given in Tables I and II, with $\alpha=0$ in (5.12, 5.13). π 's and σ 's are expressed in terms of ζ' and the dipole strengths of the bands. Using the abbreviations,

$$\left. \begin{aligned} P_{\alpha^0, \pm}(U) &= ({}^4A_2 | \bar{P}_{\alpha} | {}^4F_2 x_0, \pm) \\ P_{\alpha^0, \pm}(Y) &= ({}^4A_2 | \bar{P}_{\alpha} | {}^4F_1 a_0, \pm) \end{aligned} \right\}, \quad (5.26)$$

they are expressed as follows; for the components of ${}^2E$

$$\left. \begin{aligned} \pi_{\alpha} &= \frac{4}{3} \zeta'^2 \left| \frac{P_{\alpha^0}(U)}{W({}^2E) - W({}^4F_2)} \right|^2, \\ \sigma_{\pm\alpha} &= \frac{4}{3} \zeta'^2 \left| \frac{P_{\alpha^{\pm}}(U)}{W({}^2E) - W({}^4F_2)} \right|^2, \end{aligned} \right\} \quad (5.27)$$

Table II. The values of $|({}^4A_2 M_s | \bar{P} | {}^2F_2 M_s', M')|^2$ and $|({}^4A_2 M_s | \bar{P} | {}^2F_1 M_s', M')|^2$, in which M_s is quantized with respect to the z axis.

${}^2F_2({}^2F_1)$ M_s', M'		$2\bar{A}$		$\bar{E}_a$		$\bar{E}_b$	
${}^4A_2$ M_s		$-1/2, x_+(\alpha_+)$	$1/2, x_-(\alpha_-)$	$-1/2, x_+(\alpha_+)$	$1/2, x_-(\alpha_-)$	$1/2, x_0(\alpha_0)$	$-1/2, x_0(\alpha_0)$
3/2		$\pi_{\alpha}/2$				$\sigma'_{+\alpha}/2$	
1/2		$\sigma_{+\alpha}/3$	$\sigma^0_{+\alpha}/6$	$\pi_{\alpha}/6$	$\sigma_{-\alpha}/3$	$\pi_{\alpha'}/3$	$\sigma'_{-\alpha}/6$
-1/2		$\sigma^0_{-\alpha}/6$	$\sigma_{-\alpha}/3$	$\sigma_{+\alpha}/3$	$\pi_{\alpha}/6$	$\sigma'_{+\alpha}/6$	$\pi_{\alpha'}/3$
-3/2			$\pi_{\alpha}/2$	$\sigma^0_{-\alpha}/2$			$\sigma'_{+\alpha}/2$

$$\left. \begin{aligned} \pi_{\alpha} &= \frac{1}{2} \zeta'^2 \left\{ \left| \frac{P_{\alpha^0}(U)}{W({}^2F_2) - W({}^4F_2)} \right|^2 + \left| \frac{P_{\alpha^0}(Y)}{W({}^2F_2) - W({}^4F_1)} \right|^2 \right\}, \\ \sigma_{\pm\alpha} &= \frac{1}{2} \zeta'^2 \left| \frac{P_{\alpha^{\pm}}(U)}{W({}^2F_2) - W({}^4F_2)} \pm i \frac{P_{\alpha^{\pm}}(Y)}{W({}^2F_2) - W({}^4F_1)} \right|^2, \\ \sigma_{\pm}^0 &= 2 \zeta'^2 \left| \frac{P_{\alpha^{\pm}}(Y)}{W({}^2F_2) - W({}^4F_1)} \right|^2, \\ \pi_{\alpha'} &= 2 \zeta'^2 \left| \frac{P_{\alpha^0}(Y)}{W({}^2F_2) - W({}^4F_1)} \right|^2, \\ \sigma'_{\pm\alpha} &= \frac{1}{2} \zeta'^2 \left| \frac{P_{\alpha^{\pm}}(U)}{W({}^2F_2) - W({}^4F_2)} \mp i \frac{P_{\alpha^{\pm}}(Y)}{W({}^2F_2) - W({}^4F_1)} \right|^2, \end{aligned} \right\} \quad (5.28)$$

and for ${}^2F_1$

$$\left. \begin{aligned} \pi_{\alpha} &= \frac{1}{6} \zeta'^2 \left\{ \left| \frac{P_{\alpha^0}(U)}{W({}^2F_1) - W({}^4F_2)} \right|^2 + 9 \left| \frac{P_{\alpha^0}(Y)}{W({}^2F_1) - W({}^4F_1)} \right|^2 \right\}, \\ \sigma_{\pm\alpha} &= \frac{1}{6} \zeta'^2 \left| \frac{P_{\alpha^{\pm}}(U)}{W({}^2F_1) - W({}^4F_2)} \mp i \frac{3P_{\alpha^{\pm}}(Y)}{W({}^2F_1) - W({}^4F_1)} \right|^2, \\ \sigma_{\pm}^0 &= \frac{2}{3} \zeta'^2 \left| \frac{P_{\alpha^{\pm}}(U)}{W({}^2F_1) - W({}^4F_2)} \right|^2, \\ \pi_{\alpha'} &= \frac{2}{3} \zeta'^2 \left| \frac{P_{\alpha^0}(U)}{W({}^2F_1) - W({}^4F_2)} \right|^2, \\ \sigma'_{\pm\alpha} &= \frac{1}{6} \zeta'^2 \left| \frac{P_{\alpha^{\pm}}(U)}{W({}^2F_1) - W({}^4F_2)} \pm i \frac{3P_{\alpha^{\pm}}(Y)}{W({}^2F_1) - W({}^4F_1)} \right|^2, \end{aligned} \right\} \quad (5.29)$$

* Note that ${}^4F_2$ and ${}^4F_1$ hybridize with the neighbouring doublets ${}^2E$, ${}^2F_1$ and ${}^2F_2$ to a larger extent than that ${}^2F_2$ does with the ground quartet. Note also that ${}^2F_2$ is the only one among the doublets that couples with the ground state.

where $\alpha=z$ and $\alpha=x$ for $E//C_3$ and $E\perp C_3$ respectively.
Then we observe that, for the sum of the strengths of the split components, $\sum\alpha$, the following expressions should be given:

$$\sum\alpha(^2E)=\frac{4}{3}\{\pi_\alpha+(\sigma_{+\alpha}+\sigma_{-\alpha})\}=\frac{16}{9}\zeta'^2\sum_{k=0,+,-}\left|\frac{P_\alpha^k(U)}{W(^2E)-W(^4F_2)}\right|^2,$$

(5.30)

$$\begin{aligned}\sum\alpha(^2F_2)&=\frac{2}{3}\{2\pi_\alpha+\pi_{\alpha'}+(\sigma_{+\alpha}+\sigma_{-\alpha})+(\sigma'_{+\alpha}+\sigma'_{-\alpha})+(\sigma^0_{+\alpha}+\sigma^0_{-\alpha})\}\\&=\frac{2}{3}\zeta'^2\sum_{k=0,+,-}\left|\frac{P_\alpha^k(U)}{W(^2F_2)-W(^4F_2)}\right|^2+2\zeta'^2\sum_{k=0,+,-}\left|\frac{P_\alpha^k(Y)}{W(^2F_2)-W(^4F_1)}\right|^2,\end{aligned}$$

(5.31)

$$\begin{aligned}\sum\alpha(^2F_1)&=\frac{2}{3}\{2\pi_\alpha+\pi_{\alpha'}+(\sigma_{+\alpha}+\sigma_{-\alpha})+(\sigma'_{+\alpha}+\sigma'_{-\alpha})+(\sigma^0_{+\alpha}+\sigma^0_{-\alpha})\}\\&=\frac{2}{3}\zeta'^2\sum_{k=0,+,-}\left|\frac{P_\alpha^k(U)}{W(^2F_1)-W(^4F_2)}\right|^2+2\zeta'^2\sum_{k=0,+,-}\left|\frac{P_\alpha^k(Y)}{W(^2F_1)-W(^4F_1)}\right|^2.\end{aligned}$$

(5.32)

The relative magnitude of these quantities can thus be estimated from the observed relative strengths of the bands.

If we could neglect the effect of the vibrationally allowed part of transitions, we have

$$\pi_x=\pi_x'=\sigma_{\pm z}=\sigma'_{\pm z}=\sigma^0_{\pm z}=0,$$

(5.33)

and

$$\left.\begin{aligned}\sigma_{+x}=\sigma_{-x}&\equiv\sigma,\\ \sigma'_{+x}=\sigma'_{-x}&\equiv\sigma',\\ \sigma^0_{+x}=\sigma^0_{-x}&\equiv\sigma^0,\end{aligned}\right\}$$

(5.34)

since for the real trigonal field

$$(P_x^\pm)^*=-P_x^\mp.$$

(5.35)

Thus it becomes possible to predict several relations among the intensities of the split components. Using the parameters σ , σ^0 , $\pi=\pi_x$ and $\pi'=\pi_x'$, the calculated intensities are given in Table III. Comparing these with

Table III. The calculated absorption intensities of the line spectra corresponding to transitions to the split components of ${}^2E$, ${}^2F_2$ and ${}^2F_1$.

	$E\perp C_3$	$E//C_3$
${}^2E$	$2\bar{A}$	σ
	$\bar{E}$	$5\sigma/3$
${}^2F_2$ or ${}^2F_1$	$2\bar{A}$	$2\sigma/3+\sigma_0/3$
	$\bar{E}_d$	$2\sigma/3+\sigma_0$
	$\bar{E}_b$	$4\sigma'/3$

the experimental results given in Fig. 1 of Part B, we shall see that the assignments given in subsection (a) explain nicely the observed intensity ratios between $R_1^{\perp, //}$ and $R_2^{\perp, //}$ and between $B_1^{\perp, //}$ and $B_2^{\perp, //}$ (the superscripts denote the polarization). In order to

explain the ratios between $B_1^\perp$ and $B_2^\perp$, $R_1^\perp$ and $R_1^{\perp, //}$, and $B_1^\perp$ and $B_1^{\perp, //}$ it is necessary to know the relations among the parameters σ , σ^0 , π and π' . It will be shown in Part B that if we assume the relations $\sigma\sim 2\pi$ for ${}^2E$ and $\sigma^0\sim 2\sigma$, $\pi\sim 3\sigma$ for ${}^2F_2$, all the above-mentioned intensity ratios observed are explained.

We notice that for B_1 the absorption is stronger in the case $E//C_3$ than in the case $E\perp C_3$ while for R_2 the relation is reversed. This can be easily understood since $B_1(B_2)$ borrows most of its intensity from Y band which shows a strong absorption for the light $E//C_3$ while $R_1(R_2)$ borrows all of its intensity from U band whose anisotropy is reverse to that of Y band.

If the transitions corresponding to U and Y bands are assumed to be allowed only by the hemihedral part of trigonal field and the relation $\sigma\sim\sigma'$ is assumed to be approximately valid, we can use the observed anisotropy of these bands to get the relations among the parameters σ , σ^0 , π and π' . Putting

$$\omega(U^{\perp}): \omega(U^\perp): \omega(Y^{\perp}): \omega(Y^\perp)=1:3:3:6$$

to give approximately the observed anisotropy of the bands, we obtain the relations $\sigma\sim 1.5\pi$ for ${}^2E$ and $\sigma^0\sim 4\sigma$, $\pi\sim 2\sigma$ for ${}^2F_2$. This should be compared to the above mentioned empirical relations. The agreement is fair.

We will next see to what extent the relation (5.30) is satisfied. Inserting the observed intensity ratios of R 's absorptions, $\omega(R_1^\perp): \omega(R_1^{\perp, //}): \omega(R_2^\perp): \omega(R_2^{\perp, //})=10:2:7:4$, we obtain $\sum\alpha(^2E)/\sum\alpha(^2E)=6/17=1/3$ which nicely agrees with the observed anisotropy of U band, $\omega(U^{\perp, //})/\omega(U^\perp)=1/3$.

$\bar{E}_b(^2F_2)$ is yet unidentified. The line that will

correspond to this level will show marked anisotropy, because using the observed anisotropy of U and Y bands the relation $\pi' \sim 4\pi$ can be derived and so together with the empirical relation $\pi \sim 3\sigma$ (the approximate relation $\sigma \sim \sigma'$ is also assumed here as before) we suppose that the parallel component will be six times stronger than the perpendicular component. The strength of the parallel component of the line corresponding to $\bar{E}_b(^2F_2)$ thus calculated becomes more than twice that of B_1 .

The lines that will correspond to the components of $^2F_1$ borrow their intensities almost equally from both U and Y bands if they are located near R_1 and R_2 . The expected anisotropy of these lines (corresponding to $\bar{E}_a(^2F_1)$ and $2\bar{A}(^2F_1)$) are somewhat similar to that of R_1 and R_2 and there is a possibility that R_1 and R_2 correspond respectively to $\bar{E}_a(^2F_1)$ and $2\bar{A}(^2F_1)$. This possibility is, however, excluded by the consideration of the Zeeman effect which will be discussed in the following section.

§ 6. Zeeman Effect of the Absorption Lines

(a) Zeeman splitting of the excited states

For the discussion of the Zeeman effect of ^2E , we use the following simplified effective Hamiltonian:

$$\begin{aligned} \mathcal{H}_{\text{eff}} = & \lambda S_z T(A_2) + g_{//} \beta H_{0z} S_z \\ & + g_{\perp} \beta (H_{0x} S_x + H_{0y} S_y) \\ & + (g_{//}' \beta H_{0z} + g_{\perp}' \beta H_{0x} + g_{\perp}' \beta H_{0y}) T(A_2), \end{aligned} \quad (6.1)$$

neglecting the term of $\beta \mathbf{H}_0 \cdot \mathbf{g} \cdot \mathbf{S} \cdot \mathbf{V}(E)$ in (3.2) of IV, which is negligible in the present case.

The splitting factor g^* for $2\bar{A}(^2E)$ and $\bar{E}(^2E)$

* The sign of the $g_{//}$ -values of the split components are defined in the following way: The states correspond to the wave functions of the upper (lower) lines of (5.3), (5.4), (5.11), (5.12) and (5.13) have Zeeman energy $\frac{1}{2} g_{//} \beta H_0 (-\frac{1}{2} g_{//} \beta H_0)$. The negative sign taken for $g_{//}(\bar{E}_a)$ might be queer at the first sight. It is, however, natural if we notice that, in the present case, $\bar{M} = \bar{M}_s + M$ is the quantum number for the state $\Psi(^2T, M_s, M)$ and we take the definition of the $g_{//}$ factor, Zeeman energy = $g_{//} \beta \bar{M} H_0$, just as in the case of the Zeeman effect of free atoms.

Simple consideration based on the selection rule shows that this negative $g_{//}(\bar{E})$ value is the cause of the appearance of the side component of R_1 when $E \parallel C_3$ ($4\bar{M} \equiv 0, \text{ mod } 3$) $H_0 \parallel C_3$ and the strong central component when $E \perp C_3$ ($4\bar{M} \equiv \pm 1, \text{ mod } 3$).

when $H_0 \parallel C_3$ is readily found as

$$\left. \begin{aligned} g_{//}(2\bar{A}) &= g_{//} + 2g_{//}', \\ g_{//}(\bar{E}) &= -(g_{//} - 2g_{//}'), \end{aligned} \right\} \quad (6.2)$$

When $H_0 \perp C_3$, it is also found that

$$\left. \begin{aligned} g_{\perp}(2\bar{A}) &= 2g_{\perp}', \\ g_{\perp}(\bar{E}) &= 2g_{\perp}', \end{aligned} \right\} \quad (6.3)$$

and a magnetic field causes the shifts of $2\bar{A}$ and $\bar{E}$ as follows;

$$\left. \begin{aligned} \text{for } 2\bar{A}(^2E) & \quad \beta^2 H^2 / \lambda(^2E), \\ \text{for } \bar{E}(^2E) & \quad -\beta^2 H^2 / \lambda(^2E), \end{aligned} \right\} \quad (6.4)$$

but this is negligible if $\lambda(^2E)$ is very large compared to the Zeeman energy just as in the present case.

The orbital angular momentum is quenched in ^2E and the first order correction in $g_{//}$, $g_{//}'$ and $g_{\perp}'$ vanishes, namely

$$\sum_r \left\{ \frac{(^2E|L + 2S|^2T)(^2T|\mathcal{H}'|^2E)}{W(^2E) - W(^2T)} + \text{c.c.} \right\} = 0, \quad (6.5)$$

as long as intermediate doublets are limited to those of f_2^3 (see Fig. 2). We thus expect

$$\left. \begin{aligned} g_{//}(2\bar{A}) &\doteq 2, & g_{\perp}(2\bar{A}) &\doteq 0, \\ g_{//}(\bar{E}) &\doteq -2, & g_{\perp}(\bar{E}) &\doteq 0. \end{aligned} \right\} \quad (6.6)$$

For $^2F_2$ and $^2F_1$, we take the Hamiltonian, $\mathcal{H}_{\text{eff}} = g_{//} \beta H_{0z} S_z + g_{\perp} \beta (H_{0x} S_x + H_{0y} S_y) + g_{//}' \beta H_{0z} T_z + g_{\perp}' \beta (H_{0x} T_x + H_{0y} T_y)$. (6.7)

We find then for the components of $^2F_2$

$$\left. \begin{aligned} g_{//}(2\bar{A}) &= g_{//} - 2g_{//}', \\ g_{//}(\bar{E}_a) &= -(g_{//} \cos 2\alpha + 2g_{//}' \cos^2 \alpha), \\ g_{//}(\bar{E}_b) &= g_{//} \cos 2\alpha - 2g_{//}' \sin^2 \alpha, \end{aligned} \right\} \quad (6.8)$$

and of $^2F_1$

$$\left. \begin{aligned} g_{//}(2\bar{A}) &= g_{//} + 2g_{//}', \\ g_{//}(\bar{E}_a) &= -(g_{//} \cos \alpha - 2g_{//}' \cos^2 \alpha), \\ g_{//}(\bar{E}_b) &= g_{//} \cos 2\alpha + 2g_{//}' \sin^2 \alpha. \end{aligned} \right\} \quad (6.9)$$

When $H_0 \perp C_3$, assuming large initial splitting of the components, we find for $^2F_2$

$$\left. \begin{aligned} g_{\perp}(2\bar{A}) &= 0, \\ |g_{\perp}(\bar{E}_a)| &= |g_{\perp} \sin^2 \alpha - \sqrt{2} g_{\perp}' \sin 2\alpha|, \\ |g_{\perp}(\bar{E}_b)| &= |g_{\perp} \cos^2 \alpha + \sqrt{2} g_{\perp}' \sin 2\alpha|, \end{aligned} \right\} \quad (6.10)$$

and for $^2F_1$

$$\begin{aligned} g_{\perp}(2\bar{A}) &= 0, \\ |g_{\perp}(\bar{E}_a)| &= |g_{\perp} \sin^2 \alpha + \sqrt{2} g_{\perp}' \sin 2\alpha|, \\ |g_{\perp}(\bar{E}_b)| &= |g_{\perp} \cos^2 \alpha - \sqrt{2} g_{\perp}' \sin 2\alpha|. \end{aligned} \quad (6.11)$$

The first order correction in $g_{//}$, $g_{//}'$ and $g_{\perp}'$ vanishes also in this case, and we obtain $g_{//} \doteq 2$, $g_{\perp} \doteq 2$ (spin part) and $g_{//}' \doteq 1$, $g_{\perp}' = 1$ (orbital part). Thus we get, assuming $\alpha=0$, for ${}^2F_2$

$$\left. \begin{aligned} g_{//}(2\bar{A}) &\doteq 0, & g_{\perp}(2\bar{A}) &\doteq 0, \\ g_{//}(\bar{E}_a) &\doteq -4, & g_{\perp}(\bar{E}_a) &\doteq 0, \\ g_{//}(\bar{E}_b) &\doteq 2, & |g_{\perp}(\bar{E}_b)| &\doteq 2, \end{aligned} \right\} \quad (6.12)$$

for ${}^2F_1$

$$\left. \begin{aligned} g_{//}(2\bar{A}) &\doteq 4, & g_{\perp}(2\bar{A}) &\doteq 0, \\ g_{//}(\bar{E}_a) &\doteq 0, & g_{\perp}(\bar{E}_a) &\doteq 0, \\ |g_{//}(\bar{E}_b)| &\doteq 2, & |g_{\perp}(\bar{E}_b)| &\doteq 2. \end{aligned} \right\} \quad (6.13)$$

(b) The selection rules

The selection rules or the strengths of the Zeeman components are obtained from Tables I and II given in § 5 in case $H_0//C_3$. In case $H_0 \perp C_3$, the spin functions of the ground quartet are quantized with respect to the x axis, along which a magnetic field is applied. The ground state wave-functions, in which the quantization axis of spin is x , are expressed as a linear combination of those in which the quantization axis is z as follows;

$$\left. \begin{aligned} \Psi\left(M_s^{(z)} = \pm \frac{3}{2}\right) &= \frac{1}{2\sqrt{2}} \left\{ \pm \Psi\left(M_s^{(z)} = \frac{3}{2}\right) + \Psi\left(M_s^{(z)} = -\frac{3}{2}\right) \right. \\ &\quad \left. + \frac{\sqrt{3}}{2\sqrt{2}} \left\{ \Psi\left(M_s^{(z)} = \frac{1}{2}\right) \pm \Psi\left(M_s^{(z)} = -\frac{1}{2}\right) \right\} \right\}, \\ \Psi\left(M_s^{(z)} = \pm \frac{1}{2}\right) &= \frac{\sqrt{3}}{2\sqrt{2}} \left\{ \mp \Psi\left(M_s^{(z)} = \frac{3}{2}\right) + \Psi\left(M_s^{(z)} = -\frac{3}{2}\right) \right. \\ &\quad \left. - \frac{1}{2\sqrt{2}} \left\{ \Psi\left(M_s^{(z)} = \frac{1}{2}\right) \mp \Psi\left(M_s^{(z)} = -\frac{1}{2}\right) \right\} \right\}. \end{aligned} \right\} \quad (6.14)$$

Table IV. The Values of $\sum_{M_s', M'} |(\bar{^4A_2} M_s | \bar{P} | \bar{^2E} M_s', M')|^2$, in which M_s is quantized with respect to the x axis.

$\bar{^4A_2}$	$\bar{M_s}$	$\bar{^2E}$	
		$2\bar{A}$	$\bar{E}$
	3/2	$\pi\alpha/8 + 3(\sigma + \alpha + \sigma - \alpha)/16$	$\pi\alpha/8 + 3(\sigma + \alpha + \sigma - \alpha)/16$
	1/2	$3\pi\alpha/8 + (\sigma + \alpha + \sigma - \alpha)/16$	$\pi\alpha/24 + 11(\sigma + \alpha + \sigma - \alpha)/48$
	-1/2	$3\pi\alpha/8 + (\sigma + \alpha + \sigma - \alpha)/16$	$\pi\alpha/24 + 11(\sigma + \alpha + \sigma - \alpha)/48$
	-3/2	$\pi\alpha/8 + 3(\sigma + \alpha + \sigma - \alpha)/16$	$\pi\alpha/8 + 3(\sigma + \alpha + \sigma - \alpha)/16$

Table V. The tables of $\sum_{M_s', M'} |(\bar{^4A_2} M_s | \bar{P} | \bar{^2F_2} M_s', M')|^2$ and $\sum_{M_s', M'} |(\bar{^4A_2} M_s | \bar{P} | \bar{^2F_1} M_s', M')|^2$, in which M_s is quantized with respect to the x axis.

$\bar{^4A_2}$	$\bar{M_s}$	$\bar{^2F_2}(\bar{^2F_1})$	
		$2\bar{A}$	$\bar{E}_a$
	3/2	$\pi\alpha/8 + (\sigma + \alpha + \sigma - \alpha)/8 + (\sigma_{+\alpha}^0 + \sigma_{-\alpha}^0)/16$	$\pi\alpha/8 + (\sigma + \alpha + \sigma - \alpha)/8 + (\sigma_{+\alpha}^0 + \sigma_{-\alpha}^0)/16$
	1/2	$3\pi\alpha/8 + (\sigma + \alpha + \sigma - \alpha)/24 + (\sigma_{+\alpha}^0 + \sigma_{-\alpha}^0)/48$	$\pi\alpha/24 + (\sigma + \alpha + \sigma - \alpha)/24 + 3(\sigma_{+\alpha}^0 + \sigma_{-\alpha}^0)/16$
	-1/2	$3\pi\alpha/8 + (\sigma + \alpha + \sigma - \alpha)/24 + (\sigma_{+\alpha}^0 + \sigma_{-\alpha}^0)/48$	$\pi\alpha/24 + (\sigma + \alpha + \sigma - \alpha)/24 + 3(\sigma_{+\alpha}^0 + \sigma_{-\alpha}^0)/16$
	-3/2	$\pi\alpha/8 + (\sigma + \alpha + \sigma - \alpha)/8 + (\sigma_{+\alpha}^0 + \sigma_{-\alpha}^0)/16$	$\pi\alpha/8 + (\sigma + \alpha + \sigma - \alpha)/8 + \frac{5}{8}(\sigma_{+\alpha}^0 + \sigma_{-\alpha}^0)/16$

Using (6.14) the strengths of the Zeeman components in this case can be derived also from Tables I and II, they are given in Tables IV and V. In the predicted Zeeman patterns (Figs. 4, 5), the absence of the vibrational ef-

fect is assumed, i.e., $\pi_x = \pi'_x = \sigma_{\pm z} = \sigma_{\pm z}^0 = \sigma'_{\pm z} = 0$.

(c) Zeeman splitting of the ground state

The Zeeman levels of the ground state have been well examined by paramagnetic resc-

Fig. 4 (a). The predicted Zeeman patterns ($H_0 \parallel C_3$) for ${}^2E$. Splittings are given in βH_0 unit.

nance. To analyse optical Zeeman patterns, the knowledge about them is also necessary, so that we shall summarize it below: The energies of the split components of the ground quartet are

$$\left. \begin{aligned} W(M_s^{(z)} = \pm \frac{3}{2}) &= \pm \frac{3}{2} g_{0//} \beta H_0, \\ W(M_s^{(z)} = \pm \frac{1}{2}) &= \pm \frac{1}{2} g_{0//} \beta H_0 + \delta, \end{aligned} \right\} \quad (6.15)$$

when $H_0 \perp C_3$ and

$$\left. \begin{aligned} W(M_s^{(z)} = \pm \frac{3}{2}) &= \pm \frac{3}{2} g_{0\perp} \beta H_0 + \frac{\delta}{4}, \\ W(M_s^{(z)} = \pm \frac{1}{2}) &= -\frac{1}{2} g_{0\perp} \beta H_0 + \frac{3\delta}{4}, \end{aligned} \right\} \quad (6.16)$$

when $H_0 \perp C_3$ ($2\beta H_0 \gg \delta$).

The paramagnetic resonance experiment has shown that

$$|\delta| = 0.38 \text{ cm}^{-1}, \quad g_{0//} \doteq g_{0\perp} \doteq 2.$$

(d) The Zeeman patterns

Now we are ready to predict the Zeeman patterns, and they are illustrated in Figs. 4 and 5. From the detailed comparison of these patterns with the experimental ones that will be made in Part B, we may conclude that the assignments (5.21) for R_1 and R_2 and (5.24) for B_1 and B_2 are established.

Moreover, from such comparison, we find that δ is positive and the g -values of the split components of ${}^2E$ and ${}^2F_2$ show fairly large shift from those expected in (6.6) and (6.12).

(e) g -shifts of the excited states

The observed $g_{//}$ -shifts of the split components of ${}^2E$ are

$$\left. \begin{aligned} g_{//}(2\bar{A}) &\doteq 2 - 2\Delta, \\ |g_{//}(\bar{E})| &\doteq 2 + 2\Delta, \\ \Delta &\doteq 0.2. \end{aligned} \right\} \quad (6.17)$$

Fig. 5 (b). The predicted Zeeman patterns ($H_0 \perp C_3$).

The terms on the last three lines cancel out, and we have

$$g_{//}'(^2E) = -12K^2/\{W(^2E) - W(^2F_1)\}\{W(^2E) - W(^2F_2)\} - 6K^2/\{W(^2E) - W(^2F_2)\}^2. \quad (6.19)$$

The second term is fairly small (if $K \sim -350 \text{ cm}^{-1}$, $W(^2E) - W(^2F_2) \sim -6500 \text{ cm}^{-1}$, it becomes ~ -0.02), but the first term will make a large contribution, since $^2F_1$ is supposed to be near ^2E . If we estimate the separation of these levels from the above formula, using the empirical value of $g_{//}'(^2E) \doteq -0.2$,

$$W(^2E) - W(^2F_1) \doteq -1200 \text{ cm}^{-1}, \quad (6.20)$$

which is a reasonable value for this separation and we expect from this that the energy of $^2F_1$ is higher than that of ^2E .

Similar consideration shows that the deviation of $g_{//}'(^2E)$ from 2, $\Delta g_{//}'(^2E)$, also comes mainly from the second order correction (also see Fig. 2);

$$\begin{aligned} \Delta g_{//}'(^2E) &= 2(^2E, \frac{1}{2}, u_+ | L_z | ^2F_1, \frac{1}{2}, a_+) \{ (^2F_1, \frac{1}{2}, a_+ | V_{s0} | ^2F_2, \frac{1}{2}, x_+) (^2F_2, \frac{1}{2}, x_+ | V_{\text{trig}} | ^2E, \frac{1}{2}, u_+) + \text{c.c.} \} \\ &\quad / \{ W(^2E) - W(^2F_1) \} \{ W(^2E) - W(^2F_2) \} \\ &\quad + 2 \{ (^2E, \frac{1}{2}, u_+ | V_{s0} | ^2F_2, \frac{1}{2}, x_+) (^2F_2, \frac{1}{2}, x_+ | V_{\text{trig}} | ^2F_1, \frac{1}{2}, a_+) + \text{c.c.} \} \\ &\quad \cdot (^2F_1, \frac{1}{2}, a_+ | L_z | ^2E, \frac{1}{2}, u_+) / \{ W(^2E) - W(^2F_1) \} \{ W(^2E) - W(^2F_2) \} \\ &= -8\zeta K / \{ W(^2E) - W(^2F_1) \} \{ W(^2E) - W(^2F_2) \}, \end{aligned} \quad (6.21)$$

which is estimated as ~ 0.05 , using the values $\zeta \sim 140 \text{ cm}^{-1}$ and (6.20). Such a small value of $\Delta g_{II}({}^2E)$ also justifies the use of the simplified Hamiltonian (6.1), because the neglected terms are found to be of the order of magnitude of this deviation $\Delta g_{II}({}^2E)$ multiplied by βH_0 .

It must be remarked that a large deviation of $g_{II}({}^2E)$ and a small $g_{II}({}^2E)$ -shift are due to the special situation, $V_{\text{trig}} > V_{s0}$, in our problem.

By the same reasoning we might expect the deviation of $g_{II}({}^2F_1)$ to be of the same order of magnitude as that for $g_{II}({}^2E)$ while g -values for ${}^2F_2$ are fairly close to those given in (6.12), since any crystal level cannot be expected to lie near ${}^2F_2$ as close as ${}^2F_1$ does to ${}^2E$. Such an expectation, however, is betrayed by the experimental results (Part B §5),

$$g_{II}(\bar{2}\bar{A}) \doteq 2\Delta', \quad |g_{II}(\bar{E}_a)| \doteq 4 - 2\Delta', \quad \Delta' \doteq 0.4, \quad (6.22)$$

where the deviations of g_{II} 's from those given in (6.12) are large. Therefore we must examine another cause of such a large deviation for ${}^2F_2$.

In ${}^2F_2$, (also in ${}^2F_1$), orbital angular momentum is not quenched and it gives finite value of g_{II}' in (6.8) and (6.9);

$$\begin{aligned} g_{II}' &= (F_1 a_+ | L_z | F_1 a_+) = -(F_1 a_- | L_z | F_1 a_-) \\ &= (F_2 x_- | L_z | F_2 x_-) = -(F_2 x_+ | L_z | F_2 x_+) \\ &= k, \end{aligned} \quad (6.23)$$

where k is defined as

$$k \equiv (f_2 x_- | L_z | f_2 x_-) = -(f_2 x_+ | L_z | f_2 x_+). \quad (6.24)$$

If f_2 -orbital is constructed from pure d -orbitals, k is equal to 1 and we have (6.12) and (6.13), but if we are allowed to suppose that f_2 -orbital is deformed by making a covalent bonding with the surroundings and accordingly is not of pure d -character, k is not necessarily equal to 1. Thus, in place of g_{II} 's in (6.12) and (6.13), we have for ${}^2F_2$

$$\left. \begin{aligned} g_{II}(\bar{2}\bar{A}) &\doteq 2(1-k), \\ g_{II}(\bar{E}_a) &\doteq -2(1+k), \\ g_{II}(\bar{E}_b) &\doteq 2. \end{aligned} \right\} \quad (6.25)$$

and for ${}^2F_1$

$$\left. \begin{aligned} g_{II}(\bar{2}\bar{A}) &\doteq 2(1+k), \\ g_{II}(\bar{E}_a) &\doteq -2(1-k), \\ g_{II}(\bar{E}_b) &\doteq 2. \end{aligned} \right\} \quad (6.26)$$

To satisfy the empirical relations (6.22), we must choose

$$k \doteq 0.6. \quad (6.27)$$

In ${}^2E$ the orbital angular momentum is quenched but it contributes to $g_{II}({}^2E)$ and $\Delta g_{II}({}^2E)$ through higher order correction of type $L_z V_{\text{trig}}^2$. Thus the right hand side of (6.19) and (6.21) must be multiplied also by k . Then (6.20) becomes

$$W({}^2E) - W({}^2F_1) \doteq 700 \text{ cm}^{-1}. \quad (6.20')$$

§7. Connection to the Paramagnetic Resonance Absorption

The analysis of the optical absorption spectra affords important informations not only on the excited electronic states but also on the ground state. For instance, the analyses of the Zeeman effect of the line spectra (Part B §4) and the polarization-shift (Part B §3 (d)) show that, of the two Kramers doublets $M_s = \pm 3/2$ and $M_s = \pm 1/2$ of the ground quartet ${}^4A_2$, $M_s = \pm 3/2$ is the lower, and lead to the following value for the natural splitting

$$\delta = W(\pm 1/2) - W(\pm 3/2) = 0.36 \pm 0.03 \text{ cm}^{-1}. \quad (7.1)$$

This value should be compared with the following precise value determined by the method of paramagnetic resonance absorption

$$|\delta| = 0.38 \text{ cm}^{-1}. \quad (7.2)$$

It should be noted, however, that this method gives us only the absolute value of δ , whereas the optical absorption could determine the sign as well as the approximate value.

Since detailed knowledges of the excited states are now in our hands, we can go a little further and examine whether this value of δ is consistent or not with the other empirical values determined here.

It will then be noticed that the sign of δ is inconsistent with the sign of K if one accepts the usual theory of the natural splitting, which leads to the following formula for δ

$$\delta = \frac{4}{3} \zeta^2 K / \{W({}^4A_2) - W({}^4F_2)\}^2. \quad (7.3)$$

This formula is, however, derived under the assumption of isotropic spin-orbit interaction, and is not adequate for the present case, because the g -value of the ground quartet obtained by the paramagnetic resonance absorption shows the anisotropy⁵⁾, namely

$$\left. \begin{aligned} \Delta g_{0//} &= -g_{0//} + 2.0023 = 0.0183 \pm 0.0006 \\ \Delta g_{0\perp} &= -g_{0\perp} + 2.0023 = 0.0156 \pm 0.0006 \end{aligned} \right\} \quad (7.4)$$

and this should be understood as the indication of the anisotropy in the spin-orbit interaction which has been assumed to be isotropic in the present paper.

The anisotropy of *g*-value is correlated with the anisotropy of the spin-orbit coupling parameter ζ' in the following way:

$$\left. \begin{aligned} \Delta g_{0//} &= \frac{8}{3} k' \zeta'_{//} / \{ W(^4F_2) - W(^4A_2) \} , \\ \Delta g_{0\perp} &= \frac{8}{3} k' \zeta'_{\perp} / \{ W(^4F_2) - W(^4A_2) \} , \end{aligned} \right\} \quad (7.5)$$

where *k'* is a parameter to describe the de-

crease of the angular momentum in crystals;

$$k' = -\frac{1}{\sqrt{2}} (f_2 x_+ | l_z | e u_+) , \quad (7.6)$$

which is unity for *e* and *f*₂ function constructed from pure *d* functions. (7.5) then gives

$$\left. \begin{aligned} k' \zeta'_{//} &= 130 \sim 120 \\ k' \zeta'_{\perp} &= 110 \sim 100 \end{aligned} \right\} \quad (7.7)$$

The formula (7.3) for the expression of δ should be reexamined. The shift of the Kramers doublet due to the perturbation $\mathcal{H}'$ is given by

$$\begin{aligned} W(M_s) = & \sum_{M_s', M'} \frac{(^4A_2 M_s | V_{s0} | ^4F_2 M_s' M') (^4F_2 M_s' M' | V_{s0} | ^4A_2 M_s)}{W(^4A_2) - W(^4F_2)} \\ & + \sum_{M_s', M'} \frac{(^4A_2 M_s | V_{s0} | ^4F_2 M_s' M') (^4F_2 M_s' M' | V_{\text{trig}} | ^4F_2 M_s' M') (^4F_2 M_s' M' | V_{s0} | ^4A_2 M_s)}{\{ W(^4A_2) - W(^4F_2) \}^2} \\ & + \sum_{M_s', M'} \frac{(^4A_2 M_s | V_{\text{trig}} | ^4F_1 M_s a_0) (^4F_1 M_s a_0 | V_{s0} | ^4F_2 M_s' M') (^4F_2 M_s' M' | V_{s0} | ^4A_2 M_s)}{\{ W(^4A_2) - W(^4F_1) \} \{ W(^4A_2) - W(^4F_2) \}} + \text{c.c.} . \end{aligned} \quad (7.8)$$

Taking the difference $W(\pm 1/2) - W(\pm 3/2)$, we find after evaluating relevant matrix elements

$$\begin{aligned} \delta = & \frac{8}{9} (\zeta'_{//}{}^2 - \zeta'_{\perp}{}^2) / \{ W(^4F_2) - W(^4A_2) \} + \frac{4}{9} (2\zeta'_{//}{}^2 + \zeta'_{\perp}{}^2) K / \{ W(^4F_2) - W(^4A_2) \}^2 \\ & - 2\sqrt{\frac{2}{3}} K' \times \frac{4}{9} (2\zeta'_{//} \zeta'_{//} + \zeta'_{\perp} \zeta'_{\perp}) / \{ W(^4F_2) - W(^4A_2) \} \{ W(^4F_1) - W(^4A_2) \} , \end{aligned} \quad (7.9)$$

where $K' = -1\sqrt{2} (f_2 x_{\pm} | v_{\text{trig}} | e u_{\pm})$. $K' = K$ if *f*₂ and *e* are *d*-functions and $v_{\text{trig}} \propto 3z^2 - r^2$. The second term in the above expression corresponds to (7.3) and gives a negative contribution to δ but we find that this is almost cancelled out by the third term which has been overlooked by Van Vleck¹²⁾, if we estimate the third term assuming $K' = K$, $\zeta'_{//} = \zeta'_{//}$ and $\zeta'_{\perp} = \zeta'_{\perp}$. The first term which is positive ($\zeta'_{//} > \zeta'_{\perp}$) in the present case, gives δ with the positive sign,

$$\delta \approx 0.3 \sim 0.6 , \quad (7.10)$$

if we take $k' = k = 0.6$, which is a reasonable value. The values of ζ' 's are accordingly

$$\left. \begin{aligned} \zeta'_{//} &\sim 200 \\ \zeta'_{\perp} &\sim 170 \end{aligned} \right\} . \quad (7.11)$$

The problem of natural splitting is thus rather delicate one and we will not pursue this problem further, since the inconsistency caused by the formula (7.3) is now removed.

§ 8. Conclusion

Although several problems remain unsolved, the main purpose of the present paper, i.e.

the assignments of the absorption bands and lines of ruby Cr³⁺:Al₂O₃, has now been achieved. The results and unsolved problems are summarized below.

(a) For the *U* and *Y* bands the assignments (4.11) has been made. The anisotropy shown by these bands is understood qualitatively, but not quantitatively. The parameter *K* which is a measure of the strength of the trigonal field was determined from the splittings of the bands:

$$K = -350 \text{ cm}^{-1} .$$

(b) For *R*₁ and *R*₂ the assignments (5.21) has been made. The anisotropies of the lines are closely related to that of the bands, and this problem needs further investigations. The second order perturbation formula (5.6) leads to the following value of the spin-orbit coupling parameter for *f*₂ electrons:

$$\zeta = 140 \text{ cm}^{-1} .$$

For *B*₁ and *B*₂, the assignments (5.24) has been made. The separation between *B*₁ and *B*₂ could not be correctly given by the formulae (5.16) and (5.18) derived under the assumption

of the strong field limit.

(c) For the assignments of these lines, the analyses of the Zeeman effect offer most conclusive evidences.

(d) The large g -shifts of R_1 and R_2 excited states observed in the Zeeman patterns have been explained by taking into account the second order correction of the type $V_{\text{trig}}^2 \cdot L_z$. The correction is fairly large if the excited state ${}^2F_1$ lies near ${}^2E$. From the sign and the magnitude of the observed g -shift, ${}^2F_1$ is expected to lie at the shorter wave-length side of ${}^2E$ separated approximately by $\sim 700 \text{ cm}^{-1}$.

(e) The observed g -values of B_1 and B_2 excited states have also been explained by introducing the reduced expectation value of the orbital angular momentum (for f_2 orbital) in the crystal. As the value of the parameter k which indicates such a reduction (6.23), we have

$$k \sim 0.6.$$

(f) The line that corresponds to $\bar{E}_0({}^2F_2)$ is yet unidentified. The lines corresponding to the split components of ${}^2F_1$ are also not identified yet.

(g) It has been shown that experimental data on the excited states (optical absorption) can be reasonably connected to those on the ground state (paramagnetic resonance).

(h) As to the problem of intensity, the present theory is not satisfactory in that it is semi-empirical, and it is hoped to establish a theory that could predict the absolute intensities of bands and lines as well as the widths of the bands and the lines which have not been touched upon in this paper.

Acknowledgements

We should like to express our sincere thanks to Professor M. Kotani for his deep interest in this work and encouragement, and to Professor G. Kuwabara and Mr. A. Misu for their permission to use the experimental data of the absorption bands prior to publication. The authors also wish to express their thanks to the members of Prof. Kotani's laboratory for stimulating discussions.

Absorption Spectra of Cr^{3+} in Al_2O_3

Part B. Experimental Studies of the Zeeman Effect and Other Properties of the Line Spectra

By Satoru SUGANO

Metals, Tohoku University, Sendai*

(Received April 5, 1958)

The absorption intensities, widths and wave-numbers of R_1 , R_2 and B_1 B_2 lines of Cr^{3+} in ruby for the polarized light $E \perp C_3$ and $E \parallel C_3$ are experimentally studied at 20°K and 4.2°K. Zeeman effect is also studied, using a magnetic field $H_0 = 24,000 \phi$, for both R and B lines. The Zeeman effect has not been observed yet for the B lines, while Lehmann has already observed the Zeeman effect for R lines. In our results of R lines, the quantitative aspects of Lehmann's experiment are improved. The comparison is made with the theoretical results given in Part A and it is shown that nice agreements can be obtained when suitable assignments of the spectra are adopted and when fairly large g -shifts of the excited states are introduced.

§ 1. Introduction

Among the bound transition metal ions which show extremely narrow absorption spectra e.g., Cr^{3+} , Mn^{2+} , Co^{2+} and Ni^{2+} in complex salts or Cr^{3+} impurity in oxide crystals, ruby Cr^{3+} : Al_2O_3 seems to be the most appropriate material, as explained in §1 of the first paper of this series, to start the studies of these line spectra.

The general behaviour of the many absorption and emission spectra of ruby has been revealed by the original work of Deutschbein.¹⁾ From this we know that, among the numerous observed spectra, R_1 , R_2 lines in the red region and B_1 , B_2 in the blue region are conspicuously strong and sharp. Especially on R_1 , R_2 lines, Lehmann²⁾ has examined their optical Zeeman effect at 83°K and

has obtained the Zeeman patterns that depend on the directions of the electric vector E of the incident light and of a magnetic field H_0 relative to the crystal axis C_3 .

On the other hand, the Zeeman splitting of the ground level of ruby has been recently measured by the paramagnetic resonance method³⁾ and its splitting factors have been precisely determined. This enables us to expect that the optical Zeeman pattern must contain some Zeeman components of the ground state whose separations are already known, when the optical Zeeman pattern consists of more than two components and the excited state concerned with is considered to be a Kramers doublet. This is because that, in this case, at least two of such Zeeman components must correspond to the transitions from the different Zeeman levels of the ground state to the same Zeeman level of the excited state.

In Lehmann's Zeeman patterns, however, it is impossible to find out the Zeeman components whose separation corresponds to any separation among the Zeeman levels of the ground state. The theoretical investigation given in the first paper also showed that though the qualitative aspects of Lehmann's results could be reasonably explained, the splitting factors he had measured were far from the theoretical expectation. In such a situation, it was felt necessary to repeat the studies of the Zeeman effect of these line spectra at experimentally better condition.*

In this paper the Zeeman effects of R_1 , R_2 (§4) and B_1 , B_2 (§5) lines are studied at 20°K and 4.2°K. The Zeeman patterns of B_1 , B_2 have not been observed yet. To determine the magnitudes of Zeeman splittings precisely, we have tried to make the spectral widths narrow by using ruby of low Cr^{3+} concentration as well as by performing the experiment at very low temperatures. The concentration dependence of the spectral width and position (§3) has been found in the preliminary course of our work.

Besides the Zeeman effect, it will also be useful for the spectral assignments to examine the change of absorption wave-numbers

and intensities (anisotropy) of these spectra when we use polarized light of $E \perp C_3$ and $E // C_3$. The results of such examinations at 20°K and 4.2°K (§3) will also serve for extending Paetzold's work⁴⁾ which has aimed at the problem of the interaction between chromophoric electrons and lattice by examining the temperature dependence of the absorption wave-numbers and the widths of these spectra at temperatures higher than 80°K.

§2. The Experimental Methods

The samples used in our experiments are synthetic rubies of 4 mm thickness (sample A) and of 1 mm thickness (sample B). The crystal axes are determined by X-ray and we cut the sample to make the principal axis C_3 (optic axis) to lie in the plane, perpendicularly to which the incident light is passed. The result of chemical analysis shows that samples A and B contain 0.28 and 2.56 weight percent Cr_2O_3 respectively.

In our spectroscopic studies, a grating spectrograph in Eagle mounting with dispersion 2.5 Å/mm in the first order has been used. The light source is a 60-W Zircon lamp and the diffracted beam is detected by photographic methods. The comparison spectra are supplied by Ne-lamp (6929.468 Å, 7032.413 Å lines) or Cd-lamp (4679.156 Å, 4799.918 Å lines) corresponding to the case of determining R_1 , R_2 or B_1 , B_2 absorption wave-lengths. In the determination of the latter, however, it is sometimes more convenient to utilize the emission lines of the light source (the arc lines of Zr, 4739.478 Å, 4772.312 Å) as the comparison spectra.

To get the light beams polarized perpendicularly to each other, Wollaston's prism is placed in front of the slit and through the separated parts of the slit both polarized beams are passed simultaneously. Thus in every exposure we can get two kinds of spectral photograph corresponding to the polarized beams $E \perp C_3$ and $E // C_3$. In this case, the astigmatism of the concave grating is eliminated by the cylindrical lens suitably placed in front of the photographic plate.

Further in our absorption measurements of R_1 and R_2 , we have inserted, between the light source and the sample, the red filter in order to cut the light of shorter wave-length which lies in the region of the broad absorp-

* Prof. G. H. Dieke of the Johns Hopkins University has kindly informed us that Zeeman experiment on ruby has also been completed in his laboratory but the results are not published yet.

tion bands U and Y located at $\sim 5500\text{\AA}$ and $\sim 4000\text{\AA}$; Ruby shows relatively strong emission at the same positions as those of R_1, R_2 when it is excited by visible light in the region of U and Y and so in the absorption measurements we must suppress the undesired emission parts of R_1, R_2 lines by exclusion of such excitation light.

To keep a sample at low temperatures, it is immersed in liquid helium or liquid hydrogen contained in a Dewar vessel. The magnitude of the applied magnetic field to study the Zeeman effects is $24,000\phi$.

§ 3. Properties of the Line Spectra in Absence of a Magnetic Field

(a) *The optical anisotropies:* Though no quantitative measurement of the absorption intensities has been attempted, the optical anisotropies observed in R_1, R_2 and B_1, B_2 absorption lines are remarkable and so they are schematically described in Fig. 1. The

Fig. 1. The optical anisotropies observed in R_1, R_2 and B_1, B_2 absorption lines. Only the relative intensities are schematically represented for R 's and B 's spectra. The most intense lines $R_1^\perp$ and $B_1^\parallel$ in each group are normalized.

relation between the intensities of R_1 and R_2 is inverted when the polarization of the incident light is changed. The same situation also occurs in B_1, B_2 , though the relation between the intensities of B_1 and B_2 is just contrary to the case of R_1 and R_2 for each polarization.

The qualitative aspects of these anisotropies are not changed when temperature or concentration of Cr^{3+} is varied.

(b) *The spectral widths:* A tremendously large difference is observed between the spectral widths of the relatively dilute sample

A and highly concentrated sample B. In sample A, the spectral widths are very narrow and their approximate values are as follows;*

$R_1^\perp$	$R_2^\perp$	$R_1^\parallel$	$R_2^\parallel$
0.7,	0.6,	0.6,	0.6, (cm^{-1})
$B_1^\perp$	$B_2^\perp$	$B_1^\parallel$	$B_2^\parallel$
1.9,	2.6,	1.9,	2.6,

No noticeable difference is observed among the spectral widths observed at 86°K , 20°K and 4.2°K for R lines and between those measured at 20°K and 4.2°K for B lines. In sample B, the widths of R_1, R_2 are approximately 3 cm^{-1} and those of B_1, B_2 8 cm^{-1} which are about four times larger than those observed in sample A (also see Fig. 2).

Fig. 2. The microphotometer traces of R_1 and R_2 spectra of samples A and B observed at 20°K .

The spectral widths in sample A are such that in R_1, R_2 lines the widths of $R_1^\perp$ is a little larger than the other components and in B_1, B_2 lines the widths of $B_1^\perp$ and $B_1^\parallel$ are clearly smaller than those of $B_2^\perp, B_2^\parallel$.

(c) *The absorption wave-numbers:* The absorption wave-lengths of R_1, R_2 and B_1, B_2 absorption lines for the polarized lights ($E \perp$

* Throughout this paper, superscripts $\perp$ and $\parallel$ indicate the direction of E and subscripts $\perp$ and $\parallel$ indicate that of H_0 relative to the optic axis C_3 .

C_3 and $E//C_3$) have been measured precisely as possible and they are given in Tables I and II. The experimental error given in the tables is caused mainly by the difficulty of determining the position of an absorption peak because of the finite spreading of the spectrum.

The most remarkable fact found in such measurements is that the absorption position of the spectrum slightly shifts when the polarization of the incident light is changed (called hereafter polarization-shift). The directions and the magnitudes of these shifts are shown in the last two rows of Tables III and IV, together with the observed separa-

Table IV. The separations of B_1 and B_2 absorption spectra and their polarization-shifts $\nu^\perp - \nu^\parallel$. (cm^{-1})

	Sample A		Sample B

$\nu(B_1^\perp) - \nu(B_1^\parallel)$	-0.2	-0.3	—	—
$\nu(B_2^\perp) - \nu(B_2^\parallel)$	0.3	0.4	—	—

tions between R_1 and R_2 and those between B_1 and B_2 . These separations and polarization-shifts seem independent of the change of temperature except for the separation $\nu(R_2^\parallel) - \nu(R_1^\parallel)$ and the shift $\nu(R_1^\perp) - \nu(R_1^\parallel)$.

The temperature dependence of the absorption wave-numbers of R_1 and R_2 is illustrated in Fig. 3. When the temperature is in-

creased from 4.2°K to 20°K, these spectra shift towards the shorter wave-length side (blue-shift), while they show a red-shift at high temperatures. The shifts thus found at very low temperatures are, however, so small (the order of these magnitudes is different from that observed at high temperatures) that they cannot be observed in case of B lines, being within the experimental error.

In sample B, the absorption positions of R_1 and R_2 lines seem to be shifted towards the shorter wave-length side beyond the experimental error (Table I) in comparison with those measured in sample A, while these concentration-shifts are not clearly observed in B_1 , B_2 lines.

(d) *Discussions:* The observation of optical anisotropies provides us with a very useful information for the spectral assignment, especially in case the spectral width is broad and experimental studies of the Zeeman effect are impossible to be made. Theoretically the absorption intensities of the line spectra in our case are supplied from those of the absorption bands by interplay of spin-orbit interaction, i.e., the intensity of R lines is supplied from U band and that of B lines mainly from Y and partly from U . Thus the optical anisotropies of these lines are determined both by the anisotropies of the absorption bands and by the strengths of spin-orbit interactions. In Fig. 1, the results of the theoretical estimates of optical intensities (Part A § 5 (b)) are also given under the presumption that the spectral assignment has been made as follows,*

$$\left. \begin{aligned} R_1: & \quad {}^4A_2 \rightarrow \bar{E} \\ B_2: & \quad \rightarrow 2\bar{A} \end{aligned} \right\} {}^2E$$
$$\left. \begin{aligned} B_1: & \quad {}^4A_2 \rightarrow 2\bar{A} \\ B_2: & \quad \rightarrow \bar{E}_a \end{aligned} \right\} {}^2F_2.$$

We see that the qualitative features of the observed relative intensities for the fixed polarized light are reasonably explained by the theory, though the theory does not explain the intensity ratio between parallel and perpendicular component of a spectrum. Our experimental results recommend the following

* On the meaning of the notations, see Part A. Throughout this paper, we use the notations already used in Part A without explaining their meaning.

Fig. 3. The temperature dependences of the absorption wave-numbers of $R_1^\perp$, $R_1^\parallel$, $R_2^\perp$ and $R_2^\parallel$ (sample A).

approximate relations among the theoretically introduced parameters; $\sigma \sim 2\pi$ (for ${}^2E$), $\sigma_0 \sim 2\sigma$ and $\pi \sim 3\sigma$ (for ${}^2F_2$).

The problem of the observed separations of R_1 and R_2 and of B_1 and B_2 lines has been already discussed in Part A. The separation is determined mainly by the magnitudes of the trigonal field and the spin-orbit interaction. The remarkable constancy of the observed separations (except $\nu(R_2'') - \nu(R_1'')$) at low temperatures will indicate that little change of the crystal parameters occurs at these temperatures. The exceptional case $\nu(R_2'') - \nu(R_1'')$ is brought about by the anomalous temperature dependence of R_1'' spectrum. Although R_1'' is the faintest spectrum among R 's, its observed anomaly seems to be really the case being beyond the experimental error. This anomaly remains unexplained.

The polarization-shifts can be easily understood if attention is paid both to the selection rule and the initial splitting of the ground state (see Figs. 4 and 5 of Part A). Thus the assignments are also confirmed by observing these polarization-shifts. If the sign of δ is defined positive when the Kramers doublet $M_s = \pm 3/2$ is lower than the doublet $M_s = \pm 1/2$, the theoretically predicted polarization-shifts are as follows under the above-mentioned spectral assignments;*

$$\begin{aligned} \delta/2 < \nu(R_1^\pm) - \nu(R_1'') < \delta, \\ \nu(R_2^\pm) - \nu(R_2'') &= -\delta, \\ \nu(B_1^\pm) - \nu(B_1'') &= -\delta, \\ \delta/2 < \nu(B_2^\pm) - \nu(B_2'') < \delta. \quad (|\delta| = 0.38 \text{ cm}^{-1}) \end{aligned}$$

The experimental results given in Tables III and IV (except $\nu(R_1^\pm) - \nu(R_1'')$) satisfy these relations within the limit of the experimental error when the sign of δ is assumed positive. The exceptional case of $\nu(R_1^\pm) - \nu(R_1'')$ is because of the queer behaviour of R_1'' spec-

trum which has been already pointed out. Since the polarization-shift of R_2 spectrum is measurable with rather high precision, its measurement is one of the ways to determine optically the natural splitting δ . The value of δ thus determined from the polarization-shift of R_2 is $\delta = 0.36 \pm 0.03 \text{ cm}^{-1}$ which agrees well with the result of the paramagnetic resonance experiments, $|\delta| = 0.38 \text{ cm}^{-1}$.³⁾ Such an optical method is superior to the paramagnetic resonance method only in determining the sign of δ .

The problems of the spectral widths and the temperature-shifts will not be discussed in detail in this paper. The slight broadness of $R_1^\pm$ compared with the other components of R_1 and R_2 can be understood since theoretically $R_1^\pm$ spectrum is the superposition of two lines separated by δ while the others are singlets. To interpret the difference between the widths of B_1 and B_2 lines, however, it is necessary to take other effects into consideration. The curious temperature-shifts of R lines observed at very low temperatures show that Paetzold and Krömer's experimental formula⁵⁾ $\nu = \alpha + \beta(T/\theta)^2$ at $T \ll \theta$ (θ : Debye temperature) is not good for R lines at these temperatures.

The observed concentration-broadening and concentration-shift seem to offer very interesting problems, but to discuss such problems it will be necessary to make further experiments.

§ 4. Zeeman Effects of R_1 and R_2 Absorption Lines

The Zeeman patterns of R_1 , R_2 absorption lines of sample A obtained at 20°K and 4.2°K in the four cases, $H_0 // C_3$ $E \perp C_3$, $H_0 // C_2$ $E // C_3$, $H_0 \perp C_3$ $E \perp C_3$, and $H_0 \perp C_3$ $E // C_3$ are illustrated in Figs. 4 and 5 together with the diagrams of transitions.

The observed splitting factors g 's and the central wave-numbers ν^0 's of these patterns are listed in Table V. Among these Zeeman patterns, those of R_1 ($H_0 // C_3$ $E // C_3$) and of R_1 , R_2 ($H_0 \perp C_3$ $E // C_3$) are too faint to make direct measurements of the original plates precisely. Therefore, suitably reprinted plates with high contrast have been used for the measurements.

In the reprinted plates, it is found that, though the relative positions of absorption

*. In the following relations, inequalities occur because $R_1^\pm$ and $B_2^\pm$ are expected to be unresolved doublets separated by δ (Figs. 4 and 5, Part A) and the observed peak of an unresolved doublet is considered to be located between the middle of the unresolved doublet and the stronger component of the doublet. The observed peak will be just at the middle of the unresolved two components when their intensities are same. In the following discussions, inequalities always appear in such cases.

Fig. 4 (a) case I: Ho/Cs , $E \perp \text{Cs}$ Fig. 5 (a) case III: $\text{Ho} \perp \text{Cs}$, $E \perp \text{Cs}$ Fig. 4 (b) case II: Ho/Cs , $E // \text{Cs}$ Fig. 5 (b) case IV: $\text{Ho} \perp \text{Cs}$, $E // \text{Cs}$ Fig. 4 (c) transition-diagrams: $\begin{cases} \longrightarrow E \perp \text{Cs} \\ \dashrightarrow E // \text{Cs} \end{cases} \text{Ho}/\text{Cs}$ Fig. 5 (c) transition-diagrams: $\begin{cases} \longrightarrow \text{both } E \perp \text{Cs and } E // \text{Cs} \end{cases} \text{Ho} \perp \text{Cs}$

Fig. 4, 5. (a), (b): The observed Zeeman patterns (full curve) and the patterns (vertical lines) derived from the transition-diagrams (c). The intensities and the shapes of the observed patterns are only qualitatively illustrated. In the patterns (vertical lines) of 4.2°K, difference in electron population of the Zeeman levels of the ground state is taken into account. (c): The numbers in brackets indicate the transition probabilities when $E // \text{Cs}$ and the others (without brackets) are those when $E \perp \text{Cs}$. In the calculation of the transition probabilities, the empirical relation $\sigma \sim 2\pi$ is used and π is put equal to 1.

lines are represented fairly well, the distance between an emission (comparison spectrum) and an absorption line is sometimes slightly changed from that measured on the original plate. Thus in order to avoid the confusion such unreliable measurements on the absolute positions of the absorption may create, the central wave-numbers ν_0 's of these faint pat-

terns are not tabulated. In Table VI the quantities derived from Table V which are useful in the following discussions are also given.

All the qualitative features of the Zeeman patterns obtained at 20°K are in agreement with those obtained by Lehmann at 83°K, but the quantitative features of our patterns

Table V. The observed splitting factors (in βH_0 unit) and the central wave-numbers $\nu^0(\text{cm}^{-1})$ of R_1 , R_2 Zeeman patterns. The central wave-number ν^0 is defined as the wave-number of the central Zeeman component when three Zeeman components appear, and is defined as the wave-number in the middle of the inner two components when four components appear. On the notation of g 's, see Fig. 4.

are entirely different from those of Lehmann's.

To simplify the description, we assume from the beginning the spectral assignments given in § 3 (d) which are established most definitely from the observed Zeeman patterns.

Case I. $H_0 // C_3$ and $E \perp C_3$ (Fig. 4(a)):

The observed splitting factors of the Zeeman patterns in this case are far smaller than those theoretically expected, even though they are increased compared with those of Lehmann's.

The only way to fulfil the previously given proper requirement that the Zeeman pattern in this case must contain some of the Zeeman components of the ground state is to introduce the g -shifts of the excited states assuming the central component to be the unresolved doublet. In fact the central component seems broader than the side components. That this is due to the superposition of two lines can be made clear by observing its apparent shift relative to the side component when the temperature is varied from 20°K to 4.2°K. This is because, if the central component is the superposition of closely lo-

cated two lines, the decrease of the number of electrons populated in the upper Zeeman levels of the ground states at 4.2°K makes one line of the superposed two central lines weaker than the other. As a result, the apparent peak of the central component shifts to the stronger one while at 20°K it will be almost at the middle of the two.

The quantities $1/2(g_{I'} - g_{I'})$ measured at 20°K and 4.2°K given in the second row of Table VI show such apparent relative shifts of the central component for both R_1 and R_2 . Keeping the above-mentioned explanation of the apparent shifts in mind and referring to the theoretically obtained diagram of transitions, we expect the following values for $1/2(g'' - g')$;

$$\begin{aligned}
 & \left. \begin{aligned} 1/2(g_{I'} - g_{I'}) &= \delta \text{ for } R_1 \\ &= 0 \text{ for } R_2 \end{aligned} \right\} \text{ at } 20^\circ\text{K} \\
 & \left. \begin{aligned} &> \delta \text{ and } < \delta + |\Delta_1| \text{ for } R_1 \\ &> -|\Delta_2| \text{ and } < 0 \text{ for } R_2 \end{aligned} \right\} \text{ at } 4.2^\circ\text{K},
 \end{aligned}$$

where Δ_1 and Δ_2 denote the half g -shifts of the excited states of R_1 and R_2 respectively and their magnitudes will be determined in the following analysis. With the values Δ_1

$=0.22$, $A_2=-0.26$ and $\delta=0.34$ (in βH_0 unit), these relations are held actually in Table VI almost within the limit of experimental error. The g -shifts of the R_1 and R_2 excited states are determined from

$$\begin{aligned} 1/2(g_{//}' + g_{//}'') &= g_0 - A_1 \quad \text{for } R_1, \\ &= g_0 + A_2 \quad \text{for } R_2, \end{aligned}$$

where g_0 is the g -value of the ground state and is known as 1.98. The sum of the left hand side is made to eliminate the effect of the natural splitting δ of the ground state. From Table VI, we obtain

$$\begin{aligned} A_1 &= 0.22 \ (\pm 0.04), \quad A_2 = -0.26 \ (\pm 0.04), \\ g_{e//}(R_1) &= g_0 + 2A_1 = 2.42, \\ g_{e//}(R_2) &= g_0 + 2A_2 = 1.46, \end{aligned}$$

where $g_{e//}(R_1)$ and $g_{e//}(R_2)$ are the g -values of the R_1 and R_2 excited states respectively. Looking at these results, we notice at once the following simple relation to exist between $g_{e//}$'s,

Table VI. The useful quantities to confirm the assignments. These are derived from Table I and Table V. $g_{//}$ and $g_{\perp}$ denote the splitting factors in cases of $H_0//C_3$ and $H_0 \perp C_3$ respectively. The subscripts of $v_{//}^0$ and $v_{\perp}^0$ also indicate the direction of a magnetic field. v_0 is the absorption wave-number in case of no magnetic field.

$$\begin{aligned} g_{e//}(R_1) + g_{e//}(R_2) &\doteq 4, \\ A_1 &\doteq -A_2 \ (\neq 0). \end{aligned}$$

The explanation of such an interesting relation between the g -shifts of the R_1 and R_2 excited states is given in the first paper.

Case II. $H_0//C_3$ and $E//C_3$ (Fig. 4 (b)):

The $g_{e//}(R_2)$ -shift is more clearly observed in this case in the Zeeman pattern of R_2 where the separation of the two components $\bar{g}$ must be $2g_0 - 2A_2 = 4.52 \ (\pm 0.07)$ if the same $g_{e//}(R_2)$ -shift as determined from the pattern of R_2^+ in the previous case is used. The observed values of $\bar{g}$'s for the both temperatures (Table VI) agree with this within the limit of experimental error.

The observed Zeeman pattern of R_1'' which is the faintest among the patterns of R_1 and R_2 we have obtained, however, does not seem to be explained within our scheme even qualitatively. Against our expectation on this pattern that it consists of two weak components separated by $2g_0 + 2A_1 = 4.40 \ (\pm 0.07)$, the observed pattern consists of three components and the separation of the side components is $4.1 \ (\pm 0.1)$ even if the central component is disregarded. Our previous short report⁶⁾ has erroneously described this Zeeman pattern.

Case III $H_0 \perp C_3$ and $E \perp C_3$ (Fig. 5 (a)).

In this case, the Zeeman levels of the ground state are directly represented: The paramagnetic resonance experiment has show that the separation of the four Zeeman levels of the ground state are $g_0 - \delta/2$, g_0 and $g_0 + \delta/2$. If $g_{\perp}'''$, $g_{\perp}''$ and $g_{\perp}'$ are identified to be $g_0 - \delta/2$, g_0 and $g_0 + \delta/2$ respectively, the relations,

$$\begin{aligned} g'' &= g_0 = 1.98, \quad 1/2(g' + g'') = g_0, \\ g_{\perp}' - g_{\perp}''' &= \delta = 0.34 \end{aligned}$$

must hold among the observed $g_{\perp}$'s. Table VI shows that the observed $g_{\perp}$'s actually satisfy these relations within the limit of experimental error. The positive sign of δ is also confirmed in such a comparison. In the Zeeman patterns observed at 4.2°K, the uniformly decreasing inclination of the intensities of the longer wave-length side components which is due to the decrease in electron population of the upper Zeeman levels of the ground state at 4.2°K is consis-

tent with the above-mentioned identification of the observed $g_{\perp}$'s. In this case, the g -shifts $\Delta g_{\perp}$'s, i.e., deviations of the g -values of the excited states from zero, will split each of the four Zeeman components into two lines separated by $\Delta g_{\perp}$, but, if $\Delta g_{\perp}$'s are smaller than the spectral width, these closely located two lines cannot be resolved and the apparent position of such a superposed component will not be changed from the case of $\Delta g_{\perp}=0$. In addition to this situation, since the superposed two lines correspond to the transitions from the same Zeeman level of the ground state, the apparent temperature-variations of the splitting factors similar to those previously explained in case of $H_0//C_3$ and $E\perp C_3$ are not expected. In Fig. 5, the finite g -shifts of the both R_1 and R_2 excited states are assumed although they cannot be determined from the observed patterns.

Case IV $H_0\perp C_3$ and $E//C_3$ (Fig. 5(b)):

An accurate measurement of the splittings is impossible in this case because the intensities are weak. It may be said, however, from Table V that no noticeable difference of the splittings is observed between case III and case IV, which is reasonable from the theoretical point of view. The relative intensities of the components, which differ from those observed in case III show a nice agreement between experiment and theory.

A remaining quantity to be discussed is the central wave-number ν^0 of the Zeeman pattern whose definition is given in the footnote of Table V. According to the diagram of transitions, the difference between ν^0 and ν_0 observed in case of no magnetic field, $\Delta\nu = \nu^0 - \nu_0$, must satisfy the following relations; when $H_0//C_3$ and $E\perp C_3$

$$\begin{aligned} 0 > \Delta\nu(20^\circ\text{K}) > \delta \quad (&=0.38\text{ cm}^{-1}) \\ \Delta\nu(20^\circ\text{K}) > \Delta\nu(4.2^\circ\text{K}) > \Delta\nu(20^\circ\text{K}) - |A_1| \\ &(|A_1|=0.25\text{ cm}^{-1}) \\ &\text{for } R_1; \\ \Delta\nu(20^\circ\text{K}) &= 0 \\ |A_2| > \Delta\nu(4.2^\circ\text{K}) > 0 \quad (&|A_2|=0.29\text{ cm}^{-1}) \\ &\text{for } R_2; \end{aligned}$$

when $H_0//C_3$ and $E//C_3$

$$\Delta\nu(20^\circ\text{K}, 4.2^\circ\text{K}) = 0 \quad \text{for } R_2;$$

when $H_0\perp C_3$ and $E\perp C_3$

$$\begin{aligned} 0 > \Delta\nu(20^\circ\text{K}, 4.2^\circ\text{K}) > 3\delta/4 - \delta \\ &(&=0.10\text{ cm}^{-1}) \text{ for } R_1; \\ \Delta\nu(20^\circ\text{K}, 4.2^\circ\text{K}) &= 3\delta/4 \\ &(&=0.28\text{ cm}^{-1}) \text{ for } R_2; \end{aligned}$$

The observed $\Delta\nu$'s given in Table VI seem to deviate from these beyond the limit of experimental error. All deviations are systematic in such a way that they are negative at 20°K and positive at 4.2°K .

§ 5. Zeeman Effect of B_1 and B_2 Absorption Lines

The observed Zeeman patterns of B_1 , B_2 absorption lines are illustrated in Fig. 6 and Fig. 7 together with the diagram of transitions. The spectral widths of B_1 and B_2 lines are about three times broader than those of R_1 and R_2 , but they are still smaller or comparative to the Zeeman energies. Therefore we have obtained the Zeeman patterns, although not so clear as the case of R lines, which depend on the directions of H_0 and E relative to the crystal axis C_3 . Thus, together with the theoretical considerations given in the first paper, it is possible to establish definite assignments of B lines by using the observed patterns. For example, a possibility that one of these spectra may be identified to the transition ${}^4A_2 \rightarrow \bar{E}_g({}^2F_2)$ can be easily excluded by the fact that the theoretically predicted Zeeman patterns corresponding to it (Fig. 5, Part A) consists of an unsplit component when $H_0//C_3$ and $E//C_3$ (it consists of two components separated by $2\beta H_0$ when $H_0//C_3$ and $E\perp C_3$). We cannot find such a pattern in the observed Zeeman patterns.

In the following discussions, we will assume from the beginning the assignments given in § 3 (d), in the same way as we have done in § 4, and will show to what degree such assignments are convincing.

To observe the faint and diffuse Zeeman patterns, it was necessary to use the suitably reprinted plates instead of using the original ones.

Case I $H_0//C_3$ and $E\perp C_3$ (Fig. 6(a)):

The Zeeman splitting can be observed rather clearly in $B_1^{\perp}$ spectrum at 20°K while only vaguely in $B_2^{\perp}$ at 20°K . In the diagrams of transitions, the finite $g_{\perp}$ -shift (from zero), Δ_1' , of the B_1 excited state and also the finite

$g_{\parallel}$ -shift (from 4), $4_2'$, of the B_2 excited state are assumed. Comparing the experimental patterns with those expected from such transition diagrams, a rather good agreement can be obtained if $4_2'$ satisfies the relation $g_0 - 2\Delta_2' \sim g_{\text{obs}}(B_2) = 2.4 \pm 0.5$ (so $4_2' \sim 0.2 \pm 0.25$) and if $2\Delta_1'$ is small compared with g_0 . Even when $4_1'$ differs from zero, $g_{\text{obs}}(B_1) = 2.1 \pm 0.2$ is reasonable considering the fact that at 20°K the observed position of the apparent peak will be almost at the middle

of the closely located two lines since their intensities become equal when we assume the relation $\sigma_0 \sim 2\sigma$. The necessity that $4_1' (\neq 0)$ must be introduced will be seen in the analysis of Case II.

Case II $H_0 \parallel C_3$ and $E \parallel C_3$ (Fig. 6(b)):

Among all the observed Zeeman patterns of B_1 and B_2 , the Zeeman pattern of $B_1 \parallel$ at 20°K in this case is most clear. Thus the most definite conclusion can be derived from

Fig.6 (a) case I: $H_0 \parallel C_3, E \perp C_3$

Fig.7 (a) case III: $H_0 \perp C_3, E \perp C_3$

Fig.6 (b) case II: $H_0 \parallel C_3, E \parallel C_3$

Fig.7 (b) case IV: $H_0 \perp C_3, E \parallel C_3$

Fig.6 (c) transition-diagrams: $\rightarrow E \perp C_3, \rightarrow E \parallel C_3$ $H_0 \parallel C_3$

Fig.7(c) transition-diagrams: $\rightarrow$ both $E \perp C_3$ and $E \parallel C_3, H_0 \perp C_3$

Figs. 6, 7. (a), (b): The observed Zeeman patterns (full curve) and the patterns (vertical lines) derived from the transition-diagrams (c). The intensities and the shapes of the observed patterns are only qualitatively illustrated. The observed splitting factors are also given in βH_0 unit. In the patterns (vertical) of 4.2°K, difference of the electron population of the Zeeman levels of the ground state is taken into account. (c): The numbers in brackets indicate the transition probabilities when $E \parallel C_3$ and the others (without brackets) are those when $E \perp C_3$. In the calculation of the transition probabilities, the empirical relations $\sigma^o \sim 2\sigma$ and $\pi \sim 3\sigma$ are used and σ is put equal to 12.

this pattern. A nice agreement can be obtained between theory and experiment also in this case, when Δ_1' and Δ_2' satisfy the following relations,

$$3g_0 - 2\Delta_1' = g_{\text{obs}}(B_1) = 5.2 \pm 0.2$$

$$3g_0 + 2\Delta_2' = g_{\text{obs}}(B_2) = 5.3 \pm 0.4.$$

From these relations we obtain

$$\Delta_1' = 0.4 \pm 0.1$$

and

$$\Delta_2' = -(0.3 \pm 0.2)$$

the latter of which is consistent with the value of Δ_2' ($\Delta_2' \sim 0.2 \pm 0.25$) obtained in case I.

The g -shifts Δ_1' and Δ_2' seem to satisfy the relation $\Delta_1' + \Delta_2' \doteq 0$, and the theoretical examination of such g -shifts (§ 6(e), Part A) shows that they are directly due to the reduction of the orbital angular momentum of f_2 -electrons in the crystal.

Case III $H_0 \perp C_3$ and $E \perp C_3$ (Fig. 7(a)):

The observed patterns seem to be the envelopes of the unresolved Zeeman components. The reasonable interpretation of these patterns can be made in such a way that the observed two peaks of B_1 correspond to the stronger two side components and the pattern of B_2 is determined mainly by the inner two components which are stranger than the side components in this spectrum. The reason why none of the split structures is seen in this case (also in case IV) while they are represented in case I even though slightly in B_2 , may be due to the relatively large g -shifts (from zero) of the excited states. Thus in the transition-diagram of Fig. 7 the finite g -shifts of the excited states are assumed though their magnitudes cannot be determined from our Zeeman patterns. The reasonable splitting $g_{\text{obs}}(B_1) = 6.0 \pm 0.3$ of B_1 will not be affected by introducing such g -shifts.

Slight blue-shift of the apparent peak and narrowing of the apparent width of the un-

resolved Zeeman pattern $B_2^\perp$ at 4.2°K compared to the Zeeman pattern observed at 20°K (the situation is also the same about the Zeeman pattern $B_1^{\parallel}$ in case IV) clearly show that the observed broad pattern is the envelope of the Zeeman components.

Case IV $H_0 \perp C_3$ and $E \parallel C_3$ (Fig. 7(b)):

In the same way as explained in case III, the patterns obtained in this case can also be explained reasonably.

Acknowledgements

We should like to express our sincere thanks to Prof. E. Kanda of Tohoku University, Prof. Z. Koana and Prof. G. Kuwabara of the University of Tokyo for their continual encouragements and advices through the course of this work. We are greatly indebted to Dr. T. Imai and Mr. S. Togashi of Nippon Denkō Laboratories for their kindness of preparing the samples which are well examined chemically, and to Prof. R. Sadanaga and Dr. Y. Iitaka of Mineralogy Department of Tokyo University for their kindness of performing X-ray determination of the crystal axis and cutting. Miss K. Shimada was kind enough to prepare the suitably reprinted plates for the detection of some feeble and diffuse Zeeman patterns.

Measurement of Free Induction Decay Time and Spin-Lattice Relaxation Time of Bromine Nucleus in Sodium Bromate

By Tsuneo HASHI

Department of Physics, Faculty of Science, University of Kyoto

(Received April 5, 1958)

Using transient techniques, the free induction decay time T_2^* and the spin-lattice relaxation time T_1 were measured for Br^{79} and Br^{81} in NaBrO_3 at room temperatures. The free induction decay curves were well described by Gaussian curves with $T_2^*=10.2 \times 10^{-5}$ sec for Br^{79} and 9.8×10^{-5} sec for Br^{81} . Comparison was made with the result of the steady-state measurement. The measured values of T_1 were 2.1×10^{-3} sec for Br^{79} and 3.0×10^{-3} sec for Br^{81} . The agreement of the ratio $T_1(\text{Br}^{81})/T_1(\text{Br}^{79})=1.4$ with the known ratio $Q^2(\text{Br}^{79})/Q^2(\text{Br}^{81})=1.44$ indicates that the quadrupole relaxation is principally responsible for spin-lattice relaxation. The apparatus and procedures are also described in some detail.

§ 1. Introduction

The experiments on pure quadrupole resonance were, up to the present, performed mostly by the steady-state method. So, while the measurements of the resonance frequency were reported in abundance, those of the line width and the relaxation time were relatively few. It is due to difficulties in observing the accurate line shape with a frequency modulated superregenerative detector as ordinarily used in such experiments¹⁾, and also due to the existence of the broadening caused by the distribution of electric field gradients resulting from temperature gradient, strain and imperfection in the sample¹⁾. It is very difficult to differentiate such a broadening from others by merely the measurement of the line width.

In general, three types of mechanisms are considered for loosening precessional coherence in the spin system, namely, (1) different fixed rates of precession caused by static local fields, (2) random fluctuation of precessional frequency and phase, and (3) spin-lattice relaxation. These three contribute simultaneously to the line broadening.

Transient or pulsed techniques²⁾ offer advantages over the steady-state measurement of line width in obtaining separate informations about these three mechanisms.

In the present paper, the transient pure quadrupole resonance experiment on bromine nuclei is reported. Transient experiments on

pure quadrupole resonance were performed by Bloom, Hahn and Herzog³⁾, Herzog and Hahn⁴⁾, Proctor and Tanttila⁶⁾, and Woessner and Gutowsky⁶⁾, but these authors were chiefly concerned with Cl^{35} nucleus. When bromine compounds are used, the measurements on both Br^{79} and Br^{81} isotopes are easily performed, because of their sufficient natural abundances. The analysis of relaxation is much facilitated by comparison of the measurements on both isotopes.

The present paper includes a brief theory, the description of the apparatus and procedures, and the result of the measurements on the free induction decay time T_2^* and the spin-lattice relaxation time T_1 for Br^{79} and Br^{81} in sodium bromate. The result of experiment on the spin echo will be published in the near future.

§ 2. Theory

Quantum mechanical descriptions of the transient nuclear induction associated with nuclear quadrupole coupling have been given by Bloom, Hahn and Herzog³⁾, and Das and Saha⁷⁾. These authors treated the case where the electric field gradient had an axial symmetry. For bromine nuclei in sodium bromate, the above analyses are directly applicable.

We consider a nucleus with spin $I=3/2$ in axially symmetric field gradient. The r-f magnetic field:

$$H_x=2H_1 \cos \omega t, \quad H_y=0, \quad H_z=0, \quad (1)$$

is assumed to be applied in form of short pulse of width t_w and beginning at $t=0$, where the z -axis is chosen to be the symmetry axis of electric field gradient. The transient response of the nuclear magnetic moment to the driving pulse is described by the expectation values of I_x , I_y and I_z .

If the conditions:

$$|\omega - \omega_0'| \ll 1/t_w, \text{ and } \omega \gg 1/t_w, \gamma H_1 \quad (2)$$

are satisfied, the expectation values of I_x , I_y and I_z are given by

$$\left. \begin{aligned} \langle I_x \rangle &= \frac{\sqrt{3} \omega_0' \hbar}{4kT} \sin(\sqrt{3} \gamma H_1 t_w) \sin \omega_0'(t - t_w), \\ \langle I_y \rangle &= 0, \\ \langle I_z \rangle &= 0 \end{aligned} \right\} \quad (t \geq t_w), \quad (3)$$

where ω_0' is an angular resonance frequency associated with zero field quadrupole splitting of the bromine nucleus.

In order to take into account the static distribution of ω_0' over the sample, we assume:

$$g(\Delta\omega) = \frac{T_2^*}{\sqrt{2\pi}} \exp\left[-\frac{(T_2^* \Delta\omega)^2}{2}\right], \quad (4)$$

where $\Delta\omega = \omega_0 - \omega_0'$ and ω_0 is the center frequency of the distribution of ω_0' .

Upon averaging (3) over the distribution (4) and multiplying with $\gamma \hbar N$, the expectation values of the magnetization for the sample are obtained as:

$$\left. \begin{aligned} M_x &= \frac{\sqrt{3} N \omega_0 \gamma \hbar^2}{4kT} \sin(\sqrt{3} \gamma H_1 t_w) \sin \omega_0(t - t_w) \exp\left[-\frac{(t - t_w)^2}{2T_2^{*2}}\right], \\ M_y &= M_z = 0 \end{aligned} \right\} \quad (t \geq t_w), \quad (5)$$

where N is the total number of spins in the sample. Relaxation effects are omitted here.

The free induction voltage induced in a coil placed along the x -direction is proportional to the time derivative of M_x .

If the second pulse of the same form is applied at the time τ after the first pulse, the spin echo is obtained centering at $t=2\tau$ as follows:

$$\left. \begin{aligned} M_x &= -\frac{\sqrt{3} N \omega_0 \gamma \hbar^2}{4kT} \sin(\sqrt{3} \gamma H_1 t_w) \sin^2 \frac{\sqrt{3} \gamma H_1 t_w}{2} \sin \omega_0(t - 2\tau) \exp\left[-\frac{(t - 2\tau)^2}{2T_2^{*2}}\right], \\ M_y &= M_z = 0 \end{aligned} \right\} \quad (t \geq \tau + t_w), \quad (6)$$

§ 3. Apparatus and Procedures

The block diagram of the apparatus is shown in Fig. 1. It is divided into four parts: timer, transmitter, receiver, and synchroscope. The timer consists of a basic trigger generator, two delay multivibrators, a one-shot multivibrator, and a mixer. Each component is of usual design⁸⁾ and not described here. The output pulse of the basic trigger generator initiates the two delay multivibrators and each produces the output pulse with proper delay time. The delay multivibrators are isolated from each other by the cathode follower stages being utilized at inputs and outputs. The separation of the two pulses is continuously variable from 0 to 30 msec. After mixing,

these two pulses in turn trigger the one-shot multivibrator and produce two successive rectangular pulses, of which the widths are continuously variable from less than 3μ sec to more than 200μ sec. The repetition period of the pair of rectangular pulses is determined by the frequency of the basic trigger generator, and is chosen to be longer than the spin-lattice relaxation time T_1 in order to ensure thermal equilibrium of the spin system till the next onset of the pair of pulses. The output pulse from the basic trigger generator also trigger the synchroscope. The time sweep is adjusted so that it covers the time of interest.

When further pulses are required as in the

Fig. 1. Block Diagram of the Apparatus.

case of the stimulated echo experiment, they are easily provided by the addition of delay multivibrators of the same kind.

The transmitter consists of a pulsed oscillator, a power amplifier and a tank circuit. For observing free nuclear quadrupole precession signals, much stronger and much shorter r-f pulse is required than for the case of nuclear magnetic resonance in liquid. It is because the characteristic time T_2^* in solid is generally much shorter than in liquid, and the conditions: $T_2^* \gg t_w$ and $\sqrt{3} \gamma H_1 t_w = \pi/2$ must be satisfied for 90° pulse as shown in (2). If these conditions are not satisfied, the free induction decay time depends on H_1 and t_w ⁹⁾. For bromine nuclei in sodium bromate (NaBrO₃) the r-f pulse with H_1 of more than 10 gauss and t_w of shorter than $10 \mu\text{sec}$ is required.

The power amplifier is of usual tuned-grid and tuned-plate type and consists of two 4X-150A's connected in push-pull and the available power is sufficient to produce such r-f pulses. Since the tuning circuit with very high "Q" would cause some undesirable transients and make the tuning very critical at such high frequencies ($\sim 180 \text{ Mc/sec}$ for Br⁷⁹, $\sim 150 \text{ Mc/sec}$ for Br⁸¹), the Q's are lowered and thus the amplifier has the bandwidth of about 3 Mc/sec. The broadband character is

necessary, on the other hand, for the faithful reproduction of the envelope of the envelope of the oscillator waves. It also permits the fine adjustment of the oscillator frequency without retuning the amplifier, and is very convenient for the present experiment in which the resonance must be achieved by adjusting the frequency of the transmitter. The driving point of the amplifier tubes is chosen below cutoff by supplying a fixed bias, in order to prevent shot noise¹¹⁾.

The pulsed oscillator is normally held below cutoff and brought into oscillation by the application of rectangular pulses from the timer. The switching action is provided by a tube connected in series with the oscillator tube 2C39A. The author has not used the continuous oscillator and gated power amplifier system because the leakage past the gated amplifier in off-periods would make serious trouble to the receiver, which is extremely sensitive and tuned to the oscillator frequency.

The output power of the power amplifier is led to the tank circuit, which consists of a coil of three windings and about 1 cm diameter and a small tuning condenser. The sample is placed in the coil and subjected to the oscillating magnetic field. Since the quadrupole interaction is temperature-dependent^{10,12)}, air cooling is used to keep the sample at a con-

stant temperature, and further, the tank circuit is situated apart from the power amplifier tubes in order to prevent the sample from heating by them.

In free nuclear quadrupole experiment, the receiver should have the short recovery time of sensitivity from the saturation caused by strong r-f pulses, because the free nuclear quadrupole precession signal is weak and appears immediately after the strong driving pulse. The receiver consisting of a cascode amplifier and a converter followed by a broadband rather i-f strip³⁾ has been found to be sufficient for this purpose. The cascode amplifier and converter is a modified television superheterodyne tuner similar to those used by Bloom, Hahn and Herzog³⁾. The broadband i-f amplifier is a six-stage 6CB6 stagger tuned radar amplifier with bandwidth of about 4 Mc/sec. Its center frequency is 30 Mc/sec and the maximum gain about 110 db.

Since, as shown in (5) there is no component of the nuclear magnetization perpendicular to the axis of the applied oscillating magnetic field, the crossed coil system can not be used in the present experiment. The input coil of the cascode amplifier is therefore coaxially coupled with the tank coil. Although no special precautions are taken to reduce to reduce the receiver blocking, it has a recovery time of less than 20μ sec, when intense pulse is applied to the input. The amplitude of the detector is limited below one volt to avoid overloading of the video amplifier. Signals are displayed on the synchroscope

screen and the measurement of the relaxation time is made by photographic method.

In order to obtain accurate 90° pulses, the adjustment of both frequency and pulse width is necessary. frequency is adjusted so that the amplitude of the free induction is maximized. During the process the pulse width must be held at the minimum possible value because subsidiary maxima exist when the pulse width is longer than 90° ¹³⁾. After the adjustment of the frequency, the pulse width is increased until the maximum amplitude of the free induction is obtained. This is a proper 90° setting.

Samples were prepared by the recrystallization from aqueous solution. In order to reduce the strain and imperfection in the crystal, the recrystallization is performed by evaporation at a very slow rate.

§ 4. Results and Discussion

The free induction decay time T_2^* and the spin lattice-relaxation time T_1 have been measured for both Br^{79} and Br^{81} in sodium bromate (NaBrO_3) at room temperatures. The measured values of T_2^* and T_1 which were reproducible within the error of $\pm 5\%$ are summarized in Table I, together with the ratios between both isotopes. For samples, two single crystals and a powdered specimen were used. Single crystals were prepared by repeated recrystallization and considered to be fairly perfect, whereas the powdered specimen was not so pure as the single crystals.

The free induction decay curves obtained for these samples were all well described by

Table I. Measured values of T_2^* , T_1 and their ratio.

		$T_2^*(10^{-5} \text{ sec})$	$T_1(10^{-3} \text{ sec})$	$\frac{T_2^*(\text{Br}^{81})}{T_2^*(\text{Br}^{79})}$	$\frac{T_1(\text{Br}^{81})}{T_1(\text{Br}^{79})}$

Gaussian curves of Eq. (5) within experimental errors. In Fig. 2 is shown an oscillographic display of a typical free induction decay curve, which is due to Br⁸¹ in single crystal No. 2. The experimental free induction decay

Fig. 2. Oscillographic display of the free induction signal due to Br⁸¹ in a single NaBrO₃ crystal (No. 2) at 150 Mc/sec. Separation between time markers is 10 μ sec.

Fig. 3. Free induction decay curve for Br⁸¹ in a single NaBrO₃ crystal (No. 2).

curve was compared with a Gaussian curve as shown in Fig. 3. The values of T_2^* listed in Table I were obtained by adjusting so that the experimental decay curve could be represented by a Gaussian curve. Since the free induction signal could not be observed within the region from $t=t_w$ to about 20 μ sec later because of the receiver saturation, there was no way to examine the shape of the free induction decay curve near $t=t_w$. However, if there were any deviations from a Gaussian curve in that region, they would not affect the principal features of the experimental decay curve. The Gaussian shape of the free induction decay curve indicates the fact that the local field is essentially static, and the

effects of the fluctuation of the local field and the spin-lattice relaxation on the free induction decay is not significant⁴. The insignificance of the spin-lattice relaxation is directly confirmed by the measurements of T_1 as shown latter on. Therefore, the mechanisms mainly responsible for the free induction decay are considered to be the static part of (1) the magnetic dipole-dipole interaction with neighboring nuclei, (2) the distribution of electric field gradients in the crystal due to strain, imperfection and temperature gradient, and (3) Zeeman effect caused by the earth's magnetic field.

In order to estimate the contribution from (1), the author has calculated classically the root mean square local field parallel to Na-Br axis from both Na and Br neighbors. Such a calculation yielded $T_2^*=19.7 \times 10^{-5}$ sec for Br⁷⁹ and 18.3×10^{-5} sec for Br⁸¹, respectively, which are much longer than the observed values. It is expected that the remaining contribution to the decay is mostly due to the mechanism (2), since the contribution from (3) is small⁴. As shown in Table I, there are some changes in T_2^* with samples, which are considered principally caused by different contributions by the mechanism (2), since they are the only contributions which are considerably affected by the process of recrystallization. The longest value of T_2^* was obtained for crystal No. 1, which is then the most perfect crystal among the used samples.

The corresponding line shape in the steady state measurement which is given by the Fourier transform of the free induction decay curve^{4,16}, is Gaussian i.e. $\propto \exp[-(\Delta\omega T_2^*)^2/2]$. Using the values of T_2^* for crystal No. 1, the calculated line widths between half maximum points are 3.7 kc/sec and 3.8 kc/sec for Br⁷⁹ and Br⁸¹, respectively. These values are consistent with those obtained by Koi for a most perfect crystal¹⁶, using regenerative spectrometer. Koi concluded that the main contribution to the broadening for his most perfect crystal, should come from the mechanism (1), i.e. magnetic dipole-dipole interaction with neighboring nuclei. His argument was based on the circumstance that if the magnetic origin (1) is predominant, the broadening of the line for Br⁸¹ should be larger than that for Br⁷⁹, and the converse is true, if the elec-

tric origin (2) is predominant. Though the present measurement for crystal No. 1 is consistent with Koi's conclusion, the experimental accuracy is not sufficient to differentiate between the contribution by (1) and (2) unambiguously from the above reasoning alone. In order to examine the situation more precisely from another point of view, the author is performing a double resonance experiment, in which the changes in the free induction and echo signals for bromine nuclei are examined by the application of the continuous r-f field with resonance frequency of the sodium nuclei. The result will be published in the near future.

The spin echo signal which is like two free induction decay curves placed back-to-back³⁾, is so broad that the echo envelope decay time cannot be quantitatively measured for crystals whose T_2^* 's are relatively long. In order to make precise measurement on the echo envelope decay time, it is necessary either to apply the magnetic field or to make an artificial temperature gradient. Fig. 4 shows a typical spin echo signal in the presence of an artificial temperature gradient. Observed echo envelope decay time T_2' was relatively unaffected by the temperature gradient. The value of T_2' is of the order of 2×10^{-4} sec and much shorter than T_1 . It indicates that the effect of the fluctuation of the local field on the free induction decay is not completely absent. The measurement on spin echo will be reported more precisely in conjunction with the double resonance.

The measurement of T_1 is made by the application of two r-f pulses^{2,6)}. As the spac-

ing τ between the two pulses is increased, the initial amplitude $y(\tau)$ of the free induction signal following the second pulse rises exponentially with time constant T_1 towards the initial amplitude y_0 of the free induction signal following the first pulse. Fig. 5 shows the variation of the initial amplitude of the free induction signal following the second pulse with the spacing τ , and Fig. 6 the linear relation between $\log[y_0 - y(\tau)]$ and τ . The values of T_1 were estimated from the figure. Since these values were much longer than T_2^* , the effect of the spin-lattice relaxation on the free induction decay was not significant.

It is noted that the measured values of T_1 are almost equal for different samples, even when the T_2^* 's are apparently different. The ratio between both isotopes $T_1(\text{Br}^{81})/T_1(\text{Br}^{79})$ is

Fig. 5. Variation of the initial amplitude of free induction signal following a second pulse with the spacing from the first pulse. Signals are due to Br^{79} in a single NaBrO_3 crystal (No. 1). Separation between makers is 0.1 m/sec.

Fig. 4. Spin echo signal due to Br^{79} in a single NaBrO_3 crystal in the presence of an artificial temperature gradient. The sweep length is about 1.2 milliseconds.

so constant and almost equal to the ratio $^2(\text{Br}^{79})/Q^2(\text{Br}^{81})=1.44$. These facts show that the spin-lattice relaxation is insensitive to the homogeneity of the electric field gradient and the principal mechanism for it is the quadrupole relaxation.

Acknowledgment

The author would like to thank Professor Takahashi for his encouragement and discussion, and his thanks are also due to Mr. T. Hirai and Mr. M. Sasaki for their assistance in performing the experiment, and to Mr. M. Abata for his help in numerical calculations.

Zeeman Study on Nuclear Quadrupole Resonances* in AsI_3 and $\text{AsI}_3 \cdot 3\text{S}_8$

By Yoshihito ABE

*Department of Physics, Tokyo University of Education
Otsuka, Tokyo*

(Received April 14, 1958)

Principal axis systems and asymmetry parameter of the electric field gradient tensors were determined by studying Zeeman effect of nuclear quadrupole resonances of As^{75} and I^{127} . The iodine resonance in AsI_3 showed that there are three principal axis system whose z axes form a trigonal pyramid having an apex angle of $91.7^\circ \pm 2.5^\circ$. The fact that this angle did not agree with the bond angle of $88^\circ 02'$ supports the mechanism of resonance switching of the bond. The arsenic resonance in AsI_3 has only one principal axis system whose z axis is along the trigonal symmetry axis of arsenic tri-iodide molecule. The asymmetry parameter obtained from Zeeman study was nearly zero.

The iodine resonance in $\text{AsI}_3 \cdot 3\text{S}_8$ also showed that there are three principal axis systems. This fact well agrees with the result from X-rays that the most possible crystal structure of $\text{AsI}_3 \cdot 3\text{S}_8$ is C_{3v} . Three z axes are parallel to the edge of a trigonal pyramid with an apex angle of $101.7^\circ \pm 0.5^\circ$ which is close to the bond angle $100^\circ \pm 2^\circ$ ($\angle \text{I-As-I}$) of AsI_3 molecule in gaseous state. The electric field gradient tensor of arsenic resonance in $\text{AsI}_3 \cdot 3\text{S}_8$ was nearly axial symmetric about the trigonal symmetry axis of the molecule.

§ 1. Introduction

The pure quadrupole spectrum of arsenic tri-iodide was first studied by Kojima, Tsukada, Ogawa, Shimauchi and myself¹⁾. The isotope I^{127} has two resonance lines corresponding to the transitions of $m_z = \pm 1/2 \rightleftharpoons 3/2$ and $m_z = \pm 3/2 \rightleftharpoons \pm 5/2$. The frequencies of the lines were 206 Mc and 401 Mc at room temperature, which yielded the coupling constant of 1345 Mc and the electric field gradient asymmetry parameter of 14.5%¹⁾. These results were explained with the mechanism of resonance switching of the bond²⁾. The structure of solid arsenic tri-iodide is that any given iodine atom has two nearest neighbors of arsenic atoms at the same distance of 2.99 Å, one being molecular partner and the other belonging to the neighbor molecules and that there are no other neighbor atoms closer than 4.14 Å. From this structure Kojima *et al.*, proposed the mechanism that the covalent bond of the iodine atom is resonating between these two arsenic atoms with fractional importance of fifty percent. If the mechanism of this resonance switching is correct, the

principal z axis of the electric field gradient tensor will be perpendicular to the bond. On the other hand, if it is not applicable, the principal z axis will be along the bond. The orientation of the z axis of the electric field gradient tensor can be determined by Zeeman study on pure quadrupole spectrum³⁾. Zeeman study is also useful for the determination of crystal structure and for analysis of nature of the bond between the quadrupolar atom and its neighbors⁴⁾⁻⁷⁾.

Recently, the isotope As^{75} in arsenic tri-iodide was studied by Ogawa⁸⁾. The resonance frequency of it was 32 Mc at room temperature, since the spin number of the isotope is 3/2, the possible transition is $m_z = \pm 1/2 \rightleftharpoons \pm 3/2$. Therefore, the asymmetry parameter of the electric field gradient tensor can not be determined without Zeeman study.

In the present experiment Zeeman studies have been carried out on the resonance lines of the isotopes I^{127} and As^{75} in a single crystal of arsenic tri-iodide, whose frequencies are 201 Mc and 32 Mc, respectively.

Similar study has been carried out on sulphur molecular addition compound of arsenic tri-iodide ($\text{AsI}_3 \cdot 3\text{S}_8$). The two resonance fre-

* A doctoral thesis submitted to Tokyo University of Education.

quencies of the isotope I^{127} in this compound corresponding to the transition $m_z = \pm 1/2 \leftrightarrow \pm 3/2$ and $m_z = \pm 3/2 \leftrightarrow \pm 5/2$ were measured by Robinson, Dehmelt and Gordy⁹⁾. The frequencies were 224 Mc and 448 Mc at room temperature, which yielded that the electric field gradient tensor at the iodine nucleus is axial symmetric.

Arsenic resonance in this compound was also studied by Ogawa⁸⁾. She reported that the isotope As^{75} has a single resonance frequency of 47.5 Mc at room temperature. The asymmetry parameter of the electric field gradient tensor is not yet obtained.

It is known from X-ray analysis that in a crystal of sulphur molecular addition compound of arsenic tri-iodide each arsenic tri-iodide molecules are isolated by neighboring six sulphur molecules, although the precise arrangement of atoms in the unit cell has not been obtained. In this case the direction of the z axis of the electric field gradient tensor will be different from the case of arsenic tri-iodide previously mentioned. The z axis can be determined by the aid of Zeeman effect.

In the present experiment Zeeman study has been applied to the resonance lines of 224 Mc of the isotope I^{127} and that of 47.5 Mc of the isotope As^{75} in a single crystal of sulphur molecular addition compound of arsenic tri-iodide.

§ 2. Experimental Procedure

Arsenic tri-iodide was prepared by the reaction between a solution of arsenic trioxide in concentrated hydrochloric acid and a solution of potassium iodide in water. The precipitation of arsenic tri-iodide was filtered off and dried. Then it was recrystallized from carbon disulphide by evaporating the solvent.

Single crystals of arsenic tri-iodide of about 50 gr. were prepared with the method of pointed bottom crucible¹⁰⁾. The sample enclosed in a glass envelope, whose inside diameter is 23 mm, is slowly lowered from an oven maintained well above the melting temperature of the sample through a region having steep temperature gradient into a cold room which is cooled with a large water bath.

Sulphur molecular addition compound of arsenic tri-iodide was obtained from a solution of arsenic tri-iodide and sulphur in carbon

disulphide. Single crystals of this compound were easily grown from this solution.

Two superregenerative detectors were prepared for the observation of the resonances of two isotopes. One used for the iodine resonance was the transmission line type¹¹⁾ and the other used for the arsenic resonance was the ordinary type with LC tuned circuit¹²⁾. Frequency modulations were applied for the oscillators with a vibrating condense. The detector output was amplified and presented on an oscilloscope. In order to remove undesirable amplitude of modulation components, some filters were used.

A magnetic field for Zeeman studies was produced by Helmholtz coils¹¹⁾ which are arranged with mean separation of 7.5 cm. The Helmholtz coils were mounted on a goniometer in which azimuthal traverse was available for complete 360° . The axis of Helmholtz coils was in a horizontal plane, which contained the axis of the rotation of the sample.

The angle of the azimuthal traverse and of the rotation of crystal was read with a scale having the least count of 0.2° . The magnetic field used for the most experiments was about 100 gauss. Sometimes, however, 300 gauss was applied for the precise studies. The oscillograph display of the resonance of iodine in sulphur molecular addition compounds of arsenic tri-iodide are shown in Fig. 1, as examples. The photograph (a) in Fig. 1 shows the shape of resonance line at zero magnetic field. The photographs (b) and (c) showing the Zeeman patterns were taken when the magnetic field oriented to the direction B which is indicated in Fig. 4 and the strength of the field was 50 gauss and 350 gauss, respectively. In the field of 350 gauss the only central zerosplitting line, which will be mentioned later, remained in the oscillograph. This line changed sensitively by the rotation of the crystal as shown in Fig. 1 (c), (d) and (e). So that the direction of the magnetic field for zerosplitting can be determined accurately.

The directions of the magnetic field for the zerosplitting were measured and the loci of the directions were mapped on a sphere. From these loci the directions of the z axes of the electric field gradient tensor were determined.

After Zeeman studies the used crystal of arsenic tri-iodide was examined by X-rays.

§ 3. Method of Analysis

In a static magnetic field the twofold degeneracy of each energy levels of the pure quadrupole interaction is removed by Zeeman effect and a single resonance line, corresponding to the transition $m_z = \pm 1/2 \rightarrow \pm 3/2$ splits into four lines. The frequencies of these lines are given by the following equations^{(11), (13), (14)}:

$$\nu_{\text{I II}} = \nu_0 \pm 1/2 S \quad (1)$$

$$\nu_{\text{III IV}} = \nu_0 \pm 1/2 s \quad (2)$$

where ν_0 is the frequency of the unsplit line and S and s are the separation frequencies of outer pair and inner pair, respectively. These values for nuclear spin $I=3/2$ are expressed as follows:

$$\nu_0 = \frac{eQq_{zz}}{2h} \left(1 + \frac{1}{3} \eta^2 \right)^{1/2} \quad (3)$$

$$\left\{ \begin{matrix} S \\ s \end{matrix} \right\} = \frac{2\mu}{3h} H \left\{ [9 \cos^2 \theta + \eta^2 (\sin^2 \theta - 2 \cos^2 \theta)]^{1/2} \right.$$

$$\left. \pm \left[4 \sin^2 \theta + \cos^2 \theta - 4\eta \sin^2 \theta \cos 2\phi + \frac{\eta^2}{3} (\sin^2 \theta - 2 \cos^2 \theta) \right]^{1/2} \right\}. \quad (4)$$

Those for $I=5/2$ are expressed as follows:

$$\nu_0 = \frac{3eQq_{zz}}{20h} \left(1 + \frac{59}{54} \eta^2 \right) \quad (5)$$

$$\left\{ \begin{matrix} S \\ s \end{matrix} \right\} = \frac{4\mu}{5h} H \left\{ \left[\frac{9}{4} \cos^2 \theta + \eta^2 (4 \sin^2 \theta - 3 \cos^2 \theta) \right]^{1/2} \right.$$

$$\left. \pm \left[-\frac{1}{4} \cos^2 \theta + \frac{9}{4} \sin^2 \theta - 6\eta \sin^2 \theta \cos 2\phi + \eta^2 \left(\frac{22}{9} \sin^2 \theta - \frac{76}{81} \cos^2 \theta \right) \right]^{1/2} \right\} \quad (6)$$

The asymmetry parameter η of the electric field gradient tensor is defined by the following equation:

$$\eta = \frac{q_{xx} - q_{yy}}{q_{zz}} \quad (7)$$

where q_{xx} , q_{yy} and q_{zz} are components of the

electric field gradient tensor which are referred to the principal axis system. These components are in the following relation: $|q_{xx}| \leq |q_{yy}| \leq |q_{zz}|$. In the equations θ and ϕ designate the orientation of the static magnetic field referred to the principal axis system of the electric field gradient tensor and μ is the magnetic moment of nucleus. The equations for the nuclear spin of $I=5/2$ are calculated using the theory of 1st order Zeeman effect*.

The inner pair coalesces in a single line when the magnetic field orients along some special directions θ , ϕ which are defined by the following equations for nuclear spin $I=3/2$:

$$\sin^2 \theta = \frac{2}{3 - \eta \cos 2\phi} \quad (8)$$

and for $I=5/2$:

$$\sin^2 \theta = \frac{8 - (668/81) \eta^2}{17 - 24\eta \cos 2\phi - (1172/81) \eta^2} \quad (9)$$

The directions satisfying these relation make an elliptic cone whose axis is the z axis. This cone is called as zerosplitting cone and represented on a sphere by an elliptic locus. Corresponding to each principal axis systems, one elliptic locus is obtained. The directions of the z axis can be determined as the center of the locus. When the electric field gradient tensor has the axial symmetry, the direction of the z axis can be simply determined by averaging the maximum and minimum angles of the zerosplitting direction⁴⁾. In the usual cases where the electric field gradient tensor departs from the axial symmetry such simple determination is not available except in some special cases where the x - z plane or the y - z plane of the field gradient tensor contains the rotational axis of crystal. In this case the direction of the z axis can be determined by the method of mapping the zerosplitting loci. The asymmetry parameter η can be also calculated by the following equations: the equation for nuclear spin $I=3/2$ is

$$\eta = \frac{3(\sin^2 \theta_{\max} - \sin^2 \theta_{\min})}{\sin^2 \theta_{\max} + \sin^2 \theta_{\min}} \quad (10)$$

and the equation for $I=5/2$ is

$$\eta = \frac{17(\sin^2 \theta_{\max} - \sin^2 \theta_{\min})}{24(\sin^2 \theta_{\max} + \sin^2 \theta_{\min})} \quad (11)$$

The equation for the nuclear spin of $I=5/2$

* The paper reported by Bersohn has some misprints. We have recalculated the equations for the cases of spins $3/2$ and $5/2$.

is obtained by neglecting the small terms of the equation (9) which contain the factor of η^2 . In the cases where the nuclear spins are greater than $5/2$, η can be obtained accurately from the measurement of resonance frequencies.

The angle ξ between two directions Θ_1 , Φ_1 and Θ_2 , Φ_2 is expressed by the following equation:

$$\cos \xi = \sin \Theta_1 \sin \Theta_2 \cos (\Phi_1 - \Phi_2) + \cos \Theta_1 \cos \Theta_2 \quad (12)$$

§ 4. Results and Analysis

a) Arsenic Tri-iodide

i) *Iodine* By observing the Zeeman patterns on the oscilloscope the zerosplitting loci were obtained. The measured results for the isotope I^{127} are shown in Fig. 2, where closed loci show the zerosplitting loci for each z axes. When it is plotted on a sphere, the zerosplitting cone produces an elliptic locus. Since the loci in Fig. 2 are reproduced on a plane, the loci are deformed from ellipses. These deformed loci, however, clearly correspond to the elliptic contour on a spherical coordinate system. Three directions of the z axes were obtained. The coordinates of the z axes are given in Table I, where the directions in prime system correspond to the negative directions of the z axis. The experimental inaccuracy mainly comes from the measurement of rather weak absorption of iodine resonance, having half maximum width of about 26 kc. From the Zeeman study it was found that the zerosplitting loci show trigonal symmetry and the symmetry axis has the coordinates of $(\Theta=75^\circ \pm 1^\circ, \Phi=82^\circ \pm 1^\circ)$ and $(\Theta'=105^\circ \pm 1^\circ, \Phi'=262^\circ \pm 1^\circ)$. Using the equation (12) and the values given in Table I, the angles between each z axes in both systems were obtained. The results are listed in Table II with the angles between each z axes and the trigonal symmetry axis. The experimental error is estimated from the inaccuracy of the measurement of the angles Θ and Φ , being $\pm 1^\circ$.

ii) *Arsenic* The measured zerosplitting loci of the arsenic resonance are shown in Fig. 3. The coordinates of the z axis are given in Table III with those of the trigonal symmetry axis mentioned before. Since the resonance line of As^{76} was weaker than the resonance

line of I^{127} , the experimental error was larger than that of the iodine resonance, though it was slightly reduced by the facts that the Zeeman pattern is simple and the locus is almost circular. Only one z axis was obtained in arsenic resonance and the orientation was approximately parallel o the axis of trigonal symmetry of the zerosplitting loci in iodine resonance.

The asymmetry parameter η is probably zero. The upper limit of η was estimated by

the aid of the equation (10) to be less than 0.15. The rather large limits has its origin in the large experimental error.

b) Sulphur Molecular Addition Compound of Arsenic Tri-iodine

i) Iodine The measured zerosplitting loci of the iodine resonance are shown in Fig. 4. Since the iodine resonance in this compound was rather sharp, Zeeman studies were possible with a small crystal of about 8 gr. Although three different directions of the z axes were obtained similarly to the case in

Fig. 4. The zerosplitting loci for I¹²⁷ in AsI₃·3S₈. θ and ϕ are the polar coordinates fixed to the crystal, as before. Rotational axis was parallel to the growing direction of crystal. $C_1, \dots, C'_1, \dots$, represent the positive and the negative directions of the z axes.

arsenic tri-iodide, the pattern of zerosplitting loci was different from the pattern of arsenic tri-iodide in that the loci were crossing mutually. This indicates, as shown later, that the angle between the z axes is larger than the angle in the case of arsenic tri-iodide. The measured coordinates of the z axes are listed in Table IV. Since the iodine isotope in this compound has the electric field gradient tensor of axial symmetry, the orientation of the z axes was determined by the simple method, i.e. the coordinates θ and ϕ of the z axis were obtained by averaging the maxi-

um angle and the minimum azimuthal angle of the zerosplitting direction and those of the latitude angles respectively. The rotational axis of the crystal was along the direction of the crystallographic c axis which seemed by inspection to be in accord with the growing direction of the crystal. Angles between the z axes were obtained from the data given in Table IV by using the equation (12). The results are listed in Table V with the angles between the crystallographic c axis and each directions of the z axes. The experimental error estimated from the inaccuracy of the measurement of θ and ϕ was $\pm 0.5^\circ$.

ii) *Arsenic* The results of arsenic resonance in this compound are shown in Fig. 5. The

Fig. 5. The zerosplitting loci of the arsenic resonance in AsI₃·3S₈. In this case the rotational axis was oriented about 60° with respect to the growing direction of crystal. θ and ϕ are same as before.

accuracy of the measurement was reduced by the weakness of the arsenic resonance. Arsenic had only one z axis, whose coordinates are expressed by $\theta = 121^\circ \pm 2^\circ$, $\phi = 62^\circ \pm 2^\circ$ and $\theta' = 59^\circ \pm 2^\circ$, $\phi' = 242.5^\circ \pm 2^\circ$. In the present

case the rotational axis of the crystal was different from the axis in the case of iodine resonance and oriented about 60° from the crystallographic c axis for the sake of convenience of experiment. The zerosplitting loci were approximately circular. Owing to the inaccuracy of the measurement of the direction of magnetic field the asymmetry parameter was determined in the limits of ± 0.15 .

§ 5. Discussion

A) Arsenic Tri-iodide

The crystal structure of arsenic tri-iodide is well known¹⁶⁾. A typical arrangement of atoms in the crystal is shown in Fig. 6. Any

Fig. 6. Typical arrangement of atoms in a crystal of arsenic tri-iodide. Bond angle $\angle \text{I}-\text{As}-\text{I} = 88^\circ 02'$. Bond distance $\text{As}-\text{I} = 2.99 \text{ \AA}$.

given iodine atom has two arsenic atoms as the nearest neighbors and an arsenic atom is neighboring six iodine atoms. Then arsenic tri-iodide forms a layerlike macromolecule. From the crystal structure the bond angle $\angle \text{I}-\text{As}-\text{I}$ is estimated as $\gamma = 88^\circ 02'$ for each of three angles.

To account for the observed values of the pure quadrupole resonance is arsenic tri-iodide two alternative assumptions may be proposed: 1) Simply the solid arsenic tri-iodide consist of isolated molecules of AsI_3 . 2) The resonance switching of the bond takes place.

According to the assumption 1, the z axis will be along the bond and the angle between

the z axes will be $88^\circ 02'$. On the otherhand, the assumption 2 yields that the covalent bond of the iodine atom resonates between the two nearest arsenic atoms, so the direction of the principal axis will be different from

Fig. 7. (a) The direction of the principal axes. If the covalent bond of iodine $\text{I}_{(1)}$ resonates between two arsenic atoms $\text{As}_{(1)}$ and $\text{As}_{(2)}$, the principal axes of the field gradient tensor are as follows:

The x axis is the inner bisector of the angle $\angle \text{As}_{(1)}-\text{I}_{(1)}-\text{As}_{(2)}$ and the z axis is the normal to the plane of $\text{As}_{(1)}-\text{I}_{(1)}-\text{As}_{(2)}$.

(b) Comparison of the principal axis system. Dashed lines show the case according to the assumption 1 and solid lines the case obtained from the assumption 2. $Z_1, \dots, Z'_1, \dots$, indicate the directions of the z axes at nucleus $\text{I}_{(1)}$ in the case of assumption 1 and 2, respectively.

the bonding direction and take such a direction as shown in Fig. 7. Fig. 7 (a) shows that the z axis for the nucleus $I_{(1)}$ is perpendicular to the $As_{(1)}-I_{(1)}$ bond. However, its direction is very close to the bonding direction of $As_{(1)}-I_{(3)}$. In Fig. 7(b) it is found that three z axes orient parallel to the edges of a trigonal pyramid. The directions of three bonds are also make another trigonal pyramid. If the apex angles of these two trigonal pyramid are denoted by δ and γ , the relation between these apex angle is expressed by the following equation:

$$\delta = 2 \cos^{-1} \frac{1}{2} \sec \frac{\gamma}{2} . \tag{13}$$

Putting $88^{\circ}02'$ for the bond angle γ , δ is obtained as $91^{\circ}54'$. This value well agrees with the average value of $91.7^{\circ} \pm 2.5^{\circ}$ obtained from the experiment.

The difference between the zerosplitting loci based on the alternative assumptions is easily obtained with the help of spherical trigonometry. The obtained difference is shown in Fig. 8, where the trigonal symmetry

place in the case of assumption 1. Since the experiment indicated that there are no crossing of the loci near about the trigonal symmetry axis shown in Fig. 2, the assumption 2 is preferable.

The crystal structure indicates that an arsenic tri-iodide molecule has at trigonal symmetry axis parallel to the crystallographic c axis. So it is reasonable to assume that the arsenic has the axial symmetrical tensor of the electric field gradient whose principal z axis orients along the trigonal symmetry axis of arsenic tri-iodide molecule. As mentioned in the last section the arsenic resonance in arsenic tri-iodide showed that there is only one z axis and its direction agreed with the trigonal symmetry axis of the zerosplitting loci which were obtained from the iodine resonance. Although the measured asymmetry parameter has the error of ± 0.15 , the electric field gradient tensor at the arsenic nucleus in arsenic tri-iodide seems to be axial symmetric.

From the analysis of the Laue pattern the trigonal symmetry axis mentioned before was determined to be parallel to the crystallographic c axis. The growing direction of the crystal* obtained from the same analysis well agreed with the result of the Zeeman study.

B) Sulphur Molecular Addition Compound of Arsenic Tri-iodide

The crystal structure of this compound is shown in Fig. 9¹⁶⁾. Any given arsenic tri-iodide is surrounded by six sulphur molecules in a unit cell and is isolated completely from the other arsenic tri-iodide molecules. The bond angle and the bond distance is not yet given in the literature. The Zeeman study indicated that the iodine resonance has only three different z axes. Then, arsenic tri-iodide molecules in sulphur molecular addition compound of arsenic tri-iodide make same trigonal pyramidal form, which oriented in one direction on a crystallographic c plane. There are no up and down of apexes with respect to the c plane and total arrangement is completed by the simple translation only. Since iodine in this compound has the axial symmetric field gradient, it is reasonable to assume that the bond angle equal to the angle γ . In the present case the crystal has been grown along the direction $[210]$ —in the term of hexagonal Bravais-Miller indices.

Fig. 8. Comparison of the zerosplitting loci based on the alternative assumptions. Dashed curves show the loci according to the assumption 1 and the solid ones the case obtained from the assumption 2. The trigonal symmetry axis of the molecule is taken as the origin of the coordinates. Points represent the measured direction of the magnetic field for the zerosplitting.

axis of the molecule is taken as the origin of the coordinates. Fig. 8 shows that there is no crossing of the loci in the case of the assumption 2, whereas mutually cross takes

between the z axes of the electric field gradient tensor. Thus the bond angle $\angle \text{I-As-I}$ is determined as $101.7^\circ \pm 0.5^\circ$.

Fractional importance of ionic bond character β can be obtained from the following equation¹⁷⁾:

$$U_p = (1 - \alpha)(1 - \beta) \quad (14)$$

where α is the amount of s -hybridization of the P_σ bond and U_p is the numbers of unbalanced p -electron of the resonance atom which is obtained from the observed frequency and the atomic measurements. Introducing the value $\alpha = 0.15^{18)}$, $U_p = 1493/2292 = 0.6514$, β

Fig. 9. Arrangement of the atoms in a unit cell of the crystal of $\text{AsI}_3 \cdot 3\text{S}_8$.

$$a = 14.2 \text{ \AA} \quad c = 4.48 \text{ \AA}.$$

is obtained as 23.7%. Then, the bond distance As-I can be determined by the aid of Pauling's formula with Schomaker-Stevenson correction for ionic character¹⁷⁾. Introducing the single covalent radii for the iodine atom and the arsenic atom, the bond distance of 2.51 Å is obtained. The distance between the iodine atom and the nearest sulphur atom, being calculated as 3.28 Å, is greater than the sum of the single covalent radii of the iodine atom and the sulphur atom 2.37 Å and smaller than the sum of the van der Waal's radii of the atoms, 4.00 Å. In this estimation the position of the sulphur atom was so assumed that the distance was minimum taking into account the known structure of sulphur molecular addition compound of arsenic tri-

iodide and sulphur molecule¹⁹⁾, which forms puckered rings with S-S distance of 2.12 Å and the bond angle of 105° . Therefore, the interaction between iodine atom and sulphur molecule seems to be fairly weak one.

From the consideration of the crystal structure obtained above it can be assumed that the arsenic tri-iodide in sulphur molecular addition compound of arsenic tri-iodide has a trigonal symmetry axis oriented parallel to the crystallographic c axis. Then the similar discussion to the case of arsenic tri-iodide is possible about the arsenic resonance in sulphur molecular addition compound of arsenic tri-iodide. It was obtained from Zeeman study that arsenic has only one z axis oriented parallel to the crystallographic c axis and η is less than 0.15. Although η was not determined accurately, it should be zero from the crystallographic consideration.

§ 6. Summary and Conclusion

The structure parameter of molecule of solid arsenic triiodide, sulphur molecular addition compound of arsenic triiodide and free molecule of arsenic triiodide are summarized in Table VI. The angles between z axes in AsI_3 and $\text{AsI}_3 \cdot 3\text{S}_8$ are those determined by the present Zeeman studies. The bond angle of $\text{AsI}_3 \cdot 3\text{S}_8$ is assumed to be equal to the angle between the z axes. The bond distance in $\text{AsI}_3 \cdot 3\text{S}_8$ is estimated from the quadrupole data. The asymmetry parameter are obtained by the present Zeeman studies except those in parentheses which are obtained from the measurement of resonance frequencies. Molecular structure of arsenic tri-iodide in gaseous state was studied by electron diffraction method and found to be a trigonal pyramidal form²⁰⁾.

In Table VI it must be noticed that the molecular structure of arsenic tri-iodide in solid state is considerably different from the structure in gaseous state, though the structure in sulphur molecular addition compound of arsenic tri-iodide is near to the one in gaseous state. H. Hertel reported that the molecular structure of arsenic tri-iodide in sulphur molecular addition compound seems to be somewhat compressed form¹⁶⁾. This agrees with the shortening of the distance As-I. The bond angle $\angle \text{I-As-I}$ is close to the angle in gaseous state. The bond distance As-I of

Table VI. Constants of molecular structure of arsenic tri-iodide on three states: Solid, $\text{AsI}_3 \cdot 3\text{S}_8$ and Gaseous State*.

	Solid	$\text{AsI}_3 \cdot 3\text{S}_8$	Gaseous State
Bond angle $\angle \text{I-As-I}$	88.0°	$101.7^\circ \pm 0.5^\circ$	$100^\circ \pm 2^\circ$
Angle between the z axes	$91.7^\circ \pm 2.5^\circ$	$101.7^\circ \pm 0.5^\circ$	
Bond distance As-I	2.99 Å	2.51 Å	2.58 Å
Distance between I and the nearest neighbor atom	2.99 Å (As)	3.28 Å (S)	
η (I^{127})	0.14 ± 0.06 (0.145)	$\approx 0 \pm 0.01$ (0)	
Distance between As and the nearest neighbor atom	2.99 Å (I)	4.05 Å (I)	
η (As^{76})	$\approx 0 \pm 0.15$	$\approx 0 \pm 0.15$	

* Values in gaseous state is obtained by electron diffraction method²⁰⁾.

arsenic tri-iodide in solid state is greater than the one in gaseous state. This shows that there are more strong intermolecular interactions among arsenic tri-iodide molecules in solid state than sulphur molecular addition compound of arsenic tri-iodide. These facts support the conclusion that the resonance switching of the bond takes place in AsI_3 and does not in $\text{AsI}_3 \cdot 3\text{S}_8$.

Elementary Problems on the Configurations of a Linear High Polymer

By Kazuo NAGAI*

Department of Textile Chemistry, Kyoto University Kyoto, Japan

(Received April 28, 1958)

The studies on the configurations of a linear high polymer have based upon the problems of the random flights which have been discussed so far mainly in the form of the Fourier transformation. In this paper these problems being treated by the operational method, the general expressions for the distributions of the end-to-end distance, of the distance between the i -th segment and the centre of gravity and of the segment density around the centre of gravity are obtained. It can be seen that it is rather preferable for the random flights of which each displacement has finite length to use the operational method. This method can be applied to the general random flights problems by adopting the discontinuous integral in the form of the Laplace transformation.

§ 1. Introduction

In order to understand the physical properties of a high polymeric substance, it is very important to have knowledge of the configurations of each polymer chain of which the substance consists. Therefore, as soon as the concept that a high polymer consisted of the linear or branched sequences of the same monomer units was established, this problem began to be investigated by many authors. At present, the solution has been obtained in considerably satisfactory form.

Considering the fact that a linear high polymer consists of a number of the same units and is considerably flexible in the jointing points, the problem is equivalent in the first approximation to the random flights problem which was first studied by Lord Rayleigh¹⁾. At present, the configurations of a linear high polymer are approximated by the Gaussian distribution which can be obtained from the random flights with fixed bond length under suitable approximations. The more refined treatments tend to the calculations of the correction terms for the Gaussian distribution.

The well-know Gaussian distribution has the following form: the probability that the end-to-end distance of the random flights chain with fixed bond length b_0 has a value in the range r to $r+dr$ is equal to

$$W(r) = (3/2\pi nb_0^2)^{3/2} \exp \{-3r^2/2nb_0^2\} \cdot 4\pi r^2 dr$$

where n is the numbers of the bonds.

In the derivation of the above equation, the two assumptions i.e. (i) $r \ll nb_0$ and (ii) $n \gg 1$ have been made. For usual purposes, the above equation with the effective bond length b instead of b_0 successfully can be applied to the real polymer chain. But, when the chain configurations deviate extremely from its equilibrium one, for example, in the cases of extreme extension of rubber, the deformations under the large shearing stress in solution and crystallization, the above equation ceases to be correct.

In this paper, the problem is solved without any assumption and a useful method for treating the analogous problems is shown. Of course, the several authors have treated the same problem already. First, W. Kuhn, F. Gr $\ddot{u}$ n²⁾ and H. M. James, E. Guth³⁾ obtained the solution containing the inverse Langevin function. Second, L. R. G. Treloar⁴⁾ and M. C. Wang and E. Guth⁵⁾ obtained the rigorous expression. Following the second method of M. C. Wang and E. Guth⁶⁾, the general random flights problem is treated by the operational method, more or less skilfully.

§ 2. End-to-End Distance of a General Random Flights Chain

The problem is set up as follows. The probability that the length of the k -th displacement of the random flights chain with n displacements occurs in the range η to $\eta+d\eta$

* Present address: The Osaka Industrial Research Institute, Daini-Nishi 2-Chome Oyodoku, Osaka, Japan.

is assumed to be $\rho_k(\eta)4\pi\eta^2d\eta$. Obviously, $\rho_k(\eta)$ is equal to the density distribution of of the one end at the distance η from the other end of the k -th displacement. $\rho_k(\eta)$ is assumed to be normalized as follows:

$$\int_0^\infty \rho_k(\rho)4\pi\eta^2d\eta=1. \quad (k=1, \dots, n) \tag{1}$$

Then the probability that the end-to-end distance of the resultant random flights chain with n displacements occurs in the range r to $r+dr$ is defined by $W_n(r)dr$. As a result of Eq. (1)

$$\int_0^\infty W_n(r)dr=1. \tag{2}$$

We require the relation between $W_n(r)$ and $\rho_k(\eta)$, etc.

In this paper, fixing our eyes upon the fact that the random flight chain with k displacements results from that with $k-1$ displacements after one additional displacement, we derive the recurrence formula relating $W_k(r)$ and $W_{k-1}(r)$ and solve this by means of the operational method. The probability that, when (the end-to-end distance of) the random flights chain with $k-1$ displacements occurs in the range ξ to $\xi+d\xi$ and the k -th displacement occurs in the range η to $\eta+d\eta$, the random flights chain with k displacements occurs in the range r to $r+dr$, integrated over all possible values of ξ and η fixing r , must be the probability that the random flights chain with k displacements occurs in the range r to $r+dr$ irrespective of the situations of that with $k-1$ displacements and the k -th displacement i.e. $W_k(r)dr$.

In Fig. 1 A , B and C are assumed to be

the starting point of the first displacement, the end points of the $(k-1)$ and k -th displacements respectively. Then the probability that the end-to-end distance of the random flights chain with $k-1$ displacements being ξ , that with k displacements occurs in the range r to $r+dr$ and the length of the k -th displacement η to $\eta+d\eta$, is equal to the volume enclosed between two spherical shells, the one having its centre at A and the radii r and $r+dr$ and the other having its centre at B and the radii η and $\eta+d\eta$, multiplied by $\rho_k(\eta)d\eta$. The co-volume of two spherical shells is the volume which is produced by rotating the infinitesimal parallelogram dS about the axis $\overline{AB}$.

Let $\angle CAB=\theta$, then

$$\eta^2=\xi^2+r^2-2r\xi\cos\theta.$$

Differentiating the above equation, fixing ξ and r

$$\eta d\eta=\xi r\sin\theta d\theta.$$

Hence

$$\overline{CD}=r d\theta=\frac{\eta d\eta}{\xi\sin\theta}.$$

The area of the parallelogram is equal to

$$\frac{\eta d\eta dr}{\xi\sin\theta}.$$

Consequently, the co-volume is equal to

$$\frac{2\pi\eta r d\eta dr}{\xi}.$$

The above quantity, multiplied by $\rho_k(\eta)$ and integrated over all possible values of η , fixing r and ξ

$$\frac{r dr}{\xi} \int_{1r-\xi}^{r+\xi} 2\pi\eta \cdot \rho_k(\eta) d\eta,$$

is the probability that the random flights chain occurs in the range r to $r+dr$, fixing ξ . The above quantity, multiplied by $W_{k-1}(\xi)d\xi$ and integrated over all possible values of ξ (from 0 to ∞) must be equal to $W_k(r)dr$:

$$W_k(r)dr=rdr\int_0^\infty \frac{W_{k-1}(\xi)}{\xi}d\xi\int_{1r-\xi}^{r+\xi} 2\pi\eta \cdot \rho_k(\eta) d\eta \dots \tag{3}$$

Employing a function $F_k(r)$ defined by

$$F_k(r)=W_k(r)/r \quad (k=1, \dots, n) \tag{4}$$

$$F_k(r)=\int_0^\infty F_{k-1}(\xi) d\xi \int_{1r-\xi}^{r+\xi} 2\pi\eta \cdot \rho_k(\eta) d\eta. \tag{5}$$

For solving Eq. (5), it is inconvenient that the absolute notation is involved in the lower limit of the integration on η in the right hand side of it. To avoid this difficulty, we employ the following device. Although $\rho_k(\eta)$ and $F_k(r)$ are defined only in the positive range of their variables, the definitions are extended to the negative range so that $\rho_k(\eta)$ becomes the even function and $F_k(r)$ the odd function of their variables respectively:

$$\left. \begin{aligned} 2\pi\eta \cdot \rho_k(\eta) &= \psi_k(\eta) & \eta \geq 0 \\ \psi_k(-\eta) &= -\psi_k(\eta) \end{aligned} \right\} \quad (6)$$

$$F_k(-r) = -F_k(r) \quad (7)$$

After the above procedure, the domain of the integration of Eq. (5) illustrated in Fig. 2 by I turning into I+II, Eq. (5) becomes

$$F_k(r) = \int_{-\infty}^{\infty} F_{k-1}(\xi) d\xi \int_{r-\xi}^{\infty} \psi_k(\eta) d\eta. \quad (8)$$

Fig. 2.

Differentiating Eq. (8) with respect to r we obtain

$$F_k'(r) = - \int_{-\infty}^{\infty} F_{k-1}(\xi) \psi_k(r-\xi) d\xi. \quad (9)$$

First we treat tentatively the problem by the Fourier transformation. The right hand side of Eq. (9) is the well-known convolution type in the Fourier transformation. Operating the transformation on both sides of Eq. (9) we obtain

$$f_k(s) = -(\sqrt{2\pi}/is) \varphi_k(s) f_{k-1}(s), \quad (10)$$

where $f_k(s)$ and $\varphi_k(s)$ are the Fourier-transforms of $F_k(r)$ and $\psi_k(\eta)$ respectively with the parameter s and $i = \sqrt{-1}$. From the definition

$$W_1(r) = 4\pi r^2 \rho_1(r),$$

$$\psi_1(r) = 2\pi r \rho_1(r) = W_1(r)/2r = F_1(r)/2.$$

Hence

$$f_1(s) = 2\varphi_1(s). \quad (11)$$

From Eqs. (10) and (11) we obtain

$$f_n(s) = (-1)^{n-1} \frac{2(2\pi)^{(n-1)/2}}{i^{n-1} s^{n-1}} \varphi_n(s) \cdots \varphi_1(s). \quad (12)$$

Operating the inverse transformation on Eq. (12) the required probability is

$$W_n(r) = 2(-1)^{n-1} \frac{(2\pi)^{n/2-1}}{i^{n-1}} r \int_{-\infty}^{\infty} \frac{\varphi_n(s) \cdots \varphi_1(s)}{s^{n-1}} \times \exp(isr) ds. \quad (13)$$

The integration involved in above equation which was obtained already by Lord Rayleigh and S. Chandrasekhar is difficult to be carried out for the random flights consisting of the displacements with the finite length, as seen in their papers. It seems to the author that the procedure of the integration by M. C. Wang and E. Guth involves a question although their result is correct. But by the Laplace transformation the problem can be solved more easily as follows.

$\rho_k(\eta)$, etc. are assumed to fulfil the conditions

$$\rho_k(\eta) = 0 \quad \eta \geq M_k, \quad (14)$$

where M_k , etc. are the finite positive numbers. Under these conditions the resultant random flights chain also has a finite length:

$$F_k(r) = 0 \quad |r| \geq M, \quad (15)$$

where

$$M > \sum_{k=1}^n M_k.$$

As is well-known, the Laplace transformation is defined only in the positive range of the variable. Therefore if $F_k(r)$ is transformed directly, the procedure is erroneous in neglecting the negative part of the variable. To avoid this difficulty we define a new function $G_k(r)$ which is produced by shifting $F_k(r)$ toward the positive range of the variable by the amount M and transform this function:

$$G_k(r) = F_k(r-M). \quad (16)$$

According to Eq. (15)

$$G_k(r) = 0 \quad r \leq 0. \quad (17)$$

Using the relation Eq. (16), Eq. (9) is replaced by

$$G_k'(r) = - \int_{-\infty}^{\infty} G_{k-1}(\xi) \psi_k(r-\xi) d\xi ,$$

which reduces to

$$G_k'(r) = - \int_0^{\infty} G_{k-1}(\xi) \psi_k(r-\xi) d\xi , \quad (18)$$

according to Eq. (17). From Eq. (14) and (6) the integrand in the right hand side of Eq. (18) is zero for ξ in the range $r-\xi < -M$. Therefore Eq. (18) can be written as

$$G_k'(r) = - \int_0^{r+M} G_{k-1}(\xi) \psi_k(r-\xi) d\xi . \quad (19)$$

Again, from $\psi_k(\eta)$ we define the function $U_k(\eta)$ in the analogous way to $G_k(r)$:

$$U_k(\eta) = \psi_k(\eta-M) . \quad (20)$$

Substituting $U_k(\eta)$ for $\psi_k(\eta)$ and replacing r by $r-M$ Eq. (19) becomes

$$G_k'(r-M) = - \int_0^r G_{k-1}(\xi) U_k(r-\xi) d\xi . \quad (21)$$

The right hand side of Eq. (21) is the well-known convolution type in the Laplace transformation. If $g_k(s)$ and $u_k(s)$ are assumed to be the Laplace-transforms of $G_k(r)$ and $U_k(\eta)$ with the parameter s , after operating the transformation on both sides of Eq. (21) we obtain

$$g_k(s) = - \frac{u_k(s) \exp(Ms)}{s} \cdot g_{k-1}(s) . \quad (22)$$

After the analogous manner to Eq. (11) we obtain

$$g_1(s) = 2u_1(s) . \quad (23)$$

From Eqs. (22) and (23) we obtain

$$g_n(s) = (-1)^{n-1} 2s \left(\prod_{k=1}^n u_k(s)/s \right) \exp \{ (n-1)Ms \} . \quad (24)$$

This equation is analogous to Eq. (12) in the process employing the Fourier transformation. Although we can obtain $G_n(r)$ from Eq. (24) by the theorem of the inverse transformation it is very convenient to make use of the tables of the transformations in textbooks, if $g_n(s)$ has a simple form.

§ 3. Random Flights Chain with Fixed Bond Lengths

The random flights chain with fixed bond lengths is the most familiar and important one. In this case we may adopt

$$\rho_k(\eta) = \frac{1}{4\pi b_k^2} \delta(\eta-b_k) \quad (k=1, \dots, n) , \quad (25)$$

where $\delta(\eta)$ stands for Dirac's δ function. From Eq. (6) we obtain

$$\psi_k(\eta) = \frac{\eta}{2b_k^2} \delta'(|\eta|-b_k) . \quad (26)$$

By using Eq. (26) for $\psi_k(\eta)$ the Laplace-transform of $U_k(\eta)$ becomes

$$u_k(s) = - \frac{1 - \exp(-2b_k s)}{2b_k \exp(-b_k s)} \cdot \exp(-sM) . \quad (27)$$

Using Eq. (27) for $u_k(s)$, Eq. (24) becomes

$$g_n(s) = - \frac{1}{2^{n-1} s^{n-1}} \left(\prod_{k=1}^n \frac{1 - \exp(-2b_k s)}{b_k \exp(-b_k s)} \right) \exp(-sM) , \quad (28)$$

which is expanded in the form

$$g_n(s) = - \frac{1}{2^{n-1} b_1 \dots b_n} \left[\frac{1}{s^{n-1}} \exp \{ -s(M-L) \} - \sum_{i=1}^n \frac{1}{s^{n-1}} \exp \{ -s(N-L+2b_i) \} \right. \\ \left. + \sum_{1 \leq i < j \leq n} \frac{1}{s^{n-1}} \exp \{ -s(M-L+2b_i+2b_j) \} - \dots + (-1)^n \frac{1}{s^{n-1}} \exp \{ -s(M+L) \} \right] . \quad (29)$$

To obtain $G_n(r)$ we must know the inverse transformation of $\exp(-as)/s^{n-1}$. After a direct examination we can see that it is equal to

$$[t-a]^{n-2}/(n-2)!$$

where the bracket [] has the following meaning

$$[t] = t \quad t \geq 0 \\ = 0 \quad t < 0 .$$

Operating the inverse transformation on Eq. (29) by the aid of the above theorem we obtain

$$G_n(r) = -\frac{1}{2^{n-1}(n-2)! b_1 \cdots b_n} \left\{ [r-M+L]^{n-2} - \sum_{i=1}^n [r-M+L-2b_i]^{n-2} \right. \\ \left. + \sum_{1 \leq i < j \leq n} [r-M+L-2b_i-2b_j]^{n-2} - \cdots + (-1)^n [r-M-L]^{n-2} \right\}, \quad (30)$$

where L is the contour length of the chain:

$$L = \sum_{k=1}^n b_k.$$

Obtaining $F_n(r)$ from Eqs. (16) and (30), rewriting it by the property that it is the odd function of r and lastly using Eq. (4) we arrived at the required result

$$W_n(r) = \frac{r}{2^{n-1}(n-2)! b_1 \cdots b_n} \left\{ [L-r]^{n-2} - \sum_{i=1}^n [L-2b_i-r]^{n-2} \right. \\ \left. + \sum_{1 \leq i < j \leq n} [L-2b_i-2b_j-r]^{n-2} - \cdots + (-1)^n [-L-r]^{n-2} \right\}. \quad (31)$$

If we carry out the integration in Eq. (69) in the paper of Chandrasekhar, multiplied by $4\pi r^2$, we shall have the same expression as Eq. (31).

In the special case in which all b_i 's are equal to b Eq. (31) becomes

$$W_n(r) = \frac{r}{2^{n-1}b^n(n-2)!} \sum_{k=0}^n (-1)^k n C_k [nb-2kb-r]^{n-2}, \quad (32)$$

which coincides with the expression obtained already by Treloar and Guth and Wang.

§ 4. Reduction of the Problem of End-to-End Distance to That of the Segment Distribution around the Centre of Gravity

The problem discussed in the preceding sections can be summarized as follows

(i) Now, let

$$\eta_k = \begin{pmatrix} x_k \\ y_k \\ z_k \end{pmatrix} \quad (k=1, \cdots, n), \quad (33)$$

be n , three dimensional vectors and distribute symmetrically around the origin of each coordinate system. Assuming the probability that $\eta_k (=|\eta_k|)$ occurs in the range η_k to $\eta_k+d\eta_k$ to be

$$4\pi\eta_k^2 \rho_k(\eta_k) d\eta_k,$$

we require the probability, $W_n(r)dr$, that the absolute value of the resultant vector

$$r = \eta_1 + \eta_2 + \cdots + \eta_n \quad (34)$$

occurs in the range r to $r+dr$.

The problem which we wish to solve in this section is as follows

(ii) Let us define a new vector derived from the vectors in Eq. (33)

$$R = a_1\eta_1 + a_2\eta_2 + \cdots + a_n\eta_n. \quad (35)$$

Then we require the probability, $W_n(R)dR$, that $R (=|R|)$ occurs in the range $R+dR$. The a_k 's are arbitrary scalar quantities. If we assign the proper values for a_k 's, then R can stand for the vector from the centre of gravity to each segment.

To reduce the problem (ii) to (i) we change the variables from η_k to ξ_k as follows

$$a_k\eta_k = \xi_k, \quad (36)$$

$$\eta_k = \xi_k/|a_k|, \quad (37)$$

where $\xi_k = |\xi_k|$. After the above procedure we must solve the problem:

(iii) Let ξ_k be a vector of which the absolute value ξ_k occurs in the range ξ_k to $\xi_k+d\xi_k$ with the probability

$$(4\pi\xi_k^2/|a_k|^3) \rho_k(\xi_k/|a_k|) d\xi_k. \quad (38)$$

Then what is the probability that the absolute value R of the resultant vector

$$R = \xi_1 + \xi_2 + \cdots + \xi_n, \quad (39)$$

occurs in the range R to $R+dR$?

If we compare the problem (iii) with (i), we can see there is no difference between them except that $\rho_k(\eta_k)$ is replaced by $\rho_k(\eta_k/|a_k|)/|a_k|^3$.

§ 5. The Distance between the Centre of Gravity and Each Segment and the Segment Density around the Centre of Gravity

We first require the distribution function of the distance between the centre of gravity and each segment of the random flights chain which consists of the bonds $b_1, \dots, b_n$ in length and has the same weights on both ends and all jointing points. In this case Eq. (35) becomes

$$\mathbf{R} = a_{i1}\boldsymbol{\eta}_1 + a_{i2}\boldsymbol{\eta}_2 + \dots + a_{in}\boldsymbol{\eta}_n \quad (i=0, 1, \dots, n) \quad (40)$$

where a_{ik} 's are given by

$$\left. \begin{aligned} a_{ik} &= k/(n+1) & k \leq i \\ &= (n-k+1)/(n+1) & i < k \end{aligned} \right\} \quad (41)$$

The distribution functions of each displacement, when the problem is reduced to that of the end-to-end distance, are obtained by using

$$g_{in}(s) = -\frac{(n+1)^n}{2^{n-1}b^n i! (n-i)! s^{n-1}} \left\{ \prod_{k=1}^i \frac{1 - \exp\{-2kbs/(n+1)\}}{\exp\{-kbs/(n+1)\}} \right\} \left\{ \prod_{k=1}^{n-i} \frac{1 - \exp\{-2kbs/(n+1)\}}{\exp\{-kbs/(n+1)\}} \right\} \exp(-sM) \quad (i \neq 0, n), \quad (46a)$$

$$g_{0n}(s) = g_{nn}(s) = -\frac{(n+1)^n}{2^{n-1}n! b^n s^{n-1}} \left\{ \prod_{k=1}^n \frac{1 - \exp\{-2kbs/(n+1)\}}{\exp\{-kbs/(n+1)\}} \right\} \exp(-sM). \quad (46b)$$

For convenience we define

$$a = \exp\left\{-\frac{2bs}{n+1}\right\}, \quad (47)$$

$$L_i = \frac{b}{n+1} \left\{ \sum_{k=0}^i k + \sum_{k=0}^{n-i} k \right\} \quad (48)$$

After simple consideration we see L_i is the maximum value of the distance between the centre of gravity and the i -th segment of the chain. We define A_{ik} by

$$\prod_{k=1}^i (1-a^k) \prod_{k=1}^{n-i} (1-a^k) = \sum_{k=0}^{(n+1)L_i/b} A_{ik} a^k \quad (i \neq 0, n), \quad (49a)$$

$$\prod_{k=1}^n (1-a^k) = \sum_{k=0}^{(n+1)L_0/b} A_{0k} a^k = \sum_{k=0}^{(n+1)L_n/b} A_{nk} a^k. \quad (49b)$$

Transforming inversely Eqs. (46a) and (46b) by the same method as in section 3, we obtain the required distribution function of the distance between the centre of the gravity and the i -th segment

$$W_{in}(R) = \frac{(n+1)^n R}{2^{n-1} i! (n-i)! (n-2)! b^n} \sum_{k=0}^{(n+1)L_i/b} A_{ik} \left[L_i - \frac{2bk}{n+1} - R \right]^{n-2}. \quad (50)$$

The square bracket in Eq. (50) again has the same meaning as in Eq. (30).

If the mean numbers of the segments found in the volume element dV at a distance R from the centre of gravity is assumed to be $D_n(R)dV$, $D_n(R)$ is simply given by

Eq. (41) for a_k and Eq. (25) for $\rho_k(\eta)$ in Eq. (38)

$$\rho_{ik}(\xi_k) = \frac{1}{4\pi(\beta_{ik})^2} \delta(\xi_k - \beta_{ik}), \quad (42)$$

where

$$\left. \begin{aligned} \beta_{ik} &= kb_k/(n+1) & k \leq i \\ &= (n-k+1)b_k/(n+1) & i < k \end{aligned} \right\} \quad (43)$$

In comparison of Eq. (32) with Eq. (25) we see the procedure employed in section 3 can be applied to this case only by replacing b_k by β_{ik} . In this case Eq. (28) becomes

$$g_{in}(s) = -\frac{1}{2^{n-1} s^{n-1}} \left\{ \prod_{k=1}^n \frac{1 - \exp(-2\beta_{ik}s)}{\beta_{ik} \exp(-\beta_{ik}s)} \right\} \times \exp(-sM) \quad (44)$$

where i in $g_{in}(s)$ refers to the i -th segment. In the simplest case where

$$b_1 = b_2 = \dots = b_n = b \quad (45)$$

Eq. (44) becomes

$$D_n(R) = \frac{1}{4\pi R^2} \sum_{i=0}^n W_{in}(R). \quad (5)$$

If we define A_k by

$$\sum_{i=0}^n {}_n C_i a^{-\{(1/4)n(n+1)-(1/2)i(n-i)\}} \prod_{k=1}^i (1-a^k) \prod_{k=1}^{n-i} (1-a^k) = \sum_{k=-n(n+1)/4}^{n(n+1)/4} A_k a^k, \quad (5)$$

the required distribution function of the density of the segment becomes

$$D_n(R) = \frac{(n+1)^n}{2^{n+1} n! (n-2)! \pi b^n R} \sum_{k=-n(n+1)/4}^{n(n+1)/4} A_k \left[-\frac{2bk}{n+1} - R \right]^{n-2}. \quad (5)$$

§ 6. Conclusion

Although the distribution function discussed in this paper has only one variable, that with two variables can be treated by the analogous method⁷⁾. The method employed in this paper may be extended also to the general random flights problem as follows⁷⁾. For this purpose the discontinuous integral of Diricht, employed by S. Chandrasekhar⁸⁾ in his paper,

$$\delta_k = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{\sin(\alpha_k \rho_k)}{\rho_k} \exp(i\rho_k \gamma_k) d\rho_k,$$

which has the property

$$\begin{aligned} \delta_k &= 1 & \text{whenever} & & -\alpha_k < \gamma_k < \alpha_k \\ &= 0 & \text{otherwise,} \end{aligned}$$

must be replaced by the integral having the form of the Laplace transformation

$$\delta_k = \frac{1}{\pi i} \int_{\beta-i\infty}^{\beta+i\infty} \frac{\sinh(\alpha_k \rho_k)}{\rho_k} \exp(\gamma_k \rho_k - C_k \rho_k) d\rho_k,$$

which has the property that

$$\begin{aligned} \delta_k &= 1 & \text{whenever} & & C_k - \alpha_k < \gamma_k < C_k + \alpha_k \\ &= 0 & \text{otherwise.} \end{aligned}$$

In conclusion we may say that it is convenient to use the former expression for the random flights problem of which the distribu-

tion function of each displacement is continuous and the latter expression for that of which the distribution function of each displacement is discontinuous and limited in the finite range of the variables.

An Application of the Cellular Method to a Vacancy in Metal

By Hiroshi FUJIWARA

*Department of Physics, Minami-Bunko, Hiroshima University,
Minami-machi-3, Hiroshima City*

(Received May 10, 1956)

The distribution of electrons around a vacancy in metal is studied using a model which was introduced in our previous paper in order to treat the impurity atom.

The arrangement of nuclei of matrix metal at each lattice point, except one where the nucleus is missing, i.e., vacancy, is treated by the cellular method. The deviation of the potential in the cells neighboring to the vacancy, from the periodic one for the pure metal is taken into account. In the first approximation, the lattice distortion due to the vacancy is neglected.

The Thomas-Fermi equation, in which all the electrons, i.e., valence electrons as well as core ones, are taken into account, is solved numerically in each cell and connected smoothly by a suitable set of boundary conditions.

As a result of our calculations for the case of a vacancy in copper, we find that there is the charge of $-1.7e$ inside the atomic sphere for the vacancy.

§ 1. Introduction

In our previous paper¹⁾ (referred to as I hereafter), we have investigated the perturbing potential around a substitutional impurity atom introduced in originally perfect copper crystal by using our newly proposed model (denoted as M_1). According to this model, the positive charges of bare nuclei of foreign and matrix atoms (the atomic number of those foreign and matrix atoms are denoted as Z_i and Z respectively) are put at each lattice point and all the electrons, i.e., valence electrons as well as core ones, are treated with Thomas-Fermi (abbreviated as T. F.) method. Therefore, we need not worry about the proper choice of the number of valence or conduction electrons per atom. And with the use of the cellular method, we have been able to construct the potential which tends to the periodic potential field due to the pure matrix metal as we go far from the impurity atom.

Here in this paper, we shall apply our model M_1 to the case of a vacancy in the lattice of the matrix metal by treating the vacancy as the limit of the impurity with $Z_i=0$. Thus the problem of a vacancy, where $\Delta Z=Z_i-Z$ has very large value in absolute magnitude, can be treated quite similarly to the one of a substitutional impurity and it is considered as an extension of Slater and Krutter's treatment for pure metal.²⁾

In the treatment of vacancy, most of the authors have hitherto used a simple model in which only the conduction electrons have taken into account in T. F. method and, furthermore, the T. F. equation has been linearized. In that model, first suggested by Dexter³⁾, the vacancy in monovalent metal has to be treated as a single negative point charge in the uniform charge distribution where the positive charges due to nuclei and negative charges due to core electrons are smeared out. Consequently, according to this scheme, a Ni atom in Cu or a Pt atom in Au should have the same effect as a vacancy.

But in this paper, since we use our refined model M_1 , approximation of the smearing out of the charge is not made, and T. F. equation is solved exactly in its non-linear form. After we finished our calculation, a paper by Lee and March⁴⁾ came into our notice in which the vacancy was studied in a way quite similar to our present one. However, our treatments are more refined than theirs, because they neglected the deviation of the potential from spherical symmetry.

§ 2. General Considerations about a Vacancy in Metal

We shall now apply the model M_1 in I to the case of a vacancy in metal by simply putting $Z_i=0$. We introduce a vacant lattice

point by removing one of the matrix atoms (hereafter abbreviated as *m*-atoms) which are arranged in the face-centered cubic crystal. In the first approximation, we assume that the lattice is not distorted due to the removal of this atom and that the concentration of the vacancies is so small that the interaction between the vacancies is negligible.

We take all the electrons in the crystal into our consideration and we assume that the positive charge $+Ze$ corresponding to the bare nuclei of *m*-atoms are located at each lattice points (denoted by R_n) except one (denoted by R_0) where no positive charge is present.

Then the crystal potential can be obtained as the solution of the T. F. equation which is appropriate for these arrangements of positive charges and a vacancy.

Now let $u(r)$ be the electrostatic potential at the point r valid over the entire crystal containing the vacancies in which every atom is supposed to be at rest at its lattice point. $u(r)$ is given, as usual, by the solution of T. F. equation:

$$\nabla^2 u(r) = \alpha u^{3/2}, \quad (1)$$

where

$$\alpha = \frac{32\pi^2 e}{3h^3} (2me)^{3/2}. \quad (2)$$

As was the case for the impurity, our problem is treated by cellular method. The polyhedron P_0 , belonging to the vacant lattice point and P_n , belonging to the *m*-atoms are replaced by the spheres S_0 and S_n of equal volume. Hereafter, the potential in S_0 and S_n are denoted by u_0 and u_n respectively. Then u_0 and u_n can be obtained by solving the equation (1) under the following conditions in the vicinity of each lattice point:

$$u_0 = \text{finite}, \quad \text{near } R_0, \quad (3a)$$

$$u_n = \frac{Ze}{|r - R_n|} + \text{finite terms}, \quad (3b)$$

$$\text{near } R_n \quad n \neq 0.$$

Our following formulations can be obtained only with replacing the circumstances concerning the impurity in I with those of vacancy and all of the formulas as to the *m*-atoms are just the same as those in I. Therefore, we need not give the details of the whole treatments but only its main scheme. Hereafter, the number for the formulas expressed in italic represent those in I.

Hitherto, most of the authors who investigated the problem as to the vacancy as well as the impurity, did not take into account the deviation of the potential from spherical symmetry. But, in I, we introduced this deviation and in the present study of the vacancy, we shall follow the same procedures, i.e., we assume that (i) the potential in the atomic sphere in the distance from the vacancy must tend to that of the pure metal which is taken as spherically symmetric as usual, and that (ii) in the atomic spheres S_n neighboring to S_0 , the potential has much lower symmetry and we take into account this lower symmetry by writing:

$$u_n = U(r) + f_n(r, \theta, \phi); \quad n \neq 0, \quad (4)$$

where $U(r)$ is the potential for perfect crystal and the small term f_n expresses the deviation from the spherical symmetry. Further, (iii) in the atomic sphere S_0 of the vacancy, the potential has the spherical symmetry. Strictly speaking, the potential should have some deviation from spherical symmetry. However, due to the higher symmetry of u_0 in S_0 , we assume that the deviation f_n can be neglected in the first approximation as was the case in I.

The potentials u_0 in S_0 and u_n in its neighboring spheres S_n obtained by integrating the T. F. equation under the boundary conditions at the center of each sphere, involve a certain number of parameters which we shall determine by virtue of an appropriate set of boundary conditions at the surface.

§ 3. The Potential u_0 in a Vacancy

The potential u_0 , which we have assumed as spherically symmetric, of T. F. equation within the sphere S_0 of the vacancy is to satisfy:

$$\frac{1}{r} \frac{d^2(u_0 r)}{dr^2} = \alpha u_0^{3/2}. \quad (5)$$

As r tends to zero, u_0 tends to a finite value c_1 . c_1 remains as an adjustable parameter whose value can be determined in such a way that u_0 may be smoothly connected to u_n of its nearest neighbors.

Introducing the usual dimensionless variables (ϕ_0, x) through the following relations:

$$u_0 = \frac{e}{r} \phi_0 \quad (6a), \quad r = b \cdot x = 0.885 \cdot a_H \cdot x \quad (6b)$$

$$a_H: \text{Bohr radius}$$

the Poisson equation (5) is transformed into the following dimensionless form:

frac{d^2 phi_0}{dx^2} = frac{phi_0^{3/2}}{sqrt{x}}, (7)

with the boundary condition:

phi_0 = 0 when x -> 0. (8)

In the region where x is small, phi_0 is assumed to be expanded in the following Taylor series:

phi_0 = C_1 x + C_2 x^2 + C_3 x^3 + ... (9)

By inserting (9) into (7), we find that phi_0 is expanded with an adjustable parameter C_1 as follows:

phi_0 = C_1 x + frac{C_1 sqrt{C_1}}{6} x^3 + frac{C_1^2}{80} x^5 + ... (10)

For the interval x which corresponds to the interval (0, r_e) of r, we carry out the numerical integration for different values of C_1. Here, r_e is the atomic radius of matrix atom.

§ 4. The Potentials u_n

As to the calculation of the potentials u_n within the spheres of m-atoms in the neighborhood of the vacancy, we perform it just in the same way as in I. For the details, the readers should refer to the formulas from (7) to (24) in I. Fig. 1 (a) and 1 (b) in I express the present circumstances only by replacing the impurity i-atom with a vacancy and for the potential U(r), those values obtained in I are used. (see from (25) to (28)).

Therefore, we describe here only the outlines. We choose one of the twelve nearest neighbor m-atoms to the vacancy, for example, m_{1,1} atom (atomic sphere S_{1,1}) in Fig. 1 (a) of I. Then the boundary conditions to be satisfied are constructed between S_{1,1} and each one of its twelve nearest neighbors by assuming that the deviation f_n from the spherical symmetric potential U(r) of pure metal does not vanish only within the spheres of the nearest and the next nearest neighbor m-atoms to the vacancy. Then the deviation f_n (r, theta, phi) is expanded in spherical harmonics as follows:

f_n(r, theta, phi) = a_0 chi_0(r) + a_1 chi_1(r) P_1(cos theta) + a_2 chi_2(r) P_2(cos theta) + ... + b_2 chi_2(r) P_2^2(cos theta) cos 2 phi + b_3 chi_3(r) P_3^2(cos theta) cos 2 phi + ... (11)

Considering the number of our boundary conditions, i.e., from (11) to (17), we take into account six coefficients a_0, a_1, a_2, a_3, b_2 and b_3 in this expansion and we can express a_1...

and b_3 as multiples of a_0.

Then the remaining parameter c_1 in u_0 is determined by the following implicit equation:

A_0 = frac{u_0(r_e, c_1) - U(r_e)}{- (partial u_0 / partial r)}. (12)

This is exactly the same equation as (24) in I. As to the values A_0 and U(r_e), we use those values obtained in I. With this value of c_1, denoted as c_0, the function u_0 is completely determined and, further, the explicit value of a_0 is also determined from the boundary condition between S_0 and S_{1,1}, i.e., from the formula either (22) or (23).

§ 5. Results and Discussions

According to the above-stated general formulations as to the vacancy in face-centered cubic crystal, we have actually carried out our calculation for the vacancy in copper.

As the value of A_0 in (12) depends only upon the concerning metal, we use likewise the value 0.48 obtained in I. As stated before, the formulas and the values concerning the matrix metal obtained in I are used again and only those concerning the vacancy are calculated here.

Thus we find the following results.

(i) The correct value of C_1 in (10) corresponding to the solution u_0 is found to be 0.215.

(ii) The numerical value of a_0 is -0.00092e from (22). Consequently, the coefficients a_1, ... and b_2 ... in (11) are calculated as the multiples of a_0 as were given in Table I in I.

(iii) The total charge rho contained in the central sphere S_0 belonging to the vacancy is estimated about -1.7e from (36). As was the case in I, it is contributed mainly from the nearest neighbor m-atoms to the vacancy.

(iv) The perturbing potential V(r) caused by the presence of the vacancy might be allowed to define as V(r) = -e(u_0 - U). And our obtained curve is shown in Fig. 1. This curve agrees with that of March⁹⁾ (Figure 2 in his paper) within the accuracy of graphical representation.

(v) For the sake of explaining our results, especially the potential through S_0 and S_{1,1}, the Fig. 2 is shown, in which the potential is shown along the line R_0 R_{1,1}. (The line R_0 R_{1,1} will be referred in Fig. 1 (a) in I. In Fig. 2, our obtained potential is represented by a solid line. The potential u_0 in the vacancy is finite

Fig. 1. Perturbing potential as a function of r (atomic units used).

solid line: Our potential
dotted line: Jongenburger's result

at R_0 and monotoniously increases towards the boundary $Q_{1,1}$ and then connected smoothly with the potential u_n , which deviates from U in $S_{1,1}$ at $Q_{1,1}$. In order to compare the present case with the perfect crystal, the potential U in the perfect crystal is also shown by dotted line, which is infinite at each lattice point. The deviation f_n from U in the case of the vacancy is estimated to be about thirty per cent.

In order to investigate the vacancy in copper, Jongenburger⁶⁾ adopted, as the scattering field due to a vacancy, the negative of the Hartree field of a free Cu^+ ion, supplemented by the potential due to the spherical hole in the free electron gas. He expressed the combined potential approximately in the form $V(r) = 24/r \cdot \exp(-2.5r)$ (in a.u.). In Fig. 1, Jongenburger's potential is shown by dotted line for the sake of comparison. The use of the negative of the Hartree field seems to be reasonable in his treatment in which the periodic variation of the potential in the pure metal is completely ignored, but the shielding due to the free electrons is more or less arbitrarily represented by introducing a spherical hole in the otherwise uniform free electron distribution. In this respect, the models based on

Fig. 2. Graphical representation of the potential through S_0 and $S_{1,1}$ along the line $\overline{R_0 R_{1,1}}$.

Thomas-Fermi equation will give in principle more refined discription.

(vi) Furthermore, from the calculated values of $|a_0|$ and $|\rho|$ for the cases of $\Delta Z = -29$ (the present case), and -2 and -1 (the pre-

vious ones), it is found that these values are not linearly proportional. The values corresponding to the vacancy are about two times of the linearly extrapolated value from those of $\Delta Z = -2$ and -1 .

(vii) March *et al.*⁷⁾ pointed out in their first paper concerning the vacancy, that in T. F. method electrons are not allowed to penetrate into the regions of negative kinetic energy. Therefore, they assumed a sphere with suitable radius around the negative point charge in which there is no electrons. Though such artificial technique is certainly necessary for their model, it is not necessary for our model in which all the electrons are taken into account.

(viii) However, as stated in I, we do not believe that our model M_1 is completely satisfactory, since T. F. method can not account for the shell structure of electrons in metal. Therefore, we are developing the method in which the distribution of core electrons is represented by the use of Hartree field and the electrons outside these cores are treated by T. F. method. We hope to be able to report the results in near future.

§ 6. Acknowledgements

The author wishes to express his sincere thanks to Prof. Masao Kotani of University

of Tokyo for his continued guidance and encouragements throughout this work and Prof. Frederick Seitz of University of Illinois for his kind interest. The author's appreciations are due to Prof. K. Umeda, Dr. S. Kobayashi who kindly discussed and to Mrs. H. Komuro for her assistance in the numerical calculation.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 13, No. 8, AUGUST, 1958

Characteristics of the Beam Type Maser. II

By Koichi SHIMODA

Department of Physics, Faculty of Science, University of Tokyo

(Received April 17, 1958)

Experimental investigation of the characteristics of the ammonia maser is given and compared with theory. Observed saturation characteristics agree fairly well with the theory described in the previous paper. The change of oscillation frequency shows the expected increase with focuser voltage which arises from unresolved hyperfine structure of the 3,3 line. Small discrepancies are explained by the velocity distribution and different saturation of each hyperfine component. Frequency pulling due to cavity detuning was measured in detail and compared with theory. Thus the velocity spread of the effective molecules in the cavity can be estimated as roughly $\pm 30\%$. Tentative estimate of the center frequency on UT_2 is compared with other measurements.

§ 1. Introduction

Theory of the beam type maser which takes the velocity distribution into consideration was described in the previous paper¹⁾, hereafter referred as I. The saturation characteristics

and the frequency change of an ammonia maser with focuser voltage were theoretically calculated. In this paper some of the experimental results with the maser on the 3,3 line of ammonia are described. The use of

the 3,2 line which was suggested in I and also by Townes has already been investigated by Bonanomi *et al.*,²⁾ hence preliminary work on the 3,2 line is left out of this paper.

§ 2. Experimental Apparatus

A vertical cross-section of the experimental ammonia maser is shown in Fig. 1. In order to pump out the scattered molecules as fast as possible an oil diffusion pump is located near the beam source. A 4-inch oil diffusion pump, TOD-4F (Tokuda Mfg Co.), is connected directly below the flange. The ultimate vacuum without using liquid air trap was measured as 6×10^{-7} mmHg air equivalent.

An eight-pole focuser is surrounded by a cylindrical trap which is cooled by liquid oxygen or liquid nitrogen in a helical copper tube. Because the cold surface is fairly large, the operating tank pressure around 1×10^{-6} mmHg can be easily obtained with sufficiently

strong beam. The focuser is made of steel rods of 3.5 mm diameter and the crosssection is shown in Fig. 2 (a).

The cavity is a cylindrical TM_{010} mode cavity of 12 cm length and is slotted lengthwise, which allows tuning over 200 Mc/sec. range by squeezing the cylinder. The inlet and outlet holes are 8 mm in diameter.

Fig. 2. Cross-sections of the eight-pole focuser (a), and three types of the beam source (b) and (c).

Since several attempts to improve the beam source resulted in poor success, simpler source structures have been used in the following experiments. The typical source is made up of 12 or 19 holes 1 mm in diameter, as shown in Fig. 2 (b). When a cold diaphragm with a 10 mm hole is placed between the source and the focuser, divergent molecules are trapped or reflected to be pumped out, thereby the tank pressure and the threshold focuser voltage decrease.

A typical result of the threshold focuser voltage to start oscillation and the tank pressure as functions of the source pressure behind the 12-hole source is shown in Fig. 3. Without the diaphragm, the threshold voltage was about 4 kV and it was less dependent on the source pressure.

The threshold voltage and the tank pressure with the crinkle foil source, as shown in Fig. 2 (c), is shown in Fig. 4. The crinkle foil source is more transparent, having the transparency of about 0.5, than the 12-hole source for which the transparency is $\frac{1^2}{8^2} \times 12 = 0.19$.

The ratio, 0.5: 0.19, is very close to the inverse ratio of the corresponding source pressures in Fig. 3 and Fig. 4. However, this relation does not always hold good for any different type of sources.

The threshold voltage decreases with increasing source pressure at low source pressure, because the beam flux increases with

Fig. 1. Cross-sectional view of the experimental ammonia maser. F: focuser, C: cavity resonator, T: trap.

Fig. 3. Threshold voltage and tank pressure with the 12-hole source shown in Fig. 2 (b)

the source pressure. Beyond an optimum pressure, which is about 9 mmHg in Fig. 3 and 4 mmHg in Fig. 4, both the threshold voltage and the tank pressure increase with the source pressure. This evidently seems to be due to the collisions between ammonia molecules inside the focuser. The tank pressure was measured by a Fogel type ionization gauge attached near the cavity, and it does not quantitatively indicate the density of molecules inside the focuser, but does qualitatively. The reproducible minimum threshold voltage is 2,400 volts and the breakdown focuser voltage is approximately 27 kV. Then the maximum beam intensity is about 100 times stronger than that of the threshold of oscillation (for the 3,3 line of ammonia).

Since the focuser is insulated with teflon sheets of 1 mm thickness and the high voltage terminal is insulated with pyrex glass, the leakage current is so small that the maser oscillation continues as long as 25 minutes after the high voltage supply of 8 kV is disconnected. The measured capacitance of the focuser electrode is 102 ± 6 pF, and the insulation resistance is estimated as about 10^{13} ohms. Thus a nuclear battery might be used as a high voltage source. The breakdown voltage decreases when the ammonia frost has grown on and around the focuser after several hour's run. The microwave output from the cavity is taken out through a mica window in a wave-

Fig. 4. Threshold voltage and tank pressure with the crinkle foil source as shown in Fig. 2 (c).

guide flange and fed to a crystal mixer. A crystal tripler driven by an X-band klystron, 2K-25, tuned to about 7940 Mc/sec. is used as a local oscillator. With the intermediate frequency of around 45 Mc/sec. and a 1N26 crystal as mixer, the optimum signal-to-noise ratio was obtained at the rectified current of 30-100 μ A. The maximum rectified current of the output from the crystals tripler was 303 μ A, using the best 1N26 among 16 units.

§ 3. Amplitude of Oscillation

The amplitude of oscillation of the ammonia maser was measured and a typical result is shown in Fig. 5. The absolute rf amplitude could not be measured, but the relative amplitude was obtained on the CRO screen. The scale of the ordinate in Fig. 5 has been so adjusted that the amplitude at low focuser voltage may fit the theoretical value of I. The observed amplitude characteristics agrees fairly well with the velocity distribution theory, except that the deviation from approximate calculation with the effective average

velocity appears at lower voltage than the estimated in Fig. 3 of I.

The relative amplitude of oscillation as function of source pressure was reported by Helmer⁴⁾. An example with the 12-hole source is shown in Fig. 6 together with the operating tank pressure. The amplitude shows a maximum at an optimum pressure, as the number

Fig. 5. Observed and theoretical amplitude of oscillation. SWT: uni-velocity theory³⁾, I: velocity distribution theory¹⁾, circles: observed values.

Fig. 6. Relative amplitude and tank pressure with the 12-hole source.

Fig. 7. Change of the relative amplitude of strange oscillation with positive and negative focuser voltage.

of effective molecules at higher source pressure decreases because of the increase of collisions between molecules inside the focuser.

A strange phenomenon was experienced, when the insulator is used around the hole of the diaphragm which is put close to the end of focuser electrode. After slight discharges by applying overvoltages, the threshold focuser voltage decreased appreciably. Sometimes the maser oscillation could be observed at zero focuser voltage. In this case the amplitude of oscillation increased by applying either positive or negative voltage as illustrated in Fig. 7. Therefore, this cannot be explained by the formation of double layer on the focuser electrode. The amplitude of oscillation at zero focuser voltage increased monotonically with the source pressure as shown in Fig. 8. This

Fig. 8. Relative amplitude of strange oscillation as a function of source pressure.

may be explained from such consideration that the molecules are focused by the electric field around the diaphragm which is produced by scattered charges on the insulator.

§ 4. Center Frequency of Oscillation

A block diagram of the frequency translator employed in the precise frequency measurement of the maser is shown in Fig. 9. A part of phase lock-in multiplier for an ammonia absorption clock⁶⁾ is used for convenience and economy. The 2Mc/sec. crystal oscillator is not very stable, as the Q -value of the quartz crystal is only of the order of 10^4 , and the spectrum of the multiplied output is not pure enough to obtain clear beat notes with the maser. This is not due to the random noise but due to the phase modulation produced in the phase lock-in control. Therefore, the beat

frequency is divided down by a factor of 24 in order that the maximum frequency deviation becomes much smaller than the value of the phase modulation frequency (2 kc/sec.). Then the 2 Mc/sec. crystal oscillator is controlled so that the divided beat frequency can be phase-locked with respect to the reference signal of 82 kc/sec.

Fig. 9. Block diagram of the frequency translator for the ammonia maser on the 3,3 line.

In this way the frequency of the crystal oscillator, f_z , is controlled by the frequency of the ammonia maser, f_{maser} , with the ratio:

$$\frac{f_z}{f_{\text{maser}}} = \frac{2,000}{306,002 \times 26 \times 3 + 82 \times 24} = \frac{2}{23,870.124} \quad (1)$$

The klystron need not be phase-locked in this frequency translator, because it does not affect the beat frequency at the second mixer output written as 1.97 Mc/sec. in Fig. 9. The klystron must only be stabilized so that the beat frequencies with the VHF oscillator and with the maser can be kept within the bandwidth of two i-f amplifiers (14.5 Mc/sec. and 45.5 Mc/sec. amplifiers respectively).

The frequency of the 2 Mc/sec. crystal oscillator, locked to the maser as given in Eq. (1), is compared with the standard frequency broadcast JJY at 5 Mc/sec. and the difference (of the order of 1 cps) is recorded and counted to find the frequency of the maser. The precision of frequency comparison is about 10^{-10} , while the stability of the standard frequency broadcast is usually 1 part in 10^9 per day. Sometimes, frequency deviations of several parts in 10^9 which arose from fluctuations in wave propagation were experienced but normally a relative accuracy of about 1 part in 10^9 could be expected since the JJY station

is not far distant. A tentative estimate of the frequency change of JJY has been obtained by the absorption type ammonia clock, and the correction on *UT2* will be given later.

The frequency of oscillation depends on the cavity design, cavity tuning, focuser voltage, and the source pressure. Relative frequency change with the source pressure has already been reported.⁴⁾ Here the absolute frequency shift with the focuser voltage and cavity tuning is reported. In the following experiments the 19-hole source shown in Fig. 2 (b) at the source pressure of about 1 mmHg was used. In order to avoid any complicating effect which might be expected at higher source pressure due to scattering of molecules, lower source pressure than the optimum value was used.

When the cavity is tuned so as to deliver maximum power output or to have minimum threshold voltage, the resonant frequency of the cavity may be assumed to be tuned to the frequency of the line. The observed center frequency of the maser with in-tuned cavity is shown in Fig. 10 as a function of

Fig. 10. Center frequency of the ammonia maser on the 3,3 line as a function of the eight-pole focuser voltage.

the focuser voltage, where the frequency is based on the tentative estimate of *UT2**. The observed frequency increases with the focuser voltage as was theoretically expected in Fig.

* To obtain revised values of frequencies on *UT2* Tokyo, Jan. 1958, add +0.07 kc/sec.

7 of I. The experimental results show slower increase at low focuser voltage and do not show independency of focuser voltage even at high voltage, while the magnitude of frequency shift almost agrees with the theoretical result.

The discrepancy can be also explained by the velocity spread of effective molecules flowing into the cavity. Moreover, at higher voltages hyperfine components with $F=3$ and $F=4$ tend to be more divergent and more saturated than the $F=2$ component. Since $F=2$ component lies at a higher frequency, the oscillation frequency still increases at high focuser voltage. Lastly the frequency shift due to the presence of traveling wave in the cavity, which was discussed in SWT³⁾, must of course be considered. If $V < 4.5$ kV in the maser described here, θ is smaller than $\pi/2$ and hence the traveling wave flows in the opposite direction to the beam. At the higher focuser voltage when $V > 4.5$ kV, θ is larger than $\pi/2$ and the molecules emit radiation in the former part of the cavity while they absorb in the latter part of the cavity, resulting in the traveling wave in the same direction with the beam. Therefore, as was discussed at the end of page 1315 in ref. (3), the oscillation frequency increases with the focuser voltage by the traveling wave effect. With these considerations which were omitted in I to carry out a simpler calculation, the observed frequency shift can well be explained by the velocity distribution theory. The frequency of oscillation also increases considerably with the cavity length⁶⁾, because the longer the cavity, the larger the traveling wave effect and the more important the $F=2$ component which is less divergent becomes.

With these considerations the frequency of ammonia at thermal equilibrium is estimated to be $23,870,129.98 \pm 0.15$ kc/sec. The uncertainty comes mainly from the tentative estimate of *UT2* and on the value of the difference of eqQ between the ground and the excited states, which is 3–4 kc/sec. The resettability is of course much better.

On the other hand, the frequency of the ammonia absorption has been measured as $23,870,130.57$ kc/sec.** This value seems to

** to be published. The values reported before should be corrected by their incorrect estimate of the purity of ammonia and the pressure shift.

include frequency shift due to collision of molecules with the waveguide wall. The frequency of the maser was first measured by Bonanomi *et. al.* as 23,870,129.42 kc/sec. This was measured with the maser at rather high focuser voltage and extrapolated linearly to zero focuser voltage. Thus it seems to be consistent with more detailed result of Fig. 10, and evidently it includes frequency shift due to quadrupole hyperfine structure. Neither of these two values shows true frequency of a free ammonia molecule.

§ 5. Pulling Effect

The frequency of the maser is pulled by the cavity tuning. A crude theory was given by Gordon *et. al.*⁸⁾ and the effect of saturation was calculated by Shimoda *et. al.* based on the uni-velocity theory. However, accurate experimental results have not yet appeared.

The observed frequency of the maser on the 3,3 line of ammonia changes with the cavity tuning and with focuser voltage as shown in Fig. 11. Each curve corresponds to different cavity tuning, which could not be determined quantitatively. These curves show clearly an asymmetrical behavior for the cavity tunings at higher and lower frequencies. This is understood as the superposition of the pulling effect on the center frequency shift due to the unresolved hyperfine structure. Therefore, the frequency pulling can be evaluated by taking the difference with the center frequency shown in Fig. 10.

From Eq. (6) in SWT³⁾ the pulling is theoretically given by

$$\omega - \omega_0 = 2Q \frac{v}{L\omega_0} f_2(\theta) \cdot (\omega_c - \omega_0) \quad (2)$$
$$f_2(\theta) = \frac{1 - \cos 2\theta}{1 - \sin 2\theta/2\theta} \quad (3)$$

where ω_0 is the center frequency, ω_c the resonant frequency of the cavity, and $\theta = [(\omega - \omega_0)^2 + x^2]^{1/2} L/2v$.

Although ω_c was not measured but the starting voltage for the respective cavity setting, V_{th} , was carefully measured. From Eq. (2.6) of I, the critical radial velocity of molecules, v_o , can be calculated. The value of the critical radial velocity for the tuned cavity which corresponds to the minimum starting focuser voltage is denoted by v_{o0} . Then from Eq. (3.10) of I, one obtains

Fig. 11. Frequency change of the ammonia maser. Each curve corresponds to different cavity tuning.

$$\frac{V_{th, \min}}{V_{th}} = \frac{v_{o0}}{v_o} = \frac{\sin(\omega - \omega_0)L/2v}{(\omega - \omega_0)L/2v} \quad (4)$$

by putting $x=0$ for the starting condition. The magnitude of frequency pulling at the threshold can be calculated from this equation. The value of v may be taken equal to the

most probable velocity from the reasoning described at the end of §2 in I, since $(\omega - \omega_0)^2 \gg \alpha^2$ in this case. In order to fit it with the extrapolated value of the observed pulling at finite amplitudes, the cavity length, L , must be taken as 8 cm, although the physical length of the cavity is 12 cm. A cavity with large holes at both ends of the cylinder can not produce uniform electric field along the length of the cavity, but the field decreases at both ends in such a way that the cavity might be considered as the open ended TM_{011} mode. Thus the effective length of 8 cm is plausible.

Now, for $\alpha=0$ the magnitude of detuning, $(\omega_0 - \omega)Qv/L$, can be calculated using Eqs. (2) and (3), since $\omega - \omega_0$ is known from the threshold voltage. The observed change of frequency pulling with the amplitude of oscillation gives the experimental value of the pulling factor, $f_2(\theta)$ in Eq. (2). The value of θ as a function of the focuser voltage is obtained from Eq. (3.10) in I and Fig. 5 in

this paper.

The observed pulling factor is plotted in Fig. 12 as a function of θ . Theoretical pulling factor of the uni-velocity beam, Eq. (3), is shown by a solid curve. Although the frequency of the maser could be measured at the focuser voltage only 100 volt above the threshold, frequency pulling for small values of θ could not be obtained, because $\omega - \omega_0$ as well as α must be small for a small value of θ , and the pulling factor for slight detuning was very difficult to measure.

Deviations of the observed points from Eq. (3) are very plausibly explained by the velocity distribution of molecules flowing into the cavity. All molecules in the beam are put in a common oscillating field given by ω and α , but they have different values of θ , when their velocities are different. Therefore, the measured value of the pulling factor must be a kind of average of theoretical value of $f_2(\theta)$. As are shown by broken lines in Fig. 12, it may be estimated that the velocity spread

Fig. 12. Observed and theoretical pulling factor as a function of θ .

of effective molecules in the beam is roughly $\pm 30\%$.

In conclusion it appears that the considerations and observations described in these two papers have revealed most of the complicated behavior of beam type masers. Then it has become possible to design a more reliable frequency standard by the beam type maser.

The Maximum Disturbance Growth Rate for an Unstable Plasma Column

By Shobu KANEKO

*Department of Physics, Faculty of Science,
University of Tokyo*

(Received May 6, 1958)

A dispersion relation for a self-pinched plasma column enclosed by a conducting wall is derived for the case of a model with both surface sheet current and uniform volume current. On the basis of this dispersion relation the maximum disturbance growth rate for the instability is calculated. Both the uniform volume current and longitudinal magnetic flux outside the plasma column decrease the stability and make the growth rate faster, the effect of the magnetic flux being larger.

§ 1. Introduction

In order to make a thermonuclear reactor, it is necessary to confine a hot plasma apart from the vessel for a considerably long time. For this purpose, the application of the "pinch effect" is promising; but unfortunately a plasma column pinched by a large electric current is unstable. This instability was first investigated theoretically by Kruskal and Schwarzschild¹⁾; and their work was generalized by Tayler²⁾. Shrafranov³⁾ investigated the influence of a longitudinal magnetic field on this instability. He found that, although a sufficiently strong longitudinal magnetic field within the plasma stabilizes the plasma column against constrictions and short wavelength kinks and also against deformations of higher modes, it does not stabilize the column against long wave-length kinks. Moreover a

longitudinal magnetic field outside the plasma has the effect of increasing this instability. So he did not succeed in obtaining the completely stable configuration. Recently, Tayler⁴⁾ and Kihara⁵⁾ have pointed out independently, by using the sheet current model, that there is a perfectly stable configuration when a longitudinal magnetic field is supplied and the plasma is enclosed by a conducting wall.

In this article we rather investigate unstable regions, and calculate the maximum disturbance growth rate for the instability for the most unstable mode, kink disturbance, by the method of Kruskal and Schwarzschild.

§ 2. Basic Equations, Equilibrium Configuration and Boundary Conditions

In what follows we consider a neutral, ideally conducting plasma column in an equi-

librium state, surrounded by vacuum which is itself enclosed by an ideally conducting cylindrical wall.

Magnetohydrodynamic basic equations for the plasma are

$$\rho \frac{dv}{dt} = \mathbf{J} \times \mathbf{B} - \text{grad } p, \quad (2.1)$$

$$\frac{\partial \rho}{\partial t} = -\text{div } \rho \mathbf{v}, \quad (2.1)$$

$$\frac{\partial \mathbf{B}}{\partial t} = \text{rot } (\mathbf{v} \times \mathbf{B}), \quad (2.3)$$

$$p = \text{const } \rho^\gamma, \quad (2.4)$$

where ρ is the mass density, $\mathbf{v}$ the mass velocity, $\mathbf{J}$ the electric current density, $\mathbf{B}$ magnetic flux, p the pressure and γ the specific heat ratio. In this article the MKS rational system of units is used throughout. As regards these basic equations, Kihara⁵⁾ has recently investigated in detail and found that the induction equation (2.3) is valid when the growth rate is smaller than the cyclotron frequency of the ion (i.e. in the quasi-static case).

In the equilibrium configuration, we assume the distribution of the magnetic flux in the cylindrical coordinate system to be

$$(B_r, B_\varphi, B_z) = \begin{cases} (0, B_0 \alpha r, B_0) & \text{for } 0 \leq r < a \\ (0, B_1(a/r), B_2) & \text{for } a < r < b. \end{cases} \quad (2.5)$$

Here a and b are the radii of the plasma column and the conducting wall respectively; B_0 , B_1 and B_2 are constants and αa is assumed to be so small that its square may be neglected. Kihara⁵⁾ has pointed out that this model of a self-pinch plasma column will be close to the reality and is appropriate for mathematical treatment. The configuration is in equilibrium provided that

$$\left. \begin{aligned} J_{ze} &= \frac{2}{\mu} B_0 \alpha, \\ J_{\varphi e}^* &= \frac{1}{\mu} (B_0 - B_2), \\ J_{ze}^* &= \frac{1}{\mu} (B_1 - B_0 \alpha a), \\ p_e + \frac{B_0^2}{2\mu} &= \frac{1}{2\mu} (B_1^2 + B_2^2), \end{aligned} \right\} \quad (2.6)$$

where μ is the permeability, the asterisk means the sheet current, and the subscript e stands for the equilibrium state.

Following Kruskal and Schwarzschild, we consider perturbations about the equilibrium state in the form

$$q = q_e + q_p = q_e + q_p(r) \exp \{i(m\varphi + kz) + \omega t\}. \quad (2.7)$$

Here the subscript p stands for a perturbed variable, k is a real wave number, m is an integer positive or negative and ω is the disturbance growth rate if ω^2 is positive. Recently Hain, Lüst and Schlüter⁶⁾ have proved in general that ω^2 is real for these problems, so there is no overstable solution, that is to say, oscillating solution with increasing amplitude. The dispersion relation, [see the equation (3.12) below], shows that k , B_0/B_1 and B_2/B_1 can be taken as positive if we consider both positive and negative values of m .

Let the gas particles suffer small displacements $\xi(r) \exp \{i(m\varphi + kz) + \omega t\}$, then the surface of the plasma column is displaced by an amount of $\xi(a) \exp \{i(m\varphi + kz) + \omega t\}$. So the unit normal vector $\mathbf{n} = (n_r, n_\varphi, n_z)$ to this surface becomes

$$\mathbf{n} = (1, 0, 0) + \left\{ 0, -\frac{im}{a} \xi_r(a), -ik \xi_r(a) \right\} \times \exp \{i(m\varphi + kz) + \omega t\}. \quad (2.8)$$

Boundary condition, sufficient for obtaining the dispersion relation, is as follows

$$\left. \begin{aligned} p + \frac{1}{2\mu} B^2 & \text{ is continuous and} \\ B_n & \text{ is continuous} \end{aligned} \right\} \quad (2.9)$$

on the perturbed plasma surface, and

$$B_n \text{ vanishes} \quad (2.10)$$

on the rigid conducting wall.

§ 3. Calculation of the Perturbed Variables and the Dispersion Relation

First we consider the inside of the plasma column. In the approximation that only terms linear in perturbations are retained, the perturbation to any quantity is proportional to the displacement.

Equations (2.1) through (2.4) become in this approximation

$$\left. \begin{aligned} \rho_p &= -\rho_e \text{div } \xi, \\ \mathbf{B}_p &= \text{rot } (\xi \times \mathbf{B}_e), \\ \dot{p}_p &= -\gamma p_e \text{div } \xi, \end{aligned} \right\} \quad (3.1)$$

and

$$\omega^2 \rho_e \boldsymbol{\xi} = \gamma p_e \text{grad} \cdot \text{div } \boldsymbol{\xi} + \frac{1}{\mu} (\text{rot } \mathbf{B}_e \times \mathbf{B}_p) + \frac{1}{\mu} (\text{rot } \mathbf{B}_p \times \mathbf{B}_e) . \tag{3.2}$$

Using equations (3.1) and (3.2) and retaining terms linear in $\boldsymbol{\xi}$ and αr , we obtain simultaneous differential equations for components of the displacement $\boldsymbol{\xi}(r)$:

$$\left. \begin{aligned} (c^2 + c_H^2) D D^+ \xi_r(r) - (\omega^2 + k^2 c_H^2 + 2 \alpha k m c_H^2) \xi_r(r) + i m (c^2 + c_H^2) D \frac{\xi_\varphi(r)}{r} \\ - i \alpha k c_H^2 D \{ r \xi_\varphi(r) \} + i (k c^2 - \alpha m c_H^2) D \xi_z(r) = 0 , \\ \frac{i m}{r} (c^2 + c_H^2) D^+ \xi_r(r) - i \alpha k c_H^2 r^2 D \frac{\xi_r(r)}{r} - \left\{ \omega^2 + \frac{m^2}{r} (c^2 + c_H^2) + k^2 c_H^2 \right\} \xi_\varphi(r) \\ - \{ k m c^2 - \alpha (m^2 + k^2 r^2) c_H^2 \} \frac{\xi_z(r)}{r} = 0 , \\ i (k c^2 - \alpha m c_H^2) D^+ \xi_r(r) - \{ k m c^2 - \alpha (m^2 + k^2 r^2) c_H^2 \} \frac{\xi_\varphi(r)}{r} - (\omega^2 + k^2 c^2) \xi_z(r) = 0 . \end{aligned} \right\} \tag{3.3}$$

Here we have used the notations

$$\begin{aligned} D &= \frac{d}{dr} , \\ D^+ &= \frac{d}{dr} + \frac{1}{r} , \\ c^2 &= \gamma \frac{p_e}{\rho_e} \quad \text{square of the sound-wave velocity,} \\ c_H^2 &= \frac{B_0^2}{\mu \rho_e} \quad \text{square of the Alfvén-wave velocity.} \end{aligned}$$

From this set of equations, we get expressions for $\xi_\varphi(r)$, $\xi_r(r)$ in terms of $\xi_z(r)$:

$$\left. \begin{aligned} \xi_\varphi(r) &= \frac{1}{k^2 c^4 (\omega^2 + k^2 c^2)^2} \left[\frac{k m \kappa c^2}{r} (\omega^2 + k^2 c_H^2) + \alpha \kappa c_H^2 \frac{m^2 (c^2 + c_H^2) - k^2 r^2 c^2}{r} \left(D^+ D - \frac{m^2}{r^2} \right) \right. \\ &\quad \left. + 2 \alpha k^2 \kappa c^2 c_H^2 D + \frac{\alpha k^2 c_H^2}{r} \{ c^4 (m^2 + k^2 r^2) (\omega^2 + k^2 c_H^2) - m^2 \kappa (2 c^2 + c_H^2) \} \right] \xi_z(r) , \\ \xi_r(r) &= - \frac{i}{k^2 c^4 (\omega^2 + k^2 c_H^2)^2} \left[k \kappa c^2 (\omega^2 + k^2 c_H^2) D + \alpha m \kappa c_H^2 (c^2 + c_H^2) D \left(D^+ D - \frac{m^2}{r^2} \right) \right. \\ &\quad \left. + \frac{2 \alpha k^2 m \kappa c^2 c_H^2}{r} + \alpha k^2 m c_H^2 \{ c^4 (\omega^2 + k^2 c_H^2) - \kappa (2 c^2 + c_H^2) \} D \right] \xi_z(r) , \end{aligned} \right\} \tag{3.4}$$

where the notation

$$\kappa = \omega^2 (c^2 + c_H^2) + k^2 c^2 c_H^2$$

has been used for simplicity.

Equations (3.3) and (3.4) give a differential equation for $\xi_z(r)$:

$$D^+ D \xi_z(r) - \left[\frac{m^2}{r^2} + \beta^2 \right] \xi_z(r) = 0 , \tag{3.5}$$

where

$$\beta^2 = \frac{(\omega^2 + k^2 c^2)(\omega^2 + k^2 c_H^2)}{\omega^2 (c^2 + c_H^2) + k^2 c^2 c_H^2} - \frac{2 \alpha k m \omega^4 c^2 c_H^2}{\{ \omega^2 (c^2 + c_H^2) + k^2 c^2 c_H^2 \}^2} .$$

This is a modified Bessel equation, whose solution finite at $r=0$ is

$$\xi_z(r) = C^i I_m(\beta_1 r) = C^i \{I_m(\beta_1 r) - \beta_2 r I_m'(\beta_1 r)\} + O(\alpha^2),$$

$$\beta_1^2 = \frac{(\omega^2 + k^2 c^2)(\omega^2 + k^2 c_H^2)}{\omega^2(c^2 + c_H^2) + k^2 c^2 c_H^2}, \quad \beta_2 = \frac{\alpha k m \omega^4 c^2 c_H^2}{\beta_1 \{\omega^2(c^2 + c_H^2) + k^2 c^2 c_H^2\}^2}.$$

Here C^i is an arbitrary constant, the superscript i meaning inside of the plasma; the prime indicates derivative with respect to the argument. Substituting this solution for $\xi_z(r)$ into the equations (3.4) for $\xi_\varphi(r)$ and $\xi_r(r)$, we obtain

$$\left. \begin{aligned} \xi_z(r) &= C^i \{I_m(\beta_1 r) - \beta_2 r I_m'(\beta_1 r)\}, \\ \xi_\varphi(r) &= \frac{C^i}{k^2 c^4 (\omega^2 + k^2 c_H^2)^2} \left[\frac{k m \kappa c^2}{r} (\omega^2 + k^2 c_H^2) I_m(\beta_1 r) + 2 \alpha k^2 \kappa c^2 c_H^2 \beta_1 I_m'(\beta_1 r) \right. \\ &\quad \left. + \frac{\alpha \omega^2 c_H^2}{r} \{m^2 \omega^2 (2c^2 + c_H^2) - c^2 (m^2 + k^2 r^2) (\omega^2 + k^2 c_H^2)\} I_m(\beta_1 r) \right. \\ &\quad \left. - \beta_2 k m \kappa c^2 (\omega^2 + k^2 c_H^2) I_m'(\beta_1 r) \right], \\ \xi_r(r) &= \frac{-i C^i}{k^2 c^4 (\omega^2 + k^2 c_H^2)^2} \left[k \kappa c^2 (\omega^2 + k^2 c_H^2) \beta_1 I_m'(\beta_1 r) + \frac{2 \alpha k^2 m \kappa c^2 c_H^2}{r} I_m(\beta_1 r) \right. \\ &\quad \left. + \alpha m \omega^2 c_H^2 \{ \omega^2 (c^2 + c_H^2) - k^2 c^2 c_H^2 \} \beta_1 I_m'(\beta_1 r) \right. \\ &\quad \left. - k \kappa c^2 (\omega^2 + k^2 c_H^2) \left(\beta_1^2 + \frac{m^2}{r^2} \right) \frac{\beta_2}{\beta_1} r I_m(\beta_1 r) \right]. \end{aligned} \right\} \quad (3.6)$$

Next let us consider the outside which is vacuum. In this part there flows no electric current, so the magnetic flux is irrotational and determined by the scalar potential $\psi(r, \varphi, z)$,

$$\mathbf{B} = \text{grad } \psi, \quad \psi = \psi_e^o + \psi_p^o(r) \exp \{i(m\varphi + kz) + \omega t\}, \quad (3.7)$$

where superscript o stands for the outside of the plasma column. From this equation we obtain perturbations on the magnetic flux as follows:

$$\left. \begin{aligned} B_{pr}^o(r) &= k C_1^o K_m'(kr) + k C_2^o I_m'(kr), \\ B_{p\varphi}^o(r) &= \frac{im}{r} C_1^o K_m(kr) + \frac{im}{r} C_2^o I_m(kr), \\ B_{pz}^o(r) &= ik C_1^o K_m(kr) + ik C_2^o I_m(kr). \end{aligned} \right\} \quad (3.8)$$

Here $I_m(x)$ and $K_m(x)$ are the modified Bessel functions; and C_1^o , C_2^o are constants to be determined by the boundary conditions (2.9) and (2.10). The results are

$$\left. \begin{aligned} C_1^o &= \frac{i \xi_r(a)}{ka} (m B_1 + k a B_2) \frac{I_m'(kb)}{K_m'(ka) I_m'(kb) - I_m'(ka) K_m'(kb)}, \\ C_2^o &= -\frac{i \xi_r(a)}{ka} (m B_1 + k a B_2) \frac{K_m'(kb)}{K_m'(ka) I_m'(kb) - I_m'(ka) K_m'(kb)}. \end{aligned} \right\} \quad (3.9)$$

Now we can derive the dispersion relation by using these solutions. The boundary condition (2.9) is now expressed in the form

$$2\mu p + B_\varphi^{i2} + B_z^{i2} = B_\varphi^{o2} + B_z^{o2}.$$

By using relations

$$B_\varphi^i(a + \xi_r) = B_{c\varphi}^i(a) + \left(\frac{dB_{c\varphi}^i}{dr} \xi_r \right)_{r=a} + (B_{p\varphi}^i)_{r=a}$$

etc., and equations (3.8) and (3.9), we get

$$\begin{aligned} \mu r p_e (\operatorname{div} \xi)_{r=a} &= \frac{\xi_r(a)}{a} B_1^2 - \frac{\xi_r(a)}{a} (m B_1 + k a B_2)^2 F(ka, kb) \\ &+ \{ik \xi_z(a) - (\operatorname{div} \xi)_{r=a}\} B_0^2 + i\alpha \{m \xi_z(a) + k a \xi_\varphi(a)\} B_0^2, \end{aligned}$$

where

$$\operatorname{div} \xi = \frac{1}{r} \frac{d}{dr} \{r \xi_r(r)\} + \frac{im}{r} \xi_\varphi(r) + ik \xi_z(r),$$

and

$$F(ka, kb) = \frac{K_m(ka) I_m'(kb) - I_m(ka) K_m'(kb)}{ka [K_m'(ka) I_m'(kb) - I_m'(ka) K_m'(kb)]}.$$

Inserting the solution (3.6) for the displacement $\xi(r)$, we finally obtain the dispersion relation

$$\begin{aligned} \beta_1 a \left[\left(\frac{B_0}{B_1} \right)^2 + \frac{r \omega^2}{2(\omega^2 + k^2 c^2)} \left\{ 1 + \left(\frac{B_2}{B_1} \right)^2 - \left(\frac{B_0}{B_1} \right)^2 \right\} \right] \frac{I_m(\beta_1 a)}{I_m'(\beta_1 a)} + \alpha a L \\ = \left[1 + \left\{ m + k a \left(\frac{B_2}{B_1} \right) \right\}^2 F(ka, kb) \right] [1 + \alpha a R], \end{aligned} \quad (3.10)$$

where

$$\begin{aligned} L &= \frac{m \beta_1}{k c^2 (\omega^2 + k^2 c^2) (\omega^2 + k^2 c_H^2)} \left[\left(\frac{B_0}{B_1} \right)^2 \{ \omega^2 c_H^2 (\omega^2 + k^2 c^2) + 2 k^2 c^4 (\omega^2 + k^2 c_H^2) \} \right. \\ &\quad \left. + \frac{r}{2} \left\{ 1 + \left(\frac{B_2}{B_1} \right)^2 - \left(\frac{B_0}{B_1} \right)^2 \right\} \omega^4 c_H^2 \right] \frac{I_m(\beta_1 a)}{I_m'(\beta_1 a)} \\ &\quad - \frac{k m a \omega^4 c^2 c_H^2}{(\omega^2 + k^2 c^2) \{ \omega^2 (c^2 + c_H^2) + k^2 c^2 c_H^2 \}^2} \left[\left(\frac{B_0}{B_1} \right)^2 (\omega^2 + k^2 c^2) + \frac{r}{2} \left\{ 1 + \left(\frac{B_2}{B_1} \right)^2 - \left(\frac{B_0}{B_1} \right)^2 \right\} \omega^2 \right], \\ R &= \frac{k m \beta_1 c_H^2}{a^2 (\omega^2 + k^2 c^2)^2 (\omega^2 + k^2 c_H^2)^2} \left[2 (\omega^2 + k^2 c^2) \{ \omega^2 (c^2 + c_H^2) + k^2 c^2 c_H^2 \} - \omega^4 c^2 (\beta_1^2 a^2 + m^2) \right] \frac{I_m(\beta_1 a)}{I_m'(\beta_1 a)} \\ &\quad + \frac{m \omega^2 c_H^2 \{ \omega^2 (c^2 + c_H^2) - k^2 c^2 c_H^2 \}}{k a c^2 (\omega^2 + k^2 c_H^2) \{ \omega^2 (c^2 + c_H^2) + k^2 c^2 c_H^2 \}}. \end{aligned}$$

It is convenient for the purpose of calculating the disturbance growth rate for the instability to express this dispersion relation in terms dimensionless variables. Thus we introduce the dimensionless variables:

$$\begin{aligned} ka &= X, \quad \beta_1 a = U, \quad \alpha a = A, \quad \frac{\omega a}{c} = W, \\ \frac{b}{a} &= A, \quad \frac{c}{c_H} = C, \quad \frac{B_0}{B_1} = b_i \quad \text{and} \quad \frac{B_2}{B_1} = b_e. \end{aligned} \quad (3.11)$$

Then equation (3.10) becomes

$$U \left[b_i^2 + \frac{r W^2 (1 + b_e^2 - b_i^2)}{2(X^2 + W^2)} \right] \frac{I_m(U)}{I_m'(U)} + AL = [1 + (m + b_e X)^2 F(X, AX)] [1 + AR], \quad (3.12)$$

where

$$U = \frac{(X^2 + W^2)(X^2 + C^2 W^2)}{X^2 + (C^2 + 1)W^2},$$

$$F(X, AX) = \frac{K_m(X) I_m'(AX) - I_m(X) K_m'(AX)}{X [K_m'(X) I_m'(AX) - I_m'(X) K_m'(AX)]},$$

$$\begin{aligned} L = & \frac{mU}{X(X^2+W^2)(X^2+C^2W^2)} \left[b_i^2 \{ W^2(X^2+W^2) + 2X^2(X^2+C^2W^2) \} \right. \\ & \left. + \frac{\gamma}{2} (1+b_e^2-b_i^2) W^4 \right] \frac{I_m(U)}{I_m'(U)} \\ & - \frac{mC^2XW^4}{(X^2+W^2)\{X^2+(C^2+1)W^2\}^2} \left[b_i^2(X^2+W^2) + \frac{\gamma}{2} (1+b_e^2-b_i^2) W^2 \right], \\ R = & \frac{mXU}{(X^2+W^2)^2(X^2+C^2W^2)^2} [2(X^2+W^2)\{X^2+(C^2+1)W^2\} - W^4C^2(m^2+U^2)] \frac{I_m(U)}{I_m'(U)} \\ & - \frac{mW^2\{X^2-(C^2+1)W^2\}}{X(X^2+C^2W^2)\{X^2+(C^2+1)W^2\}}. \end{aligned}$$

This is a generalization of the equation (3.12) of Tayler's paper⁴⁾: he used the sheet current approximation, so we get his equation by putting $A=0$ in our equation. Further, let W equal zero in our equation, then we get

$$b_i^2 = \frac{I_m'(X)}{XI_m(X)} \left[1 - \frac{2mA}{X} \left\{ 1 - \frac{XI_m(X)}{I_m'(X)} \right\} \right] [1 + (m+b_eX)^2 F(X, \lambda X)]. \tag{3.13}$$

This equation was first given by Kihara⁵⁾. Considering the fact that the sings of $1-XI_m(X)/I_m'(X)$ and $F(X, \lambda X)$ are positive and negative respectively, we can easily show that the modes with negative m are more difficult to stabilize than the modes with positive m . In addition to this, the kink disturbance ($m=\pm 1$) is most difficult to stabilize (see References 2), 4)), so we shall consider

only the mode with $m=-1$ in the following. In order to find the completely stable region, Kihara calculated the minimum values of b_i^2 needed for stability as a function of X for various values of λ using the model $A=0$ and $b_e=0$. Only for this model the mode with $m=-1$ coincides with the mode with $m=1$, and the results are shown graphically in Fig. 4 of his paper⁵⁾, which is reproduced in Fig. 1 of the present article.

Then taking b_i^2 as a parameter we calculate the growth rate W , as a function of X in the region of instability and determine the maximum value w of W for each b_i^2 . The results are shown in Fig. 2. In this and the following calculations the specific heat ratio γ is assumed to be 5/3. For $b_i^2=1$ the growth rate of an unstable plasma is infinite as it

Fig. 1. Stabilizing values of b_i^2 against X for the modes with $m=0$ and $m=1$ of the sheet current model with $b_e=0$.

Fig. 2. Curves for maximum growth rate w against b_i^2 for the unstable $m=1$ mode of the sheet current model.

should be since the inertia of the plasma vanishes.

Next we take into account the effects of the uniform volume current within the plasma column and the longitudinal magnetic flux outside the column. Recently Ogasawara⁷⁾ has investigated these effects on Kihara's work. We are now interested in the variation of the "critical" value of A and the corresponding maximum disturbance growth rate for the instability. For configurations $A=1/4$, $b_e=0$ and $A=0$, $b_e=1/10$, the critical values of A are 4.735 and 3.31 respectively (see Fig. 3). In each case, the maximum disturbance

growth rate for the instability is calculated and shown in Figs. 4 and 5.

Fig. 3. Stabilizing values of $b_i^2/1+b_e^2$ against X for the unstable $m=-1$ mode of models: $A=1/4$, $b_e=0$ and $A=0$ $b_e=1/10$.

Fig. 4. Curves for maximum growth rate w against b_i^2 for the unstable $m=-1$ mode of the model $A=1/4$, $b_e=0$, $A=4.735$ and its corresponding sheet current model. For comparison a curve for the sheet current model with $A=5$ is also drawn.

Fig. 5. Curve for maximum growth rate w against $b_i^2/1+b_e^2$ for the unstable $m=-1$ mode of the model $A=0$, $b_e=1/10$, $A=3.31$ and its corresponding sheet current model with $b_e=0$. For comparison a curve for the sheet current model with $A=5$ is also drawn.

§ 4. Conclusion

From the above investigation we obtain the following results.

- (1) The weak uniform current inside the plasma slightly contracts the stable region and at the same time makes the growth rate a little faster. This is reasonable because the effective radius of the plasma column may decrease on account of the uniform current.
- (2) The longitudinal magnetic flux outside the plasma column greatly contracts the stable region and at the same time makes the growth rate much faster.

In conclusion, the author wishes to express his sincere thanks to Prof. T. Kihara for his continual guidance and for his kindness in reading the original manuscript.

Note on the Forces on an Elliptic Cylinder moving in a Viscous Liquid at Small Reynolds Numbers

By Yorisaburo TAKAISI

*Department of Physics, Faculty of Education,
Ehime University, Matsuyama*

(Received April 5, 1958)

The steady flow of a viscous liquid past an elliptic cylinder at an arbitrary angle of attack is discussed on the basis of Reynolds number expansion using conformal transformation of the general solutions of Oseen's equation, which are expressed in integral forms. Thus the expansion formulae for the lift and drag coefficients are obtained to the second approximation, which are in perfect agreement with the results obtained recently by Hasimoto and also by Imai. Although it seems difficult to obtain general expressions for various formulae, such as formulae for the lift and drag, the procedure gives not only a practical method of solving Oseen's equation for the two-dimensional slow steady flow of an unbounded viscous liquid past an arbitrary cylindrical body, but also an effective method to study the wall-effect upon a cylinder of arbitrary shape moving in a viscous liquid bounded either by a plane wall or by parallel plane walls, provided the mapping function is known for the cylinder.

§ 1. Introduction

The steady flow of a viscous liquid past an elliptic cylinder has been discussed by several authors on the basis of Oseen's linearized equation of motion, since Harrison's study¹⁾ in 1924. Symmetric flow around an elliptic cylinder whose major axis is parallel or perpendicular to the undisturbed flow has been discussed by Tomotika and Aoi²⁾, and by Tomotika and Yosinobu³⁾ by somewhat a different analysis in each case, and thus approximate expansion formulae for the drag experienced by the cylinder have been obtained. The expansion formula of the same kind has also been obtained by Sidrak⁴⁾, but his formula is unfortunately incorrect.

On the other hand, asymmetric flow when an elliptic cylinder is set in the uniform flow at an arbitrary angle of incidence ϑ has been studied by Meksyn⁵⁾. But, Lewis⁶⁾ has shown that Meksyn's solution is erroneous on account of an infinite circulation, and has given a formal method to give a correct solution on the basis of modified Oseen's approximation due originally to Southwell and Squire⁷⁾. Explicit solution by his method, however, seems to be difficult. Recently Hasimoto⁸⁾ studied the same problem and obtained the expansion formulae for the lift and drag in powers of Reynolds number to the second

approximation. In the next year, Imai⁹⁾ developed a very elegant method applicable to a cylinder of arbitrary shape on the basis of Reynolds number expansion using complex variables, and obtained the expansion formulae for the lift and drag experienced by an inclined elliptic cylinder.

However, it should be mentioned that all these results except Imai's have been derived by the use of Mathieu functions.

In this note, a new approach is proposed to the same problem without recourse to the manipulation of Mathieu functions. The method is based on a kind of Reynolds number expansion using conformal transformation of the general solutions of Oseen's equation, which are expressed in integral forms. Although it seems difficult to obtain general expressions for various formulae, such as formulae for the lift and drag coefficients, the procedure gives a practical method of solving Oseen's equation for the two-dimensional slow steady flow of an unbounded viscous liquid past an arbitrary cylindrical body, provided the mapping function is known for the cylinder. Moreover, the present method is applicable to the study of the steady slow motion of a cylinder of any shape in a viscous liquid bounded by a plane wall or by two parallel plane walls. Thus, in a

quite recent paper¹⁰⁾, the present writer has made investigations on the wall-effect upon the forces experienced by an inclined elliptic cylinder in a viscous liquid.

§ 2. Fundamental Equation and its Solutions

Let us assume that a cylindrical obstacle is placed in a uniform flow of velocity U streaming parallel to the x -axis. Then, Oseen's linearized equation of motion for the two-dimensional steady flow of a viscous liquid can be written in the form

$$\psi=\psi_1+\psi_2,$$

(2.1)

$$\Delta\psi_1=0,$$

(2.2)

$$(\Delta-k^2)(e^{-kx}\psi_2)=0,$$

(2.3)

where ψ is the stream function for the perturbation and is connected with the components of the perturbation velocity as:

$$u=\partial\psi/\partial y,\quad v=-\partial\psi/\partial x,$$

(2.4)

and $k=U/2\nu$, ν is the kinematic viscosity of the liquid and Δ stands for $\partial^2/\partial x^2+\partial^2/\partial y^2$.

The appropriate solutions of (2.2) and (2.3) which satisfy the boundary conditions at infinity are given respectively by

$$\psi_1=A_0\ln r+B_0\theta+\sum_{n=1}^{\infty}r^{-n}(A_n\cos n\theta+B_n\sin n\theta),$$

(2.5)

$$\begin{aligned}\psi_2=a_0e^{kx}K_0(kr)+b_0\int_0^\theta kr\{K_1(kr)+K_0(kr)\cos\theta\}e^{k r\cos\theta}d\theta\\+e^{kx}\sum_{n=1}^{\infty}K_n(kr)(a_n\cos n\theta+b_n\sin n\theta),\end{aligned}$$

(2.6)

where $x=r\cos\theta$, $y=r\sin\theta$, and

$$b_0=-B_0,$$

(2.7)

$K_n(x)$ is the modified Bessel function of the second kind. The condition (2.7) ensures that the stream function $\psi=Uy+\psi$ is one-valued and continuous throughout the whole field of flow.

If we confine ourselves to the second order approximation for the lift and drag experienced by an elliptic cylinder, it suffices to take only the first six terms in (2.5) and (2.6) respectively. Then, as shown in our previous paper¹¹⁾, the conjugate complex velocities can be expressed in integral forms as:

$$w_1=u_1-iv_1=\frac{1}{2}\int_{-\infty}^{\infty}\left(\frac{y}{|y|}+\frac{\alpha}{|\alpha|}\right)\{(A_0-iB_0)+i\alpha(A_1+iB_1)+\alpha^2(A_2+iB_2)\}e^{i\alpha x-|\alpha||y|}d\alpha,$$

(2.8)

$$\begin{aligned}w_2=u_2-iv_2=\frac{1}{2}\int_{-\infty}^{\infty}\left[\left(\frac{y}{|y|}+\frac{\alpha}{\lambda}\right)\left\{-a_0+\frac{i(\alpha+ik)}{k}a_1+\frac{2\lambda^2-k^2}{k^2}a_2\right\}\right.\\+\left.\left(\frac{y}{|y|}+\frac{\lambda}{\alpha}\right)\left\{-ib_0-\frac{\alpha}{k}b_1+\frac{2i\alpha(\alpha+ik)}{k^2}b_2\right\}\right]e^{i\alpha x-\lambda|y|}d\alpha,\end{aligned}$$

(2.9)

where $\lambda=\sqrt{\alpha^2+2ika}$.

In the following analysis, we assume, for the sake of convenience, $y\geq 0$ in (2.8) and (2.9). It is easy to show, however, that the same results are obtained in case when $y<0$.

§ 3. Conformal Transformation of the Solutions of Oseen's Equation

By the transformation function

$$z=x+iy=e^{-i\theta}(Z+\sigma^2Z^{-1})$$

$(0\leq\sigma\leq 1),$

(3.1)*

the unit circle $Z=e^{i\omega}$ in the Z -plane is mapped onto an ellipse (Fig. 1), which is inclined at

* In a quite recent paper cited above¹⁰⁾, we have introduced elliptic coordinates ξ, η , related with x, y by the relation $x+iy=2ae^{-i\theta}\cosh(\xi+i\eta)$, instead of (3.1). As is well known, however, the two transformations are quite equivalent.

Fig. 1.

an angle ϑ with respect to the x -axis and whose semi-major and minor axes are respectively

$$a = 1 + \sigma^2, \quad b = 1 - \sigma^2. \quad (3.2)$$

Using obvious relations:

$$x = (1/2)(z + \bar{z}), \quad y = -(1/2)i(z - \bar{z}), \quad (3.3)$$

we have on the profile, that is, for $Z = e^{i\omega}$,

$$\begin{aligned} i\alpha x - \alpha y &= -\alpha e^{-i\vartheta} (e^{-i\zeta} - \sigma^2 e^{i\zeta}), \\ -i\alpha x - \alpha y &= -\alpha e^{i\vartheta} (e^{i\zeta} - \sigma^2 e^{-i\zeta}), \end{aligned} \quad (3.4)$$

where

$$\zeta = (1/2)\pi - \omega. \quad (3.5)$$

Inserting (3.4) into (2.8), and expanding the function $\exp(\alpha\sigma^2 e^{-i\vartheta+i\zeta})$ or $\exp(\alpha\sigma^2 e^{i\vartheta-i\zeta})$ in the integrands with respect to $e^{i\zeta}$, we obtain, on performing integrations,

$$w_1 = e^{i\zeta}(A_0 - iB_0)e^{i\vartheta} + e^{2i\zeta}(iA_1 - B_1)e^{2i\vartheta} + e^{3i\zeta}\{(A_0 - iB_0)\sigma^2 e^{i\vartheta} + 2(A_2 + iB_2)e^{3i\vartheta}\} + \dots \quad \text{on the profile.} \quad (3.6)$$

On the other hand, inserting (3.3) into (2.9), we have after some appropriate transformations

$$\begin{aligned} w_2 = \frac{1}{4} k\Omega [2(iJ_0 - J_1)a_0 + 2(J_0 - iJ_1)b_0 + \{(J_1 - J_{-1}) - i(J_0 - J_2)\}a_1 \\ + \{-(J_0 + J_2) + i(J_1 + J_{-1})\}b_1 + \{(J_{-1} + J_3) - i(J_2 + J_{-2})\}a_2 + \{(J_2 - J_{-2}) - i(J_{-1} - J_3)\}b_2] \end{aligned} \quad \text{on the profile,} \quad (3.7)$$

where

$$\Omega = \exp x \quad \text{on the profile,} \quad (3.8)$$

and

$$J_m = \int_{-\infty}^{\infty} \exp\{-k \cosh s + k\sigma^2 \cosh(s + 2i\zeta) + m(s + i\zeta + i\vartheta)\} ds \quad (m = 0, \pm 1, \pm 2, 3). \quad (3.9)$$

Making use of the relations:

$$\exp\{k\sigma^2 \cosh(s + 2i\zeta)\} = \sum_{n=-\infty}^{\infty} I_n(k\sigma^2) e^{n(s + 2i\zeta)}, \quad (3.10)$$

and

$$\int_{-\infty}^{\infty} e^{-k \cosh s + ns} ds = 2K_n(k), \quad (3.11)$$

where $I_n(x)$ is the modified Bessel function of the first kind, we obtain from (3.9)

$$J_m = 2e^{mi\vartheta} \sum_{n=-\infty}^{\infty} I_n(k\sigma^2) K_{m+n}(k) e^{(m+2n)i\zeta} \quad (3.12)$$

Further, after some calculations, we can express (3.8) in terms of $e^{i\zeta}$ as:

$$\Omega = \sum_{n=-\infty}^{\infty} \lambda_n I_n(k\Theta) e^{ni\zeta}, \quad (3.13)$$

where

$$\lambda_n = (-i)^n \{(e^{i\vartheta} + \sigma^2 e^{-i\vartheta}) / (e^{-i\vartheta} + \sigma^2 e^{i\vartheta})\}^{n/2}, \quad \Theta = \{1 + \sigma^4 + \sigma^2(e^{2i\vartheta} + e^{-2i\vartheta})\}^{1/2}. \quad (3.14)$$

If we introduce (3.12) and (3.13) into (3.7) retaining only terms involving $e^{mi\zeta}$ ($m = 0, \pm 1,$

$\pm 2, 3$), then we obtain series expressions in powers of k for w_2 on the profile, where k is assumed to be small.

§ 4. Determination of the Constants in the Stream Function

Since the conditions at infinity are already satisfied by (2.8) and (2.9), the integration constants A_n , B_n , a_n and b_n ($n=0, 1, 2$) have to be determined from the boundary condition:

$$w_1 + w_2 = -U \quad \text{on the profile.} \quad (4.1)$$

We may expand the constants in powers of k as:**

$$A_0 = k^{-1}A_{00} + kA_{01} + O(k^3), \quad (4.2)$$

$$B_0 = k^{-1}B_{00} + kB_{01} + O(k^3), \quad (4.3)$$

$$\left. \begin{aligned} A_1 &= A_{10} + k^2A_{11} + O(k^4), & B_1 &= B_{10} + k^2B_{11} + O(k^4), \\ A_2 &= k^{-1}A_{20} + kA_{21} + O(k^3), & B_2 &= k^{-1}B_{20} + kB_{21} + O(k^3), \end{aligned} \right\} \quad (4.4)$$

$$a_0 = k^{-1}a_{00} + ka_{01} + O(k^3), \quad (4.5)$$

$$b_0 = k^{-1}b_{00} + kb_{01} + O(k^3), \quad (4.6)$$

$$\left. \begin{aligned} a_1 &= k\alpha_{10} + k^3\alpha_{11} + O(k^5), & b_1 &= k\beta_{10} + k^3\beta_{11} + O(k^5), \\ a_2 &= k\alpha_{20} + k^3\alpha_{21} + O(k^5), & b_2 &= k\beta_{20} + k^3\beta_{21} + O(k^5). \end{aligned} \right\} \quad (4.7)$$

We insert the expressions for w_1 and w_2 obtained in § 3 together with (4.2) ~ (4.7) into (4.1), and we neglect all terms higher than k^3 . Then, on equating to zero the terms of the same powers of k in the coefficients of $e^{mi\vartheta}$ ($m=0, \pm 1, \pm 2, 3$) and separating the real and imaginary parts, we obtain linear algebraic equations for the unknown constants A_{00} , A_{01} , $\dots$, β_{21} .

Solving these equations successively, we obtain

$$\alpha_{00} = 2\sigma^2 U \sin 2\vartheta / D_1, \quad (4.8)$$

$$\beta_{00} = -2U \{2S - (1 + \sigma^2 \cos 2\vartheta)\} / D_1, \quad (4.9)$$

where

$$\left. \begin{aligned} D_1 &= 4S^2 - (1 + \sigma^4 + 2\sigma^2 \cos 2\vartheta), \\ S &= -\gamma - \ln(k/2), \quad \gamma = 0.5772 \dots \text{ (Euler's constant).} \end{aligned} \right\} \quad (4.10)$$

$$\begin{aligned} \alpha_{01} = & -(\alpha_{00}/D_1)[2S^3 + S^2(2 + \sigma^4) + (S/8)(17 - 14\sigma^4 + 3\sigma^8) + (1/16)(13 + 4\sigma^4 - 7\sigma^8) \\ & + \{4\sigma^2 S^3 + \sigma^6 S^2 + (S/6)(\sigma^2 - 3\sigma^6) + (1/48)(67\sigma^2 - 21\sigma^6 - 5\sigma^{10})\} \cos 2\vartheta \\ & - \{(S/12)(6\sigma^4 + \sigma^8) - (1/24)(5\sigma^4 + 2\sigma^8)\} \cos 4\vartheta + (1/16)\sigma^6 \cos 6\vartheta] \\ & + (\beta_{00}/D_1)[\{\sigma^2 S^2 + (1/3)(\sigma^2 + 3\sigma^6) + (1/48)(11\sigma^2 - 3\sigma^6 - 5\sigma^{10})\} \sin 2\vartheta \\ & + \{(S/12)(3\sigma^4 - \sigma^8) - (1/12)(\sigma^4 - \sigma^8)\} \sin 4\vartheta + (1/16)\sigma^6 \sin 6\vartheta], \end{aligned} \quad (4.11)$$

$$\begin{aligned} \beta_{01} = & (\alpha_{00}/D_1)[\{4\sigma^2 S^3 - S^2(2\sigma^2 - \sigma^6) + (S/3)(4\sigma^2 - 6\sigma^6) + (1/48)(31\sigma^2 + 21\sigma^6 - \sigma^{10})\} \sin 2\vartheta \\ & - \{(S/12)(9\sigma^4 + \sigma^8) - (1/6)(2\sigma^4 + \sigma^8)\} \sin 4\vartheta + (1/16)\sigma^6 \sin 6\vartheta] \\ & - (\beta_{00}/D_1)[2S^3 + \sigma^4 S^2 + (S/8)(1 - 10\sigma^4 - \sigma^8) - (1/16)(5 - 8\sigma^4 - 3\sigma^8) \\ & - \{\sigma^2 S^2 + (S/6)(7\sigma^2 + 3\sigma^6) - (1/48)(\sigma^2 + 21\sigma^6 + \sigma^{10})\} \cos 2\vartheta \\ & + (1/24)(2\sigma^8 S + 5\sigma^4 - 4\sigma^8) \cos 4\vartheta - (1/16)\sigma^6 \cos 6\vartheta], \end{aligned} \quad (4.12)$$

** We can obtain the same results even if we use other expansions, for instance $A_n = k^{-1}A_{n0} + A_{n1} + kA_{n2} + k^2A_{n3} + O(k^3)$ etc. ($n=0, 1, 2$).

$$\begin{aligned}
 \alpha_{10} &= -(\alpha_{00}/4)\{4S-1+(8\sigma^2S-4\sigma^2)\cos 2\vartheta-\sigma^4\cos 4\vartheta\}-(\beta_{00}/4)\sigma^4\sin 4\vartheta, \\

 &\quad -(\beta_{00}/16)(4\sigma^4S-3\sigma^4+\sigma^8)\sin 4\vartheta, \\
 B_{21} &= -2\beta_{21}-(\alpha_{00}/16)[\{(16\sigma^2-8\sigma^6)S-8\sigma^2+2\sigma^6\}\sin 2\vartheta+(4\sigma^4S-5\sigma^4+\sigma^8)\sin 4\vartheta] \\
 &\quad +(\beta_{00}/16)\{(4-4\sigma^4)S-5\sigma^4+4\sigma^8-(4\sigma^4S-3\sigma^4+\sigma^8)\cos 4\vartheta\}.
 \end{aligned} \tag{4.16}^{***}$$

From (4.3), (4.6) and (4.15), we obtain the relation $b_0 = -B_0$ independently of (2.7), which ensures that the stream function ψ is one-valued and continuous throughout the field of flow.

§ 5. Formulae for the Lift and Drag Coefficients

As is well known, the lift L and drag D experienced by the cylinder under discussion per its unit length can be expressed as:

$$L = 2\pi\rho UA_0, \tag{5.1}$$

*** To this order of approximation, the constants A_{11} and α_{11} , B_{11} and β_{11} cannot be obtained separately. But, we have no difficulty in discussing the lift and drag experienced by the elliptic cylinder to the second order approximation.

$$D = 2\pi\rho U B_0, \quad (5.2)$$

where ρ is the density of the liquid concerned.

In order to define the Reynolds number R , let us take the major axis, $2a$, of the elliptic cylinder as the representative length. Thus, remembering (3.2),

$$R = 2aU/\nu = 4(1 + \sigma^2)k. \quad (5.3)$$

Making use of (5.1), (5.2) and the integration constants obtained in § 4, we have, after some reductions, for the lift and drag coefficients C_L and C_D correct to the order of R^2 as:

$$\begin{aligned} C_L &= L/(1/2 \cdot \rho U^2 \cdot 2a) \\ &= \frac{16\pi}{R} \frac{\sigma^2 \sin 2\vartheta}{D_1} \left\{ 1 - \frac{R^2}{16(1 + \sigma^2)^2} \left[2S^2 + \frac{S}{2} (1 + \sigma^4 + 2\sigma^2 \cos 2\vartheta) + \frac{1}{6} \{ 4 - (3\sigma^2 - \sigma^6) \cos 2\vartheta \} \right. \right. \\ &\quad + \frac{1}{D_1} \left[\frac{S}{4} (13 - 4\sigma^4 + \sigma^8 + 8\sigma^2 \cos 2\vartheta + 2\sigma^4 \cos 4\vartheta) \right. \\ &\quad \left. \left. + \frac{1}{6} \{ 6 + 9\sigma^4 + 3\sigma^8 + (13\sigma^2 + 6\sigma^6 + \sigma^{10}) \cos 2\vartheta + (\sigma^4 + \sigma^8) \cos 4\vartheta \} \right] \right\}, \quad (5.4) \end{aligned}$$

$$\begin{aligned} C_D &= D/(1/2 \cdot \rho U^2 \cdot 2a) \\ &= \frac{16\pi}{R} \frac{1}{D_1} \left\{ 2S - (1 + \sigma^2 \cos 2\vartheta) - \frac{R^2}{16(1 + \sigma^2)^2} \left[S^2 - \frac{S}{2} (1 - 2\sigma^4 + 2\sigma^2 \cos 2\vartheta + \sigma^4 \cos 4\vartheta) \right. \right. \\ &\quad + \frac{1}{48} \{ 15 - 36\sigma^4 + 3\sigma^8 + (8\sigma^2 - 24\sigma^6) \cos 2\vartheta + (18\sigma^4 - 4\sigma^8) \cos 4\vartheta \} \\ &\quad - \frac{1}{D_1} \left[\frac{S}{12} \{ 15 - 36\sigma^4 - 9\sigma^8 + (11\sigma^2 - 33\sigma^6 - \sigma^{10}) \cos 2\vartheta + (14\sigma^4 - 4\sigma^8) \cos 4\vartheta + 3\sigma^6 \cos 6\vartheta \} \right. \\ &\quad \left. \left. - \frac{1}{24} \{ 15 - 11\sigma^4 - 33\sigma^8 + \sigma^{12} + (26\sigma^2 - 56\sigma^6 - 12\sigma^{10}) \cos 2\vartheta \right. \right. \\ &\quad \left. \left. \left. - (10\sigma^8 + 2\sigma^{12}) \cos 4\vartheta + (4\sigma^6 - 2\sigma^{10}) \cos 6\vartheta \} \right] \right\}, \quad (5.5) \end{aligned}$$

which are in perfect agreement with the results obtained by Hasimoto and also by Imai.

§ 6. Summary

The steady flow of a viscous liquid past an elliptic cylinder at an arbitrary angle of incidence is discussed on the basis of Reynolds number expansion using conformal transformation of the general solutions of Oseen's equation, which are expressed in integral forms. Thus, the expansion formulae for the lift and drag coefficients are obtained to the second approximation, which are in perfect agreement with the results obtained recently by Hasimoto and also by Imai.

In conclusion, the writer wishes to express his cordial thanks to Professor S. Tomotika for his continual guidance and also for his kind inspection of the manuscript. The writer's thanks are also due to the Ministry of Education for a grant-in-aid for fundamental scientific research.

Adsorption of Water Vapour on Lead Borosilicate Glass in Vacuum

By Yutaka TUZI and Hiroaki OKAMOTO

Matsuda Research Laboratory, Tokyo Shibaura Electric Co., Ltd.
Kawasaki

(Received April 3, 1958)

The adsorption of water vapour on lead borosilicate glass was studied in the pressure region 10^{-5} – 10^{-6} mmHg using the modified flashing technique.

The adsorption is composed of at least two parts, the physical adsorption and the activated adsorption. The amount of the physical adsorption at 1×10^{-6} mmHg, $0 \sim 50^\circ\text{C}$ was $0.1 \sim 0.4\%$ of a monolayer, and the heat of adsorption was 11 Kcal/mole. The activation energy of adsorption of the activated adsorption was *ca.* 9 Kcal/mole, and the activation energy of desorption was $13 \sim 40$ Kcal/mole.

§ 1. Introduction

In the preceding paper¹⁾, we tried a preliminary study of adsorption of water vapour on glass, copper, nickel and alumina ceramic *in vacuo* using the time lag method of molecular flow. The results suggested that the adsorption is not a simple physical adsorption. Hence we tried a more quantitative measurement of the adsorption of water vapour on lead borosilicate glass in the pressure region of 10^{-6} mmHg using the modified flashing technique^{2), 3)}.

§ 2. Apparatus and Sample

The essential part of this apparatus is a Beeck's calorimeter type cell⁴⁾ (B) shown in Fig. 1. The lower part of the inner glass

Fig. 1. Schematic diagram of experimental apparatus.

tube of the cell (*ca.* $18 \text{ mm}\phi \times 100 \text{ mm}$) was made very thin in order to reduce the heat capacity. The space J between the inner and

the outer walls was evacuated for heat insulation. About 4 m (*ca.* 400 ohms) of $0.07 \text{ mm}\phi$ tungsten wire was wound over the tube B, which served in two ways, as a resistance thermometer and heating element. The Pirani gauge P, which was read on a $3 \times 10^{-6} \text{ V/div.}$ galvanometer, was muffled with a thick copper tube and was immersed in a water bath. A sensitivity of $5 \times 10^{-8} \text{ mmHg/div.}$ in the range $10^{-5} \sim 10^{-6}$ mmHg could be attained in this way. The calibration of the gauge which we carried out before each experiment against the ion gauge (I) proved that the reading of the former was fairly reproducible. C_1 and C_2 are greaseless stopcocks, and L_1 is a capillary tube of known conductance G (5.4 cc/sec for H_2O vapour at 25°C). The whole apparatus was constructed with lead borosilicate glass.

During the evacuation, the apparatus was baked at 450°C for 2–3 hours while the trap T_1 was immersed in liquid oxygen. The pressure was then reduced to $1 \times 10^{-8} \sim 1 \times 10^{-9}$ mmHg*.

The adsorbent was a Nonex type lead borosilicate glass powder. The glass, originally in the form of a tube, was first heated to its working temperature by $\text{H}_2\text{--O}_2$ flame, annealed in an electric furnace, and then crushed to powder finer than 200 mesh and washed in acetone. The glass powder was spread on the inner wall of B. The real surface area of the adsorbent was measured by the B.E.T. method using ethylene as the adsorbate^{5), 6)}, and was

* Measured by the Bayard-Alpert gauge.

found to be 394 cm².

§ 3. Experimental Method

At the beginning of the experiment, B is kept at a high temperature T_1 (ca. 200°C) in order to avoid the adsorption, and the pressure of H₂O vapour is kept at a constant value p_0 . In order to keep the pressure of H₂O at any desired value down to 10⁻⁵ mmHg during the experiment, the flow method was used. H₂O vaporized from thoroughly evacuated distilled water W (Fig. 1), was allowed to flow (from reservoir T_2) through a capillary leak L_2 and a cook C_2 to the pumping system.

After the adsorption on the walls of the apparatus reached equilibrium, opening and closing C_1 showed no change in the indication of the Pirani gauge. When this equilibrium state was reached, C_1 was closed, the heating current of B was cut off, and B was cooled down to a temperature T_2 (e.g. 1°C). The pressure slowly reduces to a minimum, and again rises to the initial value as is illustrated in Fig. 6. The amount of adsorption can be estimated from this figure. For brevity, we call this method the "cooling method".

There is another procedure of estimating the amount of adsorption on the sample, which we named the "heating method". If B is suddenly reheated to a high temperature T_3 after a time interval Δt after cutting off the heating current, the pressure will abruptly rise to a maximum as is shown in Fig. 2*.

Fig. 2. Pressure variation in heating method.

* Throughout the experiments, the adsorbed H₂O can be regarded to be desorbed as H₂O (cf. ref. (8), (1)).

Theoretically, the amount of adsorption can be obtained from the area enclosed between the curve H and the ground line D of Fig. 2. This is however, impracticable, because for this purpose we have to extrapolate the curve H to $t = \infty$. In order to avoid the ambiguities accompanying this extrapolation, we examined the time constant of the pressure decrease and adopted the method of calculation based on the time constant which is to be given later.

As is described in § 4, the heating method estimates the amount of the physical adsorption exclusively, whereas the cooling method estimates the total adsorption. We tried both, and compared the results.

§ 4. Results

4.1. Results obtained by the Heating Method

It was found that Δp , the pressure rise caused by reheating (see Fig. 2), depended not only on p_0 and T_2 but also on some other factors. Experiments proved that

- (1) $\Delta p = 0$ if $\Delta t < 2$ min.;
- (2) Δp increases with Δt in the range 2 min. $< \Delta t < 20$ min.;
- (3) Δp shows no variation with Δt if $\Delta t > 20$ min.; and
- (4) Δp increases with T_3 until it reaches ca. 150°C. At higher temperatures Δp seems to be almost constant.

The Δt -dependence ((1), (2), (3)) can be explained by the variation of the temperature of the sample during the cooling period (see Fig. 3). It can be estimated that (1) corres-

Fig. 3. Δp and sample temperature versus cooling time.

ponds to the fact that practically no adsorption takes place above 50°C.

It was also noticed that the desorption occurred not only when B was reheated but

also when it was evacuated at T_2 for 20~30 minutes. Hence the heating method seems to do with the reversible or physical adsorption.

A typical pressure variation is given in Fig. 2, in which the experimental conditions were as follows: $p_0 = 3.4 \times 10^{-6}$ mmHg, $T_2 = 1^\circ\text{C}$ and $\Delta t = 19.5$ min.

As is seen in Fig. 2, the reduction of pressure of the desorbed H_2O vapour is very slow. The time constant is much greater than the value calculated from the volume V enclosed by C_1 and the conductance of L_1 (32.5 sec). This was supposed to be due to the desorption of the adsorbed H_2O from the walls of the apparatus. In order to check this point, we filled V with H_2O vapour of low pressure (B being kept at T_1), closed C_1 , evacuated H_2O through L_1 , and measured the pressure decrease. The pressure decrease curves in both cases were quite similar, as is seen in Fig. 4. It seems that the time constant τ is

Fig. 4. Comparison of pressure variation in V .

composed of two parts, τ_1 , which is of the order of the "calculated" value, and τ_2 , which is about ten times as long as τ_1 . The latter represents the desorption effect.

Now the amount of adsorption on the sample, or the amount of H_2O evacuated after the "reheating", v_h , could be regarded to be composed of two parts, v_f and v_i . The de-

crease of pressure of v_f and v_i , p_f and p_i , are characterized by the time constant τ_1 and τ_2 respectively. There are some confusing factors on τ_1 . τ_2 represents, however, the desorption effect of H_2O from the walls of the apparatus, and can be calculated in the following way. The amount of H_2O adsorbed on the walls of the apparatus, v_w , depends on p_f and p_i . The reduction of p_f is, however, very rapid, and p_f will become negligibly small against p_i shortly after the reheating. Hence, during the greater part of the pressure reduction process of p_i , H_2O desorbs from the walls of the apparatus, and v_w can be assumed to be proportional to p_i :

$$v_w = ap_i, \quad (1)$$

where a is a constant.

As the rate of reduction of p_i is slow, we may assume

$$\frac{dv_w}{dt} = a \frac{dp_i}{dt}. \quad (2)$$

From this, it follows that

$$V \frac{dp_i}{dt} = -a \frac{dp_i}{dt} - Gp_i. \quad (3)$$

If $p_i = p_{i0}$ at $t = 0$,

$$p_i = p_{i0} \exp\left(-\frac{G}{V+a}t\right) = p_{i0} \exp\left(-\frac{t}{\tau_2}\right). \quad (4)$$

Thus

$$\tau_2 = \frac{V+a}{G}. \quad (5)$$

The amount of v_h can be calculated in the following way (cf. § 3). Assuming $p_f = p_{f0}$ at $t = 0$, we obtain

$$p_f = p_{f0} \exp\left(-\frac{t}{\tau_1}\right). \quad (6)$$

Thus

$$v_f = \int_0^\infty Gp_f dt = \int_0^\infty Gp_{f0} \exp\left(-\frac{t}{\tau_1}\right) dt = p_{f0}G\tau_1, \quad (7)$$

$$v_i = \int_0^\infty Gp_i dt = \int_0^\infty Gp_{i0} \exp\left(-\frac{t}{\tau_2}\right) dt = p_{i0}G\tau_2, \quad (8)$$

and

$$v_h = v_f + v_i = p_{f0}G\tau_1 + p_{i0}G\tau_2. \quad (9)$$

For the numerical evaluation, p_{f0} , p_{i0} , τ_1 and τ_2 were graphically determined from Fig. 4. The calculated amounts of adsorption under various conditions are shown in Fig. 5. As the number of H_2O molecules necessary to

Fig. 5. Amount of H₂O adsorbed versus temperature.

form a monolayer is $9.52 \times 10^{14}/\text{cm}^2$, the amount of physical adsorption at $p_0 = 1 \times 10^{-6}$ mmHg and at $0 \sim 50^\circ\text{C}$ is $0.4 \sim 0.1\%$ of a monolayer.

4.2. Results obtained by the Cooling Method

Before we begin to cool B, we expose the apparatus to a constant H₂O pressure, p_0 , so that the adsorbed layer of H₂O on the walls of the apparatus are in equilibrium with p_0 . Starting from this condition if we begin to

cool B, the pressure in V, p_c , will be reduced, and the H₂O molecules will be supplied from the walls and through L₁. The rate of desorption can be assumed to be similar with Eq. (2), because there is no portion of H₂O corresponding to p_f and the variation of p_c is very slow.

α the rate of adsorption on B, will depend on the amount adsorbed on B. In order to simplify the calculation, it is desirable to obtain the variation of p_c during a short period in which α can be regarded as a constant. This we achieved by opening and closing C₁ intermittently. Hence the experimental curve is composed of many steps. The zero point drift of the Pirani gauge reading can also be checked conveniently by this procedure.

A typical pressure variation in the cooling method is illustrated in Fig. 6. The experimental conditions were; $p_0 = 8.4 \times 10^{-6}$ mmHg, $T_1 = 350^\circ \sim 380^\circ\text{C}$ and $T_2 = 28.4^\circ\text{C}$.

Now that one can assume that α is a constant during a step, the variation of p_c in V during that step will be given by

$$V \frac{dp_c}{dt} = -a \frac{dp_c}{dt} + (p_0 - p_c)G - p_c \alpha. \quad (10)$$

Assuming $p_c = p_0$ at $t = 0$, we obtain

$$p_c = \frac{1}{G + \alpha} \left\{ \alpha p_0 \exp\left(-\frac{G + \alpha}{V + a} t\right) + G p_0 \right\}. \quad (11)$$

Fig. 6. Pressure variation in cooling method.

Hence, the amount of adsorption v_c becomes

$$v_c = \int_0^t \alpha p_c dt = \frac{1}{G + \alpha} \left[\alpha^2 p_0 \left\{ -\frac{V + a}{G + \alpha} \right. \right. \\ \left. \left. \times \exp\left(-\frac{G + \alpha}{V + a} t\right) + G \alpha p_0 t \right\} \right]. \quad (12)$$

In this equation, a can be determined by the heating method. α can be evaluated using

Eq. (11), substituting the numerical values for various combinations of p_0 , p_0 and t . The results are illustrated in Fig. 7. Thus the amount of adsorption v_c can be determined from Eq. (12).

4.3. Comparison of the Results obtained by Both Methods

Fig. 7. Rate of activated adsorption vasus amount of H₂O adsorbed.

If we continue the observation in the cooling method for a long time, the adsorption on the specimen as well as on the walls will reach equilibrium with p_0 . This happens to be the condition needed for the commencement of the heating method. Thus we can obtain both v_c and v_h in a series of experiments. v_c and the corresponding v_h obtained in this way are given in Table I.

The difference of v_c and v_h suggests the existence of the activated adsorption of H₂O on glass surface. In fact, the activated desorption was observed by heating the sample which had adsorbed H₂O to a high temperature (higher than the heating temperature of the heating method). The rate of desorption thus obtained as a function of temperature is given in Fig. 8.

3	7.4	26	65	4.9	1.35

Fig. 8. Rate of desorption versus temperature.

§ 5. Discussion

The heat of adsorption q can be calculated

from Fig. 5, using the Clausius-Clapeyron equation

$$q=R\left(\frac{d \ln p_0}{d(1/T_2)}\right)_{v_h}, \tag{13}$$

where R , represents the gas constant. The calculated mean value of the heat of the adsorption was found to be 11 Kcal/mole. It is believed that the adsorption detected by the heating method is a mobile physical adsorption, because the heat of adsorption is nearly equal to the heat of vaporization of water (10.43 Kcal/mole at 30°C)(cf. § 4.1).

In the cooling method, the activation energies of the activated adsorption and desorption can be calculated in the following way⁷⁾. The rate of adsorption per unit area depends on four factors:

(1) The rate of collision of molecules on the surface, which, on unit area at a pressure p is equal to $p/\sqrt{2mkT}$, where m , k and T represent the mass of the gas molecule, the Boltzmann constant and the absolute tempera-

ture respectively.

(2) The condensation factor σ .

(3) The activation energy E .

(4) The probability for a molecule to strike an available site. Since this probability usually depends on the fraction of the surface covered, θ , it is designated by $f(\theta)$.

If A represents the surface area of the sample, the rate of adsorption, α/A , is given by

$$\frac{\alpha}{A} = \frac{\sigma p}{\sqrt{2\pi mkT}} f(\theta) \exp\left(-\frac{E}{RT}\right). \quad (14)$$

Now, in the low pressure region, we may assume with good approximation $\sigma=1$, and $f(\theta)=1$. Hence the activation energy E can be evaluated using Eq. (14), if we assume an appropriate value for α . This was obtained in Fig. 7. There are some confusing factors, however, in the present case. We want the rate of adsorption, α , for the *activated* adsorption, while the values of α in Fig. 7 do not necessarily give what we want. Considering the experimental conditions, it would be most appropriate to assume $\alpha=2\text{cc/sec}$ for the activated adsorption. Thus we arrive at $E=9\text{ Kcal/mole}$.

The rate of desorption similarly depends on three factors:

(1) The number of sites, $f(\theta)'$, from which desorption is possible.

(2) The activation energy of desorption E' .

(3) The rate constant K' .

The rate of desorption, u' , is then

$$u' = K' f(\theta)' \exp\left(-\frac{E'}{RT}\right). \quad (15)$$

Although, K' , $f(\theta)'$ and E' vary with θ in general, these factors can be assumed to be constant in our case, because the interaction between the adsorbed molecules are negligible for the density of the adsorbed molecules is very low. We calculated E' from the gradient of the curve in Fig. 8, and obtained $E'=13\sim40\text{ Kcal/mole}$. The greater value of E' , estimated from the upper part of the curve, is nearly equal to the activation energy of diffusion of H_2O through the Nonex glass⁸⁾ (38 Kcal/mole). Therefore, the activated ad-

sorption might have something to do with diffusion.

The experiments were repeated several times in the period of two months. The results were quite reproducible. It is believed consequently that the surface of the sample glass has experienced practically no change by the repeated adsorption and desorption of H_2O in the pressure range $10^{-5}\sim10^{-6}\text{ mmHg}$.

§ 6. Conclusion

The following points can be concluded for the adsorption of water vapour on lead borosilicate glass *in vacuo*: (1) The adsorption is composed of at least two parts, the physical adsorption and the activated adsorption. (2) The amount of physical adsorption at $p_0=1\times10^{-6}\text{ mmHg}$ and $0\sim50^\circ\text{C}$ is $0.4\sim0.1\%$ of a monolayer (Fig. 5). (3) The heat of physical adsorption is 11 Kcal/mole . (4) The physically adsorbed molecules are desorbed by heating at $100\sim150^\circ\text{C}$ or by prolonged evacuation at room temperatures. (5) The activation energy of the activated adsorption is *ca.* 9 Kcal/mole . (6) The activation energy of desorption of the activated adsorption is $13\sim40\text{ Kcal/mole}$.

The authors are indebted to Prof. K. Kinoshita for his kindness in reading the manuscript and discussions, to Mr. C. Hayashi and Prof. G. Tominaga for their discussions.

Variation of the Optical Properties of Iron at Transition Temperature

By Akira KINBARA

Department of Applied Physics University of Tokyo, Tokyo, Japan

(Received May 13, 1958)

The light emitted from a smooth plane surface of a heated metallic plate is polarized, because the emissivities of the component polarized in parallel with the emitting plane and that polarized perpendicular to it are different from each other. These emissivities are denoted by E_p and E_s , respectively.

The degree of polarization E_s/E_p depends on the angle of emission.

To study this, the emitted light from metallic surfaces was divided into the parallel and the perpendicular component by a Rochon prism and each component was led separately to two photomultipliers as shown in Fig. 1. The ratio of the

Fig. 1. The schematic illustration of the experimental arrangement.

two photocurrents was measured every 10 degree of the emitting angle φ .

An iron plate was used as the sample as it was expected that the relation $E_s/E_p - \varphi$ varies according as the temperature is above or below the transition point, 910°C.

The surface of the sample was polished by emery paper of 500 meshes. The sample plate (2 cm×4 cm) which could be rotated around a vertical rod was placed in a vacuum vessel and heated by radiation from an incandescent tungsten filament which was located just behind the plate. To avoid oxidation of the surface, the vessel was filled with hydrogen (above 1 mmHg).

The relation between E_s/E_p and φ was observed at various temperatures, which were measured by an optical pyrometer. Although optical filters were not used in this experiment, multiplying the spec-

tral sensitivity of the photomultiplier 931 Å by the spectral energy distribution, it was found that only the light in the vicinity of about 6000 Å was detected.

The experimental results (Fig. 2) show that, only when the temperature is near 910°C, $E_s/E_p - \varphi$ curve takes a special form, i.e., has a maximum. It means that iron has special bulk or surface properties near the transition temperature.

Fig. 2. E_s/E_p as a function of φ .

Fig. 3. n and k as a function of temperature.

Now according to the classical theory of electromagnetism, the relation between E_s/E_p and φ is given as follows¹⁾,

$$E_s/E_p = \cos^2 \varphi - \{\sin^2 \varphi (-\cos 2\varphi + 2n \cos \varphi) / (n^2 + k^2)\}$$

where n is the refractive index and k the extinction coefficient.

At each temperature a pair of n and k was determined so that the equation might fit to corresponding $E_s/E_p - \varphi$ curve. n and k thus obtained are given in Fig. 3.

It shows that n and k decrease remarkably only in the vicinity of the transition temperature, while they are approximately constant in both states of b.c.c. and f.c.c..

If the Drude's theory can be applied in this case, this fact corresponds to the decrease of the electric conductivity near the transition point, but as to this point, farther investigations are required.

Electrical Conductivity in N-Type InSb Under Strong Electric Field

By Yasuo KANAI

Electrical Communication Laboratory,
Musashinoshi, Tokyo

(Received June 6, 1958)

Under strong electric field, the conducting carriers in solids obtain sufficient energy from field. Hence, even when the field is not so strong as the ionization of carriers sets in, the distribution function for carriers fairly deviates from the form for thermal equilibrium state. In this case the carriers are called as being "hot",¹⁾ and the Ohm's law ceases to be valid. This hot electron phenomena were investigated a few years ago; experimental studies were made by Ryder²⁾ for Ge and Si crystals and theoretical considerations for non-polar semiconductors were made by Shockley¹⁾ and by Yamashita and Watanabe³⁾. Following the theoretical calculations, the critical field E_c , where the current-voltage characteristic began to deviate from Ohm's law, was given by the next formula;

$$\mu_0 E_c (\equiv v_{ac}) = 1.51 v_s$$

where μ_0 : the drift mobility under weak electric field

v_s : the averaged value of sound velocity in the crystal

v_{ac} : the drift velocity of carriers at E_c .

(The fact was that the experimental values of E_c were 2-5 times larger than the theoretical estimation, and this discrepancy was studied theoretically by Shibuya⁴⁾.) Above this critical field, drift velocity, and hence the current density, became proportional to $E^{1/2}$. At higher electric field, they became independent to E , and were followed by the occurrence of carrier ionization.

As is well known, the electron mobility in InSb is rather large. Hence we can expect that, as in the case of Ge and Si, if the interaction with the acoustic modes of lattice vibration is the main process of energy loss for electrons in InSb, E_c will be rather low in this material. For instance, putting the value of v_s and μ_0 as 4×10^6 cm/sec.⁵⁾ and 1×10^5 cm²/volt sec. respectively, we can expect about 6 volts/cm as the value of E_c . (Considering the case of Ge and Si, we can also expect about 10-30 volts/cm as the value of E_c for electrons in InSb.)

The current-voltage characteristics of *n*-type InSb single crystals were measured under pulsed strong electric field. A typical example of our results at 90°K is shown in Fig. 1. The sample had the following character at 90°K; resistivity (ρ)= 2.41×10^{-2} ohm-cm, and Hall coefficient (R)= -4.23×10^3 cm³/

Fig. 1. Current-voltage characteristic and Hall coefficient of a *n*-type InSb single crystal at 90°K.

coul. (Putting the value of the effective mass of electron in InSb as $0.013 m_0$,⁶⁾ the degenerate temperature of this crystal was about 50°K.) Fig. 1 shows that there is no deviation from Ohm's law near the expected field strength, but at rather high field, about 2×10^3 volts/cm, the deviation sets in. It also shows that the current density increases very rapidly with increasing E above 2×10^3 volts/cm.

To decide whether the deviation from Ohm's law at about 2×10^3 volts/cm was caused by the hot electrons in InSb or caused by the carrier ionization process from the full band, we measured the Hall effect in the same region of electric field. (As the donor impurities in InSb were fully ionized at 90°K, the ionization process from the impurity states would not occur at all). The Hall coefficient of the same sample is also shown in Fig. 1. From the behaviour of R we can believe that the cause of the deviation from Ohm's law is the carrier ionization process from the full band.

From our data shown in Fig. 1, the following results will be drawn.

- a) The main process of energy loss of electrons in InSb is not the interaction with the acoustic modes of vibration, but will be the interaction with the optical modes. This result is consistent with the Ehrenreich's calculation⁷⁾.
- b) When the drift velocity of an electron in InSb reaches the value of about 2×10^7 cm/sec, the carrier ionization process sets in.

Further investigations are now in progress and the results will be published in this Journal.

Low Temperature Anomaly in the Proton Resonance of Some Nickel Salts

By Pil Hyon KIM

Department of Physics,
Tokyo Metropolitan University, Tokyo

and

Tadashi SUGAWARA

The Research Institute for Iron,
Steel and Other Metals,
Tohoku University, Sendai

(Received June 2, 1958)

Recently, it has been shown that the deviation from the Curie-Weiss law observed in some nickel salts can be explained as due to the Stark splitting of the ground state of Ni^{2+} 1).

In connection with this, a study was made of the shift and the spin-lattice relaxation time of the proton magnetic resonance in some hydrated and ammoniated salts of nickel.

In single crystals of $NiSiF_6 \cdot 6H_2O$, $NiK_2(SO_4)_2 \cdot 6H_2O$ and $Ni(BrO_3)_2 \cdot 6H_2O$, the proton lines were observable down to $1.4^\circ K$, the lowest temperature attainable with our cryostat; while, in powders and single crystals of $Ni(NH_3)_6Cl_2$, $Ni(NH_3)_6(ClO_4)_2$ and $NiCl_2 \cdot 6H_2O$, the lines disappeared at a definite temperature characteristic of each salt. cf. Table I.

Table I. The temperature of line disappearance.

Compound	$Ni(NH_3)_6Cl_2$	$Ni(NH_3)_6(ClO_4)_2$	$NiCl_2 \cdot 6H_2O$
T(dis.) ($^\circ K$)	1.6	~ 7	8

The proton line of these salts is expected to show a shift proportional to the mean magnetic moment of Ni^{2+} ion or to the susceptibility of the salt.

This was the case in most of the salts studied. In Fig. 1, as an example, the shift and the susceptibility of $Ni(NH_3)_6Cl_2$ (powder)²⁾ are plotted against temperature.

However, the circumstances were quite different in $NiCl_2 \cdot 6H_2O$. In powder and single crystal samples of this salt, the shift showed quite different temperature dependency as compared with the sus-

ceptibility¹⁾ as shown in Fig. 2.

According to Moriya³⁾, the spin-lattice relaxation time of protons in a salt of which the spin degeneracy is completely lifted by the crystalline electric field is expected to increase exponentially below the temperature comparable to an interval of the splitting of lowest spin levels. In contradiction to this, the T_1 values of the above salts were shorter than 10^{-3} sec. down to the temperature below which the proton line could not be observed.

Fig. 1. The shift in 2000 oe. and the susceptibility in powdered $Ni(NH_3)_6Cl_2$.

Fig. 2. A comparison of the shift in 2000 oe. and the susceptibility in powdered $NiCl_2 \cdot 6H_2O$.

It is worth noticing that the paramagnetic resonance has not been observed in the salts in which the proton line disappeared at low temperature⁴⁾.

It seems interesting to extend this work to the salts of Fe^{2+} and Cr^{2+} having zero field splitting like Ni^{2+} .

In conclusion one (P.H.K.) of the authors wishes to express his thanks to Prof. K. Kido and Prof. E. Kanda for their continued encouragements throughout this work.

A New Compound in Au-Pb Alloy System

By Yoshibumi FUJIKI, Ryōji SUGANUMA
and Toshiho YOSHIDA
*Physical Institute, Kyōto
Prefectural Medical College*
(Received June 9, 1958)

In the course of our electron diffraction study on vacuum evaporated metal films, a new compound in Pb-rich side of Au-Pb alloy system was found and was also confirmed by X-ray diffraction and metallographic investigations with bulk specimens.

In this alloy system, two intermetallic compounds, Au_3Pb and $AuPb_2$, have already been known, and from our electron diffraction study, it is known that the composition of the new phase is between the eutectic (about 15 wt.% Au) and $AuPb_2$ (32.2 wt.% Au). Then for the purpose of accurate determination of the composition, we examined by the ordinary metallographic method the specimens prepared in the range of 15~26 wt.% Au differing by one or two percents, and the results were compared with the X-ray diffraction patterns of the same specimens. The alloy constituents in Terex glass tube were melted in vacuum at about 400°C, quenched in a mixture of ice and NaCl or air-cooled to room temperatures, and annealed for an appropriate time (26.5~53 h.) at about 200°C. After these heat treatments in vacuum, specimens were polished, etched and microscopically investigated.

The air-cooled specimens containing 15 wt.% Au showed the typical eutectic structure. The quenched sample containing 24 wt.% Au indicated the presence of two phases, $AuPb_2$ plus eutectic (Fig. 1 (d)), which were completely transformed by further annealing into 'one phase' by the peritectic reaction (Fig. 1 (b)). It seems that this phase is not a solid solution but a compound like Au_3Pb or $AuPb_2$ (cf. Fig. 1 (a), (b) and (c)). This result should be compared with a theoretical value of 24.08 wt.% Au

* These lines are observed by electron diffraction method.

for the formula unit $AuPb_3$.

The X-ray diffraction powder pattern of this new compound can be indexed on the basis of a tetragonal unit cell with $a=11.95_8$ Å, $c=5.87_8$ Å (Table I). The measured density was found to be 12.8 g.cm⁻³.

Fig. 1. $\times 150 \times 1/2$.
(a) 23 wt. % Au annealed for 28 hours at 200°C ($AuPb_3$ +eutectic)
(b) 24 wt. % Au annealed for 26.5 hours at 200°C ($AuPb_3$)
(c) 25 wt. % Au annealed for 53 hours at 200°C ($AuPb_3$ + $AuPb_2$)
(d) 24 wt. % Au quenched ($AuPb_2$ +eutectic)

while the density calculated on the basis of 8 molecules per unit cell is 12.93 g.cm.^{-3} .

As mentioned above, the quenched specimens containing 24 wt.% Au indicate the presence of only two phases, AuPb_2 plus eutectic, but not AuPb_3 phase. Similar results were obtained for air-cooled specimens of other compositions between 26 wt.% Au and 17 wt.% Au. These facts seem to suggest that the peritectic point is very close to the eutectic temperature. In fact, our electron diffraction observations on the highest temperature of stability for AuPb_3 phase support this suggestion, but the precise determination of the above-mentioned temperature requires further investigations.

The authors wish to thank Prof. K. Iwase and Dr. M. Kyōtani of Kyōto University for their kind advice and discussions.

Etch Pits in Lead Crystals

By Yosio HIKI

*The Government Mechanical Laboratory,
Tokyo*

(Received June 4, 1958)

The relation of etch pits with dislocations has been often discussed. In some cases one-to-one correspondence was established between the pits and the points where dislocations emerge on crystal surfaces¹⁾. It was sometimes shown, however, that the association of the dislocations with impurity atoms was necessary to the formation of the etch pits²⁾. In the present note, some observations on the etched surfaces of lead single crystals are reported.

Single crystals were prepared by the moving-furnace method from lead of 99.99% purity. The impurities determined by chemical analysis were: C 0.007, Fe 0.0005 and Sn 0.0004 in weight per cent. Good results were obtained to reveal the pits by adopting the electrolytic etching instead of chemical one. The standard procedure of the etching was as follows: First, the specimen was etched chemically with the solution of CH_3COOH and H_2O_2 (1:3) for 15–30 sec, and then washed by alcohol, the surface becoming very flat and bright. Next, it was etched electrolytically using 1 weight per cent aqueous solution of purest sulfamic acid at 18°C for 45 sec with current density of 0.2 Amp./cm^2 . When the etching time was increased further, the sizes of the pits were enlarged while the number of the pits per unit area did not increase.

The effect of annealing on the etch figures was mainly studied. The specimen was annealed at

Fig. 1. Etched surface of lead single crystal as grown (a), and annealed at 150°C for 3 hrs. (b), 5 hrs. (c), 15 hrs. (d), 33 hrs. (e) and 60 hrs. (f).

150°C in ethylene glycol and the surface was observed after etching. As the annealing time was prolonged, the shapes of the pits became clear and the number of them increased gradually and approached to a some saturated value, as shown in Fig. 1. In a well annealed specimen, the surface density of the pits was $1.7 \times 10^7/\text{cm}^2$, and it could not be increased by changing the etching conditions. The shapes of the pits were different if the specimens had different crystallographic orientations.

In the present case, it is likely that dislocations originate etch pits in co-operation with impurity atoms. The stresses due to dislocations may be so locally concentrated that they cannot produce the pits. When the specimen is annealed, the impurity atoms are activated thermally and segregate around the dislocation lines under the influence of the stress field, and thus Cottrell's atmospheres may be created. These atmospheres will then serve as the centers of the etch pits. The migration of the impurities to the dislocations was also verified through the measurements of the internal friction of lead single crystals. The details of this investigation will be published elsewhere.

The number of pits per unit area was about one tenth of the dislocation density in lead powder determined by us using a X-ray technique³⁾. This discrepancy may be explained as follows. (1) Only the edge dislocations gather the impurity atoms and contribute to the formation of the etch pits. (2) The line density of the segregated impurities may not be uniform along the dislocations. Only a small portion of the total dislocations which emerge on the crystal surface has enough concentration of atmosphere to form the pits⁴⁾. (3) Specimens prepared in different methods may have different densities of dislocation.

Paramagnetic Resonance Spectrum of Manganese in Single Crystals of Alkali Halide Grown from the Melt

By Kuniya FUKUDA, Yoichi UCHIDA
and Hisamitu YOSHIMURA
*Department of Physics,
University of Kyoto, Kyoto*
(Received June 6, 1958)

The experiments have been carried out at 290°C with a usual field modulation spectrometer, working at 1 cm. The paramagnetic resonance spectrum has been observed in single crystals of LiCl and KCl¹⁾ grown from the melting phase containing 1 mol % manganese.

We took up LiCl and KCl from consideration of the magnitude of ionic radius of Mn²⁺ relative to those of alkali metal ions (the Goudsmidt radii of these ions are Mn²⁺=0.80 Å, Li⁺=0.68 Å, and K⁺=1.33 Å, respectively). Applying Haven's method²⁾ to the two phase system of alkali halide and MnCl₂, the solution energies of Mn in these alkali halide crystals are estimated as 0.8 ev for LiCl and as 1.71 ev for KCl, provided that *n* in 1/*r_n* of repulsive force in MnCl₂ is 8, the value consistent with the experimental value of solution energy of Mn in NaCl given by Haven³⁾.

The spectrum of KCl/Mn can be classified into three kinds: (a) overlapping lines of about 30 gauss and about 100 gauss (peak to peak) observed after annealing; (b) only one line of about 30 gauss observed after quenching from 300~500°C; (c) hyperfine structure of six lines and a line of about 30 gauss (see Fig. 1), which are observed after quenching from 500°C. The width of hyperfine line is about 20 gauss under the field modulation of 15 gauss amplitude. The *g*-value is 2.005±0.002. The hyperfine splitting constant is 96±5 gauss. The hyperfine structure in KCl grown from the melt, which has not yet been reported, is very similar to

those on KCl grown from solution by Forrester and Schneider and Low¹⁾. The resonance lines are unstable and bleach at room temperature within a period of 20 hours leaving only the single center peak of 30 gauss width (peak of *c* in Fig. 1). The appearance of hyperfine structure is somewhat critical as inferred from the calculated value of solution energy so that in heat treatment some cautions must be paid for freezing Mn in a transient state; quenching an annealed specimen after heating at 500°C for about an hour results in the single narrow peak of 30 gauss. Further some heat treatment leads to the decrease of this peak and at the same time to the appearance of hyperfine structure. The period of heating, though it depends on Mn concentration in crystals, is determined by monitoring the resonance lines.

The spectrum of LiCl/Mn consists of strong six hyperfine lines at *g*=2.003±0.001 with the mean value of hyperfine splitting constant *A*=82±5 gauss and some orientation dependent lines. LiCl crystal was taken out of furnace in the course of crystal growing and quenched to room temperature from the temperature near melting point. The crystals were so hygroscopic that the sample in cavity was coated with polyvinyl film. The hyperfine structure lines are stable and do not bleach so easily as in KCl. The orientation dependent lines are observed in low and high field sides of center six lines; in (100) direction four lines in both low and high field sides, while in (110) direction two lines in each side. The separation of lines is shown in Fig. 2.

Besides these observations, we carried out the measurements on resonance spectrum in LiF/Mn. In the crystal annealed to room temperature from 600°C for 12 hours, two overlapping peaks of about 200 gauss and about 40 gauss were observed. A broad peak of 200 gauss remained after quenching, but no hyperfine splitting appeared by any heat treatment up to 800°C.

The improvement of our spectrometer is now in progress. Experiments are being carried on to obtain finer results on the anisotropy of hyperfine

Fig. 2. (a) A part of the observed spectrum of LiCl in (100) direction. (b) and (c) are the schematic representations of the observed spectra corresponding to (100) and (110) directions, respectively. The lengths of lines show rough magnitude of order of relative intensity. The outer two lines in (100) and the outer one line in (110) on both sides of resonance pattern were difficult to confirm their exact positions due to low S/N ratio, but the magnitude of separation between these lines was about 95 gauss.

structure and thereby to examine the model of resonance center from the analysis by spin Hamiltonian.

Some Electrical and Optical Properties of Tin Monosulphide

By Tadaichi YABUMOTO

*Institute of Electrical Engineering,
Shizuoka University,
Hamamatsu, Japan*

(Received May 19, 1958)

Among the sulphides of the fourth group elements of periodic table, PbS has only been studied by many investigators.

Recently the author has studied GeS as one example of these sulphides and showed that it has also good characteristics on photoconductivity in visible region¹⁾.

As for tin monosulphide there will be no experiment on its electrical and optical properties.

Metal tin of spectrographically standard grade of Johnson Matthey Co. was distilled in vacuum and excluded other impurities than Cu, Fe.

Sulphur was recrystallised four times by carbon disulphide and distilled in vacuum.

Such metal tin and sulphur was weighed by stoichiometric ratio of SnS and put into silica tube which was evacuated in high vacuum and sealed off.

This silica tube was heated in the electric furnace at 900°C for about 5 hours and 1000°C for about 6 hours respectively and then cooled.

The crystal form of SnS is orthorhombic and its melting point is about 882°C.

Samples were tested by X-ray diffraction and confirmed to be SnS.

Resistivity of tin monosulphide is about 10^6 ohm cm and lower than germanium monosulphide (about 10^{10} ohm cm) at room temperature.

Measurements of optical absorption and photoconductivity were carried out on films which were evaporated to the thickness of about 5 microns and had the resistance in dark of about 10^6 ohm.

Fig. 1. Optical absorption of SnS films.

Fig. 2. Spectral photocurrent for equal energy of illumination.

Fig. 3. Temperature dependence of electrical conduction of SnS.

Photoconductivity was measured in high vacuum with Nesa coating as electrodes.

Electrical conductivity was measured on a bulk crystal.

These results are shown in Fig. 1, 2, 3, respectively.

Band gap between the conduction band and the filled band is 1.6 ev from optical absorption, 1.7 ev from maximum value of photoconductivity and is in good agreement.

From the temperature dependency of conductivity activation energy is 0.54 ev at high temperatures and 0.26 ev at lower temperatures.

The true activation energy given from the conductivity at high temperatures subtracted the one at lower temperatures is 1.1 ev.

It will correspond to thermal activation energy and is somewhat lower than optical value.

In this case activation energy at lower temperature, 0.26 ev will correspond to some impurity level.

Band gaps of GeS, SnS, PbS are about 1.8 ev, 1.6 ev and 0.4 ev respectively and its order of magnitude is reasonable.

The author wishes to express his sincere thanks to Mr. Sakio Suzuki for the helpful assistance to do this experiment.

*Vols. 7 and succeeding ones	\$ 8.00 each (single copy: \$1.50)

Back number prices are effective for volumes other than last four (4) volumes (the current volume inclusive).

Thus, volumes 1 through 16 will be regarded as back numbers while volume 20 is being published.

The revised prices will be effective on and after August 1, 1958.

Dipolar Broadening of the Quadrupole Resonance Line in Crystals NaClO_3 , NaBrO_3

By Kenji KANŌ

Faculty of Liberal Arts and Education, Kagawa University

(Received June 4, 1958)

A few formulae have been derived for the contribution of the dipolar broadening to the second moment of the resonance line in pure quadrupole resonance experiment for crystals in which the following conditions are satisfied:

- (1) All nuclear spins involved, both resonant and nonresonant, have spin $3/2$.
- (2) The electric field gradient tensor at all nuclear sites have axial symmetry. For resonant nuclei the gradient of the electric field has the same magnitude but the symmetry axes of the electric field gradient at several nuclear sites in the unit cell have different directions.
- (3) As for the nonresonant nuclei no restriction has been set the magnitude of the electric field gradient and its directions.

A comparison is made with the line widths for NaClO_3 and NaBrO_3 observed by Kōi et al.

§ 1. Introduction

The possible causes of the line broadening in the pure quadrupole resonance experiment are the spin-lattice relaxation, magnetic dipole interaction and field fluctuation due to the crystal strain. Though in a few compounds the electron-coupled spin-spin interaction was found to contribute to the line broadening, in most compounds the above three are important hence we are interested in their contributions to the observed line width.

Recently, the pure quadrupole resonance line widths in crystals containing bromine and chlorine isotopes have been investigated by T. Wang¹⁾, Y. Kōi²⁾ and T. Fuke^{2),5)} and T. Hasi⁴⁾ and his co-workers⁴⁾.

Further Y. Kōi^{2,3,5)} has shown that the main cause of the line width in NaClO_3 or NaClO_4 is the magnetic dipole interaction in view of the ratio of the line width of bromine isotopes Br^{79} and Br^{81} or chlorine isotopes of Cl^{35} and Cl^{37} . Therefore it is interesting to confirm his argument theoretically.

A. Abragam and K. Kambe⁶⁾ have given the expressions for the second moment of the resonance line in the case of pure quadrupole resonance assuming that the resonant nuclei are identical and experiencing axial electric field gradients of common directions and magnitudes; however, the case in which the gradient of the electric field at the sites of resonant nuclei has the same magnitude

but different directions has not yet been considered. The purpose of the present article is to give theoretical expressions for the second moment of the resonance line investigated by Kōi et al. We here treat the problem following the method of Van Vleck⁷⁾, and A. Abragam and K. Kambe with necessary modification. The calculation in our case is more involved than that of A. Abragam and Kambe but we get rather simple results.

The effects of the relative directions of the electric field gradient at the nuclei will be shown graphically. In the next section, let us consider the interaction between resonant nuclei, and in the last section, the theoretical values of the second moment of the resonance lines for NaClO_3 and NaBrO_3 are estimated, and they are found to be in fairly good agreement with the experimental data^{2,3,5)}.

§ 2. Interaction between Resonant Nuclei

In this section we consider the case in which the gradient of the electric field at resonant nuclei are the same in magnitude but different in direction.

For the cases in which the symmetry axis of the electric field at different nuclei have three or more different directions, it is easy for us to generalize the following results of two directions. Thus we assume that the directions of the symmetry axes of the electric field gradients at nuclear sites are either along

the z -axis or along z' -axis.

We should designate the nuclear spin operators as I_j ($j=1, 2, 3, \dots, N$), where I_j is the nuclear spin operator of the j -th nucleus for which the axis of the symmetry is taken as the x -axis, and I_k' is the nuclear spin operator of the k -th nucleus for which the axis of the symmetry is taken as the z' -axis.

Fig. 1 shows the z and z' -axis and the vector r_{jk} .

Fig. 1.

The total Hamiltonian $\mathcal{H}$ for the spin system can be written as $\mathcal{H} = \mathcal{H}_0 + \mathcal{H}'$ where $\mathcal{H}_0$ is the unperturbed Hamiltonian and $\mathcal{H}'$ is the Hamiltonian representing the magnetic interactions. Here $\mathcal{H}_0$ and $\mathcal{H}'$ can be written as

$$\begin{aligned}\mathcal{H}_0 &= \mathcal{H}_1 + \mathcal{H}_2 \\ \mathcal{H}_1 &= -\delta \sum_j I_{zj}^2 \\ \mathcal{H}_2 &= -\delta \sum_k I_{z'k}^2 \\ &= -\delta \sum_k \{ \alpha \cdot I_{zk}' + \beta \cdot I_{yk}' + \gamma \cdot I_{xk}' \}^2 \\ \mathcal{H}' &= \mathcal{H}'_1 + \mathcal{H}'_2 + \mathcal{H}'_{12} \\ \mathcal{H}'_{12} &= \sum_{jk} W_{jk} = \mu_0^2 \sum_{jk} |r_{jk}|^{-3} \cdot \\ &\quad \{ (J_j \cdot I_k) - 3r_{jk}^{-2} \cdot (I_j \cdot r_{jk})(I_k' \cdot r_{jk}) \}, \quad (1)\end{aligned}$$

where α, β, γ are the direction cosines of the z' -axis with respect to x, y, z -axis, I_{zk}', I_{yk}' and I_{xk}' are x, y and z components of I_k' respectively, and δ is a parameter proportional to the strength of the quadrupole interaction, making the resonance frequency $\nu_0 = 2\delta/h$ for the spin $3/2$. $\mathcal{H}'_1$ is the Hamiltonian of dipolar interaction among the spins I_j , $\mathcal{H}'_2$ is the Hamiltonian among the spins I_k' , $\mathcal{H}'_{12}$ is the Hamiltonian between the spins I_j and I_k' .

The matrix representation of $\mathcal{H}_1 + \mathcal{H}_2$ is diagonal when the axes of quantization for I_j and I_k' are chosen along the directions of z and z' axes respectively. This means that the axis of quantization varies as going from I_j to I_k' . Thus the calculation of the matrix

elements of $\mathcal{H}'$ becomes more cumbersome than in the case of A. Abragam and K. Kambe⁶⁾.

We performed the calculation by introducing the appropriate transformation matrix S which transforms the axis of quantization from z to z' . First we express the matrix elements of all the Hamiltonian taking the axis of quantization as z axis for I_j as well as I_k' , then we transform the quantization for I_k' by means of S . Thus the matrices of $\mathcal{H}_1$ and $\mathcal{H}_2$ are diagonalize and the interaction Hamiltonian is expressed in the quantization relevant nucleus is I_j or I_k' .

In order to discard the matrix elements which contribute only to the satellite lines, we have to truncate the interaction Hamiltonian $\mathcal{H}'$ suitably. Thus the truncated Hamiltonian $\bar{\mathcal{H}}$ becomes

$$\bar{\mathcal{H}} = \mathcal{H}_0 + \bar{\mathcal{H}}'$$

where $\bar{\mathcal{H}}$ is the part of $\mathcal{H}'$ which commute with $\mathcal{H}_0$.

The interaction between the oscillating field and spin system can be expressed of the spin operators, and it should also be truncated appropriately.

We denote this truncated interaction operator as $\bar{R}$. Then we can express the second moment as

$$h^2 \langle \Delta \nu^2 \rangle = -sp \{ \bar{\mathcal{H}}' \bar{R} - \bar{R} \bar{\mathcal{H}}' \}^2 / sp \bar{R}^2.$$

The second moments can be divided into three parts as

$$h^2 \langle \Delta \nu^2 \rangle = h^2 \langle \Delta \nu_1^2 \rangle + h^2 \langle \Delta \nu_2^2 \rangle + h \langle \Delta \nu_{12}^2 \rangle,$$

where $\langle \Delta \nu_1^2 \rangle$, $\langle \Delta \nu_2^2 \rangle$ and $\langle \Delta \nu_{12}^2 \rangle$ arise from $\bar{\mathcal{H}}'_1$, $\bar{\mathcal{H}}'_2$ and $\bar{\mathcal{H}}'_{12}$ respectively. Since $\langle \Delta \nu_1^2 \rangle$ and $\langle \Delta \nu_2^2 \rangle$ have already been given by A. Abragam and K. Kambe⁶⁾, we will have only to evaluate $\langle \Delta \nu_{12}^2 \rangle$. When the sample is an assemblage of small perfect crystal grains which are distributed at random we can calculate the spatial average, so-called the powder mean, for the second moment. Now we denote the spatial average by $\langle \Delta \nu_{12}^2 \rangle$. Then after some lengthy matrix manipulations, we finally obtain

$$\begin{aligned}h^2 \langle \Delta \nu_{12}^2 \rangle &= \mu_0^4 \sum_j |\gamma_{jk}|^{-6} \cdot U_{jk} \\ U_{jk} &= 6 - \frac{9}{16} \{ \cos^2 \xi_{jk} + \cos^2 \eta_{jk} \} \\ &\quad + \frac{15}{16} \cdot \{ \cos \xi - 3 \cos \xi_{jk} \cdot \cos \eta_{jk} \}^2. \quad (2)\end{aligned}$$

Fig. 1 shows ξ_{jk} and η_{jk} and ζ . Fig. 2 and Fig. 3 and Fig. 4 show graphically the effect of the directions of electric field gradient in Eq. (2) for several special nuclear sites.

§ 3. Interaction between Resonant and Non-resonant Nuclei

In this section we shall consider the case where the resonant nuclei interact only with the non-resonant nuclei and both nuclei have spin 3/2 and the non-resonant nuclei have quadrupole splitting. The interaction Hamiltonian $\mathcal{H}_{12}''$ is written below with index j for resonant k' for nonresonant spins,

$$\mathcal{H}_{12}'' = \sum_{jk'} \mathbf{W}_{jk} = \mu_0^2 \cdot \mu_{0'}^2 \sum_{jk'} |\mathbf{r}_{jk'}|^{-3} \cdot \{ (\mathbf{I}_j \cdot \mathbf{I}_{k'}) - 3 |\mathbf{r}_{jk'}|^{-2} \cdot (\mathbf{I}_j \cdot \mathbf{r}_{jk'}) \cdot (\mathbf{I}_{k'} \cdot \mathbf{r}_{jk'}) \}.$$

Following the same procedures described in the foregoing section we get

$$h^2 \langle \Delta \nu_{12}^2 \rangle = \mu_0^2 \mu_{0'}^2 \sum_{jk'} |\mathbf{r}_{jk'}|^{-6} \cdot U'_{jk'},$$

$$U'_{jk'} = \frac{15}{4} + \frac{9}{4} \cos^2 \eta_{jk'}, \tag{3}$$

Fig. 2. The case of $\xi_{jk}=0$ and $\eta_{jk}=\zeta$.

Fig. 3. The case of $\xi_{jk}=\pi/2$ and $\eta_{jk}=\pi/2$.

where $\eta_{jk'}$ have the same meaning as in the previous section. All other things being equal, the non-resonant nuclei having quadrupole splitting are less effective in broadening than that having no quadrupole splitting and we get

$$0.3 \leq \frac{U'_{jk'} \text{ (with quadrupole splitting)}}{U'_{jk'} \text{ (no quadrupole splitting)}} \leq 0.5.$$

§ 4. Line Width of Chlorine in NaClO₃ and Bromine in NaBrO₃

Y. Kôji^{2,3,6)} has resently shown that the main cause of the line width in NaClO₃ and NaBrO₃ is the magnetic dipole interaction in view of the ratio of the widths of lines corresponding to chlorine and bromine isotopes. Therefore, it is interesting to make sure of these results by our theory. The crystals of NaClO₃ and NaBrO₃ have cubic structure with the lattice constants 6.689 Å. and 6.555 Å. respectively⁸⁾, and unit cell contains four molecules. Their structures are given in Fig. 5.

L. Pauling⁹⁾ has shown that the bonds between Na ion and BrO₃ ion or ClO₃ ion in NaBrO₃ or NaClO₃ are on the whole ionic. The BrO₃ ion or ClO₃ ion are the flat trigonal pyramid having the there oxygen atoms as its base. The binding between O-Br or O-Cl are largely the covalent structures. From the symmetry of the flat triagonal pyramid of oxygens, the symmetrical axes of the gradient of the electric field at the nuclear spins of Br or Cl are the line passing through the Na and Br or Cl nuclei. Fig. 5 shows this axis of symmetry.

As for the Na-Br distances in NaBrO₃, the ionic radius of Na ions is 0.95 Å, and that of Br ion is 1.95 Å., the sum of them is 2.90 Å. and this is shorter than the nearest distance of Na-Br, 3.42 Å.. This means that the binding between Na-Br is partly covalent and the nuclear spin levels of Na has quadrupole splittings, and the symmetry axis of the field gradient at Na

nucleus is the same as that of Br and this is also true for NaClO_3 having the almost same crystal structure as NaBrO_3 .

The experimental measurements on the full width of the nuclear quadrupole resonances of chlorine and bromine isotopes in these solids have been made to an accuracy of about 0.01 KC. The observed and calculated second moments are given in Table I.

The agreement between our theory and experiment in Table I seems to be on the whole satisfactory as considering the accuracy of the experimental measurements, especially the agreement is good for NaClO_3 .

Table I. Calculated and observed frequency deviations in NaClO_3 and NaBrO_3

isotopes	$\langle \Delta\nu^2 \rangle$ (obs.)	$\langle \Delta\nu^2 \rangle$ (calc.)
Cl^{35} (NaClO_3)	0.210 (KC) ^{2*}	0.204 (KC) ²
Cl^{37} (NaBrO_3)	0.149 (KC) ^{2*}	0.142 (KC) ²
Br^{79} (NaBrO_3)	2.68 (KC) ^{2**}	0.98 (KC) ²
Br^{81} (NaBrO_3)	3.02 (KC) ^{2**}	2.33 (KC) ²

*: Fuke and Kōi⁽⁵⁾
**: Y. Kōi⁽²⁾ (The observed $\langle \Delta\nu^2 \rangle$ is calculated by the observed full width and Gaussian assumption of the line shape.)

The author wishes to express his sincere thanks to professor K. Kambe for his valuable advice and kind reading of the manuscript. He also wishes to thank professor Y. Kōi for valuable suggestions and communicating the result of his experiment before publication.

The Thermoelectric, Galvanomagnetic and Thermomagnetic Effects of Monovalent Metals. III. The Galvanomagnetic and Thermomagnetic Effects for Anisotropic Media.

By Mikio TSUJI

General Education Department, Kyushu University, Fukuoka

(Received June 6, 1958)

A variational principle for the electron transport in a magnetic field is described, and the principle is applied to the calculation of the transverse effects of cubic metals in the transverse magnetic field by using an approximate trial function. Our method gives exact solution for the spherical energy band model. For the anisotropic energy band, our method gives an approximate solution which coincides with the exact solution if the energy dependent relaxation time exists. Relations between the transverse galvanomagnetic and thermomagnetic coefficients, which hold for arbitrary scattering mechanism, are derived.

§ 1. Introduction

In the part I¹⁾, we have investigated, based on the spherical band model, the thermoelectric effects and transverse galvanomagnetic and thermomagnetic effects in the transverse magnetic field for the case of high temperatures where the time of relaxation exists. At low temperatures, however, the time of relaxation does not exist, and the spherical band model is no longer a good approximation. Therefore in the part II²⁾, we have investigated the thermoelectric power of monovalent metals at low temperatures based on the anisotropic energy band model. In this part, we shall calculate the galvanomagnetic and thermomagnetic effects for cubic metals by using a variational method.

Kohler³⁾ has investigated the Hall effect and magnetoresistance of metals based on the two band model by using a variational principle. His method, however, is not easy to generalize for the anisotropic band. Ziman⁴⁾ has proposed a different form of the variational principle*. His variational function is not proportional to the entropy production due to the scatterings of the electrons, and so he suggested a modification of the formula for the entropy production in the magnetic field. In § 2 we give a variational method in which the variational function is proportional to the en-

tropy production and, in the connection to the thermodynamical principle, no trouble occurs in the formula of the entropy production. However, the consequence of our variational principle is equivalent to those of Kohler and Ziman.

Using this variational principle, we solve Boltzmann's equation for a cubic metal in the presence of a magnetic field in § 3. In § 4 we show certain relations between the coefficients (Eqs. (47), (48) and (49)), which hold irrespective of the scattering mechanism. Eq. (47) is a well known relation which has been derived by Callen⁵⁾ from Onsager's reciprocal relations. Eq. (48) has been derived by Meixner⁶⁾ by assuming the existence of the relaxation time, and by Sondheimer⁷⁾ by using the free electron model. However, it is a new result of our calculations that (48) holds for any cubic metal irrespective of the scattering mechanism. Eq. (49) is also a new result which is a generalization of Eq. (86) in I. In § 5, we discuss certain special cases, and it is shown that our method of variational principle gives the exact solution, if it is applied to an anisotropic metal in which the energy dependent relaxation time exists. The formulae for the spherical energy band model and those for the pure cubic metals at low temperatures are given also.

§ 2. Variational Principle in the Presence of a Magnetic Field

In this section we consider formally a most general case. We put the distribution func-

* (Added in proof) F. Moliner and S. Simons (Proc. Camb. Phil. Soc. **53** (1957), 848) have extended the variational principle of the form of Ziman to the case including the boundary scatterings.

tion of the electron

$$f_k = f_0 - \Phi_k \frac{\partial f_0}{\partial E}, \quad (1)$$

where f_0 is the Fermi distribution. If there are an electric field $\mathbf{F}$, a magnetic field $\mathbf{H}$ and a temperature gradient ∇T in a metal, Boltzmann's equation is written schematically in the form

$$L(\Phi_k) = X_k - M(\mathbf{H})\Phi_k, \quad (2)$$

where

$$L(\Phi_k) \equiv - \left(\frac{\partial f_k}{\partial t} \right)_{\text{coll}}, \quad (3)$$

$$X_k \equiv \frac{1}{\hbar} \left\{ e\mathbf{F} - T \text{grad}_r \frac{E - \zeta}{T} \right\} \cdot \text{grad}_k E \frac{\partial f_0}{\partial E}, \quad (4)$$

and

$$M(\mathbf{H}) \equiv \frac{e}{\hbar^2 c} \frac{\partial f_0}{\partial E} \text{grad}_k E \cdot \mathbf{H} \times \text{grad}_k. \quad (5)$$

If there is no magnetic field, the solution of (2) is obtained⁸⁾ by maximizing an integral

$$(\Phi_k, \Phi_k) \equiv \int \Phi_k L(\Phi_k) d\mathbf{k}, \quad (6)$$

subject to a subsidiary condition

$$(\Phi_k, \Phi_k) = \int \Phi_k X_k d\mathbf{k}. \quad (7)$$

In the presence of a magnetic field, it is shown easily that

$$\int \Phi_k M(\mathbf{H}) \Phi_k d\mathbf{k} = 0, \quad (8)$$

and so, as has been stated by Ziman⁴⁾, a simple generalization of (6) and (7) leads to a contradictory solution which is just the solution of the equation without magnetic field. A variational principle which gives the true solution of (2) can be formulated as follows:

Let Φ_k be the solution of (2) and Ψ_k an arbitrary function which satisfies a subsidiary condition

$$(\Psi_k, \Psi_k) = \int \Psi_k X_k d\mathbf{k} - \int \Psi_k M(\mathbf{H}) \Phi_k d\mathbf{k}. \quad (9)$$

Then the function Φ_k which maximizes the expression (6) is the solution of (2).

(Proof)

Using Lagrange's undetermined multiplier λ , we maximize

$$(1 + \lambda)(\Psi_k, \Psi_k) - \lambda \int \Psi_k X_k d\mathbf{k} + \lambda \int \Psi_k M(\mathbf{H}) \Phi_k d\mathbf{k}. \quad (10)$$

Eq. (10) must be stationary for any variation $\delta\Psi_k$. From the linearity of the collision operator L and the symmetry relation

$$(\delta\Psi_k, \Psi_k) = (\Psi_k, \delta\Psi_k), \quad (11)$$

we have

$$(2 + 2\lambda)L(\Psi_k) - \lambda X_k + \lambda M(\mathbf{H})\Phi_k = 0, \quad (12)$$

and from (9) and (12) we find $\lambda = -2$. Therefore (12) becomes

$$L(\Psi_k) - X_k + M(\mathbf{H})\Phi_k = 0, \quad (13)$$

which shows that Ψ_k is the solution of (2). This method can be used for any equation of type of Eq. (2) in which the operator M does not have the symmetry character, and we have used this method in the calculation of the phonon drift problem⁹⁾.

If we use the symmetry character of L and the fact that (Ψ_k, Ψ_k) is positive definite and that (9) can be rewritten as

$$(\Psi_k, \Psi_k) = (\Psi_k, \Phi_k), \quad (14)$$

the proof is also straightforward.

Now (Ψ_k, Ψ_k) is proportional to the entropy production due to the collisions, and so our variational principle corresponds to the thermodynamical principle of an irreversible process. There is no trouble such as discussed by Ziman⁴⁾. The electric and magnetic field do not contribute to the entropy production directly. The entropy produced is transferred to the temperature bath in the steady state.

The actual procedure of the application of the variational principle is given in the following section.

§3. Application to an Anisotropic Metal

We consider a cubic metal in which a magnetic field $\mathbf{H}$ is along z axis and an electric field $\mathbf{F}$ and a temperature gradient ∇T are in the x - y plane, and we put as an approximation,

$$\Phi_k = c_x(\eta) \frac{\partial E}{\partial k_x} + c_y(\eta) \frac{\partial E}{\partial k_y}, \quad (15)$$

where $\eta = (E - \zeta)/\kappa T$. Eq. (15) is an exact expression for an isotropic metal and may be a fairly good approximation for a cubic metal. The change of the distribution function for the electrons due to the scatterings by the lattice waves or the lattice defects may be written in the form

$$\left(\frac{\partial f}{\partial t}\right)_{\text{coll}} = -L(\Phi) = -\frac{1}{\hbar} \left\{ \frac{\partial E}{\partial k_x} \mathcal{L}(c_x) + \frac{\partial E}{\partial k_y} \mathcal{L}(c_y) \right\} \frac{\partial f_0}{\partial E}. \quad (16)$$

Then the Boltzmann equation (2) becomes

$$\begin{aligned} \frac{\partial E}{\partial k_x} \mathcal{L}(c_x) + \frac{\partial E}{\partial k_y} \mathcal{L}(c_y) = & \left(eF_x + T \frac{\partial}{\partial x} \frac{\xi}{T} + \frac{E}{T} \frac{\partial T}{\partial x} \right) \frac{\partial E}{\partial k_x} + \left(eF_y + T \frac{\partial}{\partial y} \frac{\xi}{T} + \frac{E}{T} \frac{\partial T}{\partial y} \right) \frac{\partial E}{\partial k_y} \\ & - \frac{eH}{\hbar c} \left\{ \left(\frac{\partial^2 E}{\partial k_x^2} \frac{\partial E}{\partial k_y} - \frac{\partial^2 E}{\partial k_x \partial k_y} \frac{\partial E}{\partial k_x} \right) c_x - \left(\frac{\partial^2 E}{\partial k_y^2} \frac{\partial E}{\partial k_x} - \frac{\partial^2 E}{\partial k_x \partial k_y} \frac{\partial E}{\partial k_y} \right) c_y \right\}. \end{aligned} \quad (17)$$

We put a trial function for (15) as

$$\Psi_k = b_x(\eta) \frac{\partial E}{\partial k_x} + b_y(\eta) \frac{\partial E}{\partial k_y}, \quad (18)$$

and then we have (by omitting a constant factor)

$$(\Psi_k, \Psi_k) = \iint \frac{(\partial E / \partial k_x)^2}{|\text{grad}_k E|} b_x \mathcal{L}(b_x) \frac{\partial f_0}{\partial \eta} dS d\eta + \iint \frac{(\partial E / \partial k_y)^2}{|\text{grad}_k E|} b_y \mathcal{L}(b_y) \frac{\partial f_0}{\partial \eta} dS d\eta, \quad (19)$$

where the integration with respect to dS is carried out over a constant energy surface. We expand c_x and c_y as

$$\left. \begin{aligned} c_x &= c_{x,0} + c_{x,1}\eta + c_{x,2}\eta^2 + \dots, \\ c_y &= c_{y,0} + c_{y,1}\eta + c_{y,2}\eta^2 + \dots, \end{aligned} \right\} \quad (20)$$

and b_x and b_y as

$$\left. \begin{aligned} b_x &= b_{x,0} + b_{x,1}\eta + b_{x,2}\eta^2 + \dots, \\ b_y &= b_{y,0} + b_{y,1}\eta + b_{y,2}\eta^2 + \dots. \end{aligned} \right\} \quad (21)$$

Then the variational function (19) and the subsidiary condition (9) become

$$(\Psi_k, \Psi_k) = \sum_r \sum_s (b_{x,r} b_{x,s} + b_{y,r} b_{y,s}) d_{rs} \quad (22)$$

and

$$\begin{aligned} C \equiv & \sum_r \sum_s (b_{x,r} b_{x,s} + b_{y,r} b_{y,s}) d_{rs} - \sum_r \sum_s (b_{x,r} c_{y,s} \gamma_{rs} - b_{y,r} c_{x,s} \gamma_{rs}) \\ & - \sum_r \left[\left\{ \left(eF_x + T \frac{\partial}{\partial x} \frac{\xi}{T} \right) \alpha_r^{(1)} + \frac{1}{T} \frac{\partial T}{\partial x} \alpha_r^{(2)} \right\} b_{x,r} \right. \\ & \left. + \left\{ \left(eF_y + T \frac{\partial}{\partial y} \frac{\xi}{T} \right) \alpha_r^{(1)} + \frac{1}{T} \frac{\partial T}{\partial y} \alpha_r^{(2)} \right\} b_{y,r} \right] = 0, \end{aligned} \quad (23)$$

where

$$d_{rs} \equiv \frac{1}{3} \iint |\text{grad}_k E| \eta^r \mathcal{L}(\eta^s) \frac{\partial f_0}{\partial \eta} dS d\eta = d_{sr}, \quad (24)$$

$$\gamma_r \equiv \frac{eH}{\hbar c} \int \left\{ \frac{\partial^2 E}{\partial k_x^2} \left(\frac{\partial E}{\partial k_x} \right)^2 - \frac{\partial^2 E}{\partial k_x \partial k_y} \frac{\partial E}{\partial k_x} \frac{\partial E}{\partial k_y} \right\} \frac{\eta^r}{|\text{grad}_k E|} \frac{\partial f_0}{\partial \eta} dS d\eta, \quad (25)$$

$$\alpha_r^{(n)} \equiv \frac{1}{3} \int E^{n-1} |\text{grad}_k E| \eta^r \frac{\partial f_0}{\partial \eta} dS d\eta. \quad (26)$$

Integrating the right side of (25) with respect to η , we have

$$\left. \begin{aligned} r_0 &= -\frac{eH}{\hbar c} f_5, \\ r_1 &= -\frac{eH}{\hbar c} \frac{\pi^2 \kappa T}{3} \frac{df_5}{dE}, \\ r_2 &= -\frac{eH}{\hbar c} \frac{\pi^2}{3} f_5, \end{aligned} \right\} \quad (27)$$

where

$$f_5(E) = \int \left\{ \left(\frac{\partial E}{\partial k_x} \right)^2 \frac{\partial^2 E}{\partial k_y^2} - \frac{\partial E}{\partial k_x} \frac{\partial E}{\partial k_y} \frac{\partial^2 E}{\partial k_x \partial k_y} \right\} \frac{1}{|\text{grad}_k E|} dS. \quad (28)$$

By using the cubic symmetricity, (28) can be rewritten as

$$f_5 = \frac{1}{3} \int \left(\frac{1}{\rho} \right) |\text{grad}_k E|^2 dS,$$

where $(1/\rho)$ is the mean curvature of the constant energy surface at the point $\mathbf{k}$ and the sign of the radius of curvature ρ is taken to be positive when the center of curvature is inside (lower energy side) of the surface. The values of $\alpha_r^{(n)}$ have been given in the appendix of II in terms of an integral f_1 and its derivative, where

$$f_1(E) = \frac{1}{3} \int |\text{grad}_k E| dS. \quad (29)$$

By putting the partial derivatives of $(\Psi_k, \Psi_k) + \lambda C$ with respect to $b_{x,r}$ and $b_{y,r}$ to be zero, we have $\lambda = -2$. Then, by putting $b_{x,r} = c_{x,r}$ and $b_{y,r} = c_{y,r}$, we obtain a set of equations

$$\left. \begin{aligned} \sum_s c_{x,s} d_{rs} - \sum_s c_{y,s} \gamma_{r+s} - \left(eF_x + T \frac{\partial}{\partial x} \frac{\xi}{T} \right) \alpha_r^{(1)} - \frac{1}{T} \frac{\partial T}{\partial x} \alpha_r^{(2)} &= 0, \\ \sum_s c_{y,s} d_{rs} + \sum_s c_{x,s} \gamma_{r+s} - \left(eF_y + T \frac{\partial}{\partial y} \frac{\xi}{T} \right) \alpha_r^{(1)} - \frac{1}{T} \frac{\partial T}{\partial y} \alpha_r^{(2)} &= 0, \end{aligned} \right\} \quad (30)$$

from which we can determine the expansion coefficients of (20). Actually, for our purpose to obtain the leading terms of the relevant quantities, it suffices to take the first two terms of (20). Then the solutions of (30) can be written in the forms

$$\left. \begin{aligned} c_{x,0} &= \left(eF_x + T \frac{\partial}{\partial x} \frac{\xi}{T} \right) c_0^{(1)} + \frac{1}{T} \frac{\partial T}{\partial x} c_0^{(2)} + \left(eF_y + T \frac{\partial}{\partial y} \frac{\xi}{T} \right) \bar{c}_0^{(1)} + \frac{1}{T} \frac{\partial T}{\partial y} \bar{c}_0^{(2)}, \\ c_{x,1} &= \left(eF_x + T \frac{\partial}{\partial x} \frac{\xi}{T} \right) c_1^{(1)} + \frac{1}{T} \frac{\partial T}{\partial x} c_1^{(2)} + \left(eF_y + T \frac{\partial}{\partial y} \frac{\xi}{T} \right) \bar{c}_1^{(1)} + \frac{1}{T} \frac{\partial T}{\partial y} \bar{c}_1^{(2)}, \\ c_{y,0} &= - \left(eF_x + T \frac{\partial}{\partial x} \frac{\xi}{T} \right) \bar{c}_0^{(1)} - \frac{1}{T} \frac{\partial T}{\partial x} \bar{c}_0^{(2)} + \left(eF_y + T \frac{\partial}{\partial y} \frac{\xi}{T} \right) c_0^{(1)} + \frac{1}{T} \frac{\partial T}{\partial y} c_0^{(2)}, \\ c_{y,1} &= - \left(eF_x + T \frac{\partial}{\partial x} \frac{\xi}{T} \right) \bar{c}_1^{(1)} - \frac{1}{T} \frac{\partial T}{\partial x} \bar{c}_1^{(2)} + \left(eF_y + T \frac{\partial}{\partial y} \frac{\xi}{T} \right) c_1^{(1)} + \frac{1}{T} \frac{\partial T}{\partial y} c_1^{(2)}, \end{aligned} \right\} \quad (31)$$

where

$$c_0^{(n)} = \frac{1}{|D|} \times \begin{vmatrix} \alpha_0^{(n)} & d_{01} & -\gamma_0 & -\gamma_1 \\ \alpha_1^{(n)} & d_{11} & -\gamma_1 & -\gamma_2 \\ 0 & \gamma_1 & d_{00} & d_{01} \\ 0 & \gamma_2 & d_{10} & d_{11} \end{vmatrix}, \quad (32)$$

$$\bar{c}_0^{(n)} = \frac{1}{|D|} \times \begin{vmatrix} 0 & d_{01} & -\gamma_0 & -\gamma_1 \\ 0 & d_{11} & -\gamma_1 & -\gamma_2 \\ \alpha_0^{(n)} & \gamma_1 & d_{00} & d_{01} \\ \alpha_1^{(n)} & \gamma_2 & d_{10} & d_{11} \end{vmatrix}, \quad (33)$$

$$c_1^{(n)} = \frac{1}{|D|} \times \begin{vmatrix} -\alpha_0^{(n)} & d_{00} & -\gamma_0 & -\gamma_1 \\ -\alpha_1^{(n)} & d_{10} & -\gamma_1 & -\gamma_2 \\ 0 & \gamma_0 & d_{00} & d_{01} \\ 0 & \gamma_1 & d_{10} & d_{11} \end{vmatrix}, \quad (34)$$

$$\bar{c}_1^{(n)} = \frac{1}{|D|} \times \begin{vmatrix} 0 & d_{00} & -r_0 & -r_1 \\ 0 & d_{10} & -r_1 & -r_2 \\ -\alpha_0^{(n)} & r_0 & d_{00} & d_{01} \\ -\alpha_1^{(n)} & r_1 & d_{10} & d_{11} \end{vmatrix}, \quad (35)$$

where

$$|D| = \begin{vmatrix} d_{00} & d_{01} & -r_0 & -r_1 \\ d_{10} & d_{11} & -r_1 & -r_2 \\ r_0 & r_1 & d_{00} & d_{01} \\ r_1 & r_2 & d_{10} & d_{11} \end{vmatrix}, \quad (36)$$

From (31), we can calculate the electrical and thermal currents, and the results are

$$\left. \begin{aligned} J_x &= K_{11}e \left(eF_x + T \frac{\partial}{\partial x} \frac{\zeta}{T} \right) + K_{12} \frac{e}{T} \frac{\partial T}{\partial x} - K_{13}e \left(eF_y + T \frac{\partial}{\partial y} \frac{\zeta}{T} \right) - K_{14} \frac{e}{T} \frac{\partial T}{\partial y}, \\ J_y &= K_{13}e \left(eF_x + T \frac{\partial}{\partial x} \frac{\zeta}{T} \right) + K_{14} \frac{e}{T} \frac{\partial T}{\partial x} + K_{11}e \left(eF_y + T \frac{\partial}{\partial y} \frac{\zeta}{T} \right) + K_{12} \frac{e}{T} \frac{\partial T}{\partial y}, \\ w_x &= -K_{21} \left(eF_x + T \frac{\partial}{\partial x} \frac{\zeta}{T} \right) - K_{22} \frac{1}{T} \frac{\partial T}{\partial x} + K_{23} \left(eF_y + T \frac{\partial}{\partial y} \frac{\zeta}{T} \right) + K_{24} \frac{1}{T} \frac{\partial T}{\partial y}, \\ w_y &= -K_{23} \left(eF_x + T \frac{\partial}{\partial x} \frac{\zeta}{T} \right) - K_{24} \frac{1}{T} \frac{\partial T}{\partial x} - K_{21} \left(eF_y + T \frac{\partial}{\partial y} \frac{\zeta}{T} \right) - K_{22} \frac{1}{T} \frac{\partial T}{\partial y}, \end{aligned} \right\} \quad (37)$$

where

$$\left. \begin{aligned} K_{11} &= \frac{1}{4\pi^3\hbar} (c_0^{(1)}\alpha_0^{(1)} + c_1^{(1)}\alpha_1^{(1)}), \\ K_{12} &= \frac{1}{4\pi^3\hbar} (c_0^{(2)}\alpha_0^{(1)} + c_1^{(2)}\alpha_1^{(1)}), \\ K_{13} &= -\frac{1}{4\pi^3\hbar} (\bar{c}_0^{(1)}\alpha_0^{(1)} + \bar{c}_1^{(1)}\alpha_1^{(1)}), \\ K_{14} &= -\frac{1}{4\pi^3\hbar} (\bar{c}_0^{(2)}\alpha_0^{(1)} + \bar{c}_1^{(2)}\alpha_1^{(1)}), \\ K_{21} &= \frac{1}{4\pi^3\hbar} (c_0^{(1)}\alpha_0^{(2)} + c_1^{(1)}\alpha_1^{(2)}), \\ K_{22} &= \frac{1}{4\pi^3\hbar} (c_0^{(2)}\alpha_0^{(2)} + c_1^{(2)}\alpha_1^{(2)}), \\ K_{23} &= -\frac{1}{4\pi^3\hbar} (\bar{c}_0^{(1)}\alpha_0^{(2)} + \bar{c}_1^{(1)}\alpha_1^{(2)}), \\ K_{24} &= -\frac{1}{4\pi^3\hbar} (\bar{c}_0^{(2)}\alpha_0^{(2)} + \bar{c}_1^{(2)}\alpha_1^{(2)}). \end{aligned} \right\} \quad (38)$$

It is easily verified that the reciprocal relations

$$\left. \begin{aligned} K_{21} &= K_{12}, \\ K_{23} &= K_{14}, \end{aligned} \right\} \quad (39)$$

hold. For the calculation of the coefficients of the transverse galvanomagnetic and thermomagnetic effects, we merely need to calculate $K_{m,n}$'s up to the terms of the order of $(\kappa T/\zeta)^2$ and the linear terms of H . The calculations are straightforward (see §5 of I.), and we have;

(1) Hall constant:

$$R = -\frac{4\pi^3}{ec} \frac{f_5}{f_1^2}, \quad (40)$$

(2) Ettingshausen coefficient:

$$A_E = \frac{4\pi^3 T}{cf_1^3 d_{11}} \left\{ \left(f_1 \frac{df_5}{dE} - \frac{df_1}{dE} f_5 \right) d_{11} - \frac{f_1 f_5}{\kappa T} d_{01} + \frac{\pi^2}{3} \frac{df_1}{dE} f_5 d_{00} \right\}, \quad (41)$$

(3) Isothermal Ettingshausen-Nernst coefficient:

$$B_{EN}^i = \frac{\pi^4 \kappa^2 T}{9c\hbar f_1 d_{11}^2} \left\{ \left(f_1 \frac{df_5}{dE} - \frac{df_1}{dE} f_5 \right) d_{11} - \frac{f_1 f_5}{\kappa T} d_{01} + \frac{\pi^2}{3} \frac{df_1}{dE} f_5 d_{00} \right\}, \quad (42)$$

(4) Righi-Leduc coefficient:

$$B_{RL} = -\frac{\pi^2 e}{3\hbar c} \frac{f_5}{d_{11}}, \quad (43)$$

(5) Electrical conductivity:

$$\sigma = \frac{e^2 f_1^2}{4\pi^3 \hbar d_{00}}, \quad (44)$$

(6) Thermal conductivity:

$$\kappa_T = \frac{\pi \kappa^2 T f_1^2}{36\hbar d_{11}}, \quad (45)$$

(7) Absolute thermoelectric power:

$$S = -\frac{\pi^2 \kappa^2 T}{3ed_{11}} \left\{ \frac{1}{f_1} \frac{df_1}{dE} d_{11} - \frac{1}{\kappa T} d_{01} + \frac{\pi^2}{3} \frac{1}{f_1} \frac{df_1}{dE} d_{00} \right\}. \quad (46)$$

§ 4. General Relations between the Coefficients

From the results obtained in § 3, we have the general relations between the coefficients which hold irrespective of the scattering mechanism and the shape of the energy surface (but which must be cubic). They are

$$\frac{B_{EN}^i}{\kappa_T} = \frac{A_E}{T}, \quad (47)$$

$$\frac{RB_{EN}^i}{A_E B_{RL}} \left(= \frac{R\kappa_T}{TB_{RL}} \right) = \frac{\pi^2}{3} \left(\frac{\kappa}{e} \right)^2. \quad (48)$$

Callen⁵⁾ has shown that Eq. (47) is a general consequence of Onsager's reciprocal relation. From our calculations, it has become clear that (48) is also a most general relation which holds not only for monovalent metals but also for all cubic metals irrespective of the scattering mechanism. It has shown by Meixner⁶⁾ that the relation (48) can be derived if we assume the existence of the relaxation time. Sondheimer⁷⁾ has also shown that (48) holds for the free electron model at all temperatures.

Further we have a relation which holds irrespective of the scattering mechanism,

$$\frac{1}{T} \left(n_H c A_E + \frac{3e}{\pi^2 \kappa^2} S \right) = \frac{1}{f_5} \frac{df_5}{dE} - \frac{2}{f_1} \frac{df_1}{dE}, \quad (49)$$

where

$$n_H \equiv -\frac{1}{Rec}, \quad (50)$$

and we shall call n_H the Hall number of electrons. For a given metal, the right side of (49) is a constant. Therefore, if S/T increases by a change of the scattering mechanism (for instance, change of temperature or doping of small concentration of impurity atoms) in a metal having a negative Hall constants, A_E/T must decrease. This is a generalization of Eqs. (86) and (92) in I.

§ 5. Special Cases

For the scatterings by lattice waves at high temperatures or by impurity atoms, the time of relaxation τ exists and may be approximated to depend only on the energy of the electronic state¹⁰⁾. Then, the solution of the

Boltzmann equation (2) is easily obtained by iteration^{6),11)} and the coefficients of the effects can be calculated exactly up to the terms of desired order of H . On the other hand, we can derive the results up to the linear terms of H from the general formulae obtained in § 4 by putting

$$\mathcal{L}(c) = -\frac{\hbar}{\tau} c(\eta). \quad (51)$$

The results obtained by the variational method for this case is identical with the exact solutions up to the linear terms. This gives a verification of the validity of our variational procedure. The results are as follows,

$$A_E = \frac{4\pi^3 T}{c} \frac{f_5}{f_1^2} \left\{ \frac{1}{\tau} \frac{d\tau}{dE} + \frac{1}{f_5} \frac{df_5}{dE} - \frac{1}{f_1} \frac{df_1}{dE} \right\}, \quad (52)$$

$$B_{EN}^i = \frac{\pi^2 \kappa^2 T \tau}{3 \hbar^2 c} \frac{f_5}{f_1} \left\{ \frac{1}{\tau} \frac{d\tau}{dE} + \frac{1}{f_5} \frac{df_5}{dE} - \frac{1}{f_1} \frac{df_1}{dE} \right\}, \quad (53)$$

$$R_{RL} = -\frac{e\tau}{\hbar^2 c} \frac{f_5}{f_1}, \quad (54)$$

$$\sigma = \frac{e^2 \tau}{4\pi^3 \hbar^2} f_1, \quad (55)$$

$$\kappa_T = \frac{\kappa^2 T \tau}{12\pi \hbar^2} f_1, \quad (56)$$

$$S = -\frac{\pi^2 \kappa^2 T}{3e} \left\{ \frac{1}{\tau} \frac{d\tau}{dE} + \frac{1}{f_1} \frac{df_1}{dE} \right\}. \quad (57)$$

In this case, besides Eqs. (47), (48) and (49),

a relation

$$R\sigma = B_{RL} \quad (58)$$

holds, which is a consequence of Eq. (48) and the Wiedemann-Franz law. Meixner⁶⁾ has shown that (58) holds for any metal (not necessarily cubic) when the relaxation time exists.

Now we consider another special case. If we use the values of d_{rs} given in the appendix of II, the coefficients of pure metals at low temperatures can be derived easily. We write here only the expression of A_E at low temperatures ($T \ll \theta$),

$$A_E = \frac{4\pi^3 T}{cf_1^2 f_2} \left\{ \left(\frac{1}{f_5} \frac{df_5}{dE} - \frac{1}{f_1} \frac{df_1}{dE} \right) f_2 f_5 - f_4 f_5 \right\}, \quad (59)$$

where

$$f_4 = \frac{1}{3} \int \frac{\partial^2 E / \partial n^2}{|\text{grad}_k E|^2} dS. \quad (60)$$

Other coefficients are obtained easily from (47) and (48).

For the spherical band model, (49) reduces to

$$\frac{1}{T} \left(ncA_E + \frac{3e}{\pi^2 \kappa^2} S \right) = -\frac{3}{\alpha k_0}. \quad (61)$$

In I, we have derived (61) for the case of high temperatures, but in this paper it has become clear that this equation remains valid at all temperatures. If we put Eq. (35) of I into (61), we have

$$A_E = \frac{\kappa T}{nc} \frac{\rho_i \left(\frac{1}{\alpha k_0} + \frac{2\beta}{\alpha^2} - \gamma_1 \right) + \rho_0 \left\{ \left(\frac{1}{\alpha k_0} + \frac{2\beta}{\alpha^2} \right) - \frac{3}{\pi^2} \frac{k_0^2}{q_0^2} \frac{1}{\alpha k_0} \left(\frac{\theta}{T} \right)^2 \right\}}{\rho_i + \rho_0 \left\{ 1 + \frac{3}{\pi^2} \frac{k_0^2}{q_0^2} \left(\frac{\theta}{T} \right)^2 \right\}}, \quad (62)$$

where the symbols are identical with those used in I. For the free electron model, (62) reduces to the interpolation formula obtained by Sondheimer⁷⁾. It is seen from (62) that the Ettingshausen coefficients for pure metals which have spherical energy band are always negative at low temperatures. In the case of the thermoelectric power, the simple representations of the parameters α and β of the spherical band approximation given by (47) and (50) in II have hold. For the galvanomagnetic and thermomagnetic effects, however, there are no simple correspondence such as those in the case of the thermoelectric power.

If the band structure of a metal were known

completely, the right side of (59) would be calculated thoroughly, but at present we have no such a complete knowledge about the band structure.

§ 6. Conclusion

Using an approximate distribution function given by (15), we have solved the Boltzmann equation for an cubic metal in the magnetic field by variational method described in § 2. The method gives in principle the exact solution for metals which have the spherical energy band. For cubic metals which have the energy dependent relaxation time, the method also gives exact solution up to the linear terms of the magnetic field. The reason that the

approximate function gives the exact solution in this case is possibly that the coefficients of the effects linear in the magnetic field are the scalar quantities and insensitive comparatively to the anisotropy of the band structure. Therefore the solutions obtained in §3 for the general case may be valid at least semi-quantitatively. This is also a profitable point of the variational method. (See §2 in II.) However, for the effects of the second order in the magnetic field such as the magnetoresistance, our approximation (15) fails. Really if we calculate K_{mn} 's up to the second order of H , we easily see that the magnetoresistance disappears. These effects are highly sensitive to the anisotropy of the band structure, and so to investigate these effects in the case where the relaxation time does not exist, we must use more complicated function ϕ_k instead of (15).

Paramagnetic Resonance in Copper Propionate Monohydrate

By Hidetaro ABE

The Institute for Solid State Physics, University of Tokyo

(Received June 7, 1958)

Paramagnetic resonance absorption was investigated at centimeter wavelength region in single crystals of copper propionate monohydrate $\text{Cu}(\text{CH}_3\text{CH}_2\text{COO})_2 \cdot \text{H}_2\text{O}$.

The spectrum obtained is not a normal one expected for a ^2D state of Cu^{++} ions in crystals but similar to that observed in copper acetate monohydrate $\text{Cu}(\text{CH}_3\text{COO})_2 \cdot \text{H}_2\text{O}$ and more complicated. This spectrum can be explained by an effective spin Hamiltonian with an equivalent spin value $S=1$. This may lead us to a conclusion that each of the magnetic complexes in this crystal consists of a pair of copper ions under a strong interaction and may be created from a bimolecular structure, $\text{Cu}_2(\text{CH}_3\text{CH}_2\text{COO})_4 \cdot 2\text{H}_2\text{O}$ as in the case of the acetate. The unit cell of this crystal contains six spatially inequivalent pairs, of which three can be derived from the others by a reflection in its ac -plane. Each pair of ions in this crystal is considered to be under a very similar environment, except the direction of the pairs. The rhombicity in its crystalline field is smaller than that of the acetate.

§ 1. Introduction

It was considered to be of interest to examine a series of paramagnetic salts by the method of paramagnetic resonance absorption changing their hydration number or chemical composition systematically.

So we had a plan to study the divalent copper salts derived from the series of monocarboxylic acids: copper formate, copper acetate, copper propionate, copper butylate, and so on. The iron group ions have incomplete 3d-shell which is completed by filling up with 10 electrons. Divalent copper ion has 9 electrons in its 3d-shell, so it can be simply considered as having one electron hole in its 3d-shell, giving $^2D_{5/2}$ as the free ion state. When the copper ion is placed in the crystalline solids, interplay of the spin-orbit coupling and the cubic crystalline electric field splits the orbital quintet, resulting a lower orbital doublet and an orbital triplet lying several thousands cm^{-1} higher.

The crystalline electric field with lower symmetry removes the orbital degeneracy completely, remaining the orbital singlet as the lowest which has the Kramers doublet (spin doublet) and can be lifted only by an externally applied magnetic field. Then the resonance field H is proportional to the measuring frequency ν as

$$h\nu = g\beta H \quad (1)$$

without any initial splitting, where h is the Planck constant, β the Bohr magneton, and g the spectroscopic splitting factor. By the existence of upper orbital levels, the g -value is affected to deviate from 2.00, the value for the free electron, through the second order perturbation.

In cases of the usual hydrated copper salts, $g_{\parallel}$, the g -value to be observed when the static magnetic field is applied parallel to the axial direction of the crystalline field, ranges from 2.3 to 2.4 according to the sort of salts and $g_{\perp}$, that to be observed when the magnetic field is perpendicular to this axis, ranges from 2.05 to 2.10.

In copper acetate, however, anomalous paramagnetism was found in its static susceptibility,^{1),2)} paramagnetic resonance absorption,^{3),4)} and optical dichroism.⁵⁾ All of the anomalies can be explained by an interesting atomic configuration in its crystal structure which was afterwards clarified by its x -ray analysis.⁶⁾ Copper acetate monohydrate $\text{Cu}(\text{CH}_3\text{COO})_2 \cdot \text{H}_2\text{O}$ has a bimolecular character in its crystalline state which can be thoroughly expressed as $\text{Cu}_2(\text{CH}_3\text{COO})_4 \cdot 2\text{H}_2\text{O}$. As for the paramagnetic resonance spectrum observed in the single crystals of the copper acetate, there appear many lines to be not described by the usual resonance condition, Eq. (1), for the copper ion, but by an energy scheme with an

initial splitting as in the case of Ni^{++} ion.

Copper propionate monohydrate, studied by the method of paramagnetic resonance, also showed many lines in its single crystals, which can not be described by the ordinary resonance condition, equation (1). In powdered sample of this crystal prepared by crashing single crystals, a very broad absorption line was observed. Fig. 1. is a derivative curve observed

Fig. 1. Derivative curve of the paramagnetic resonance absorption observed at 3.2 cm wavelength in a powdered sample of the copper propionate monohydrate.

at $\lambda=3.2$ cm. Since this curve observed in the powered copper propionate differs from that of usual copper salts and well resembles to that of copper acetate, the circumstances similar to that of copper acetate may be expected in this crystal. In this paper, the results of analysis obtained in the copper propionate monohydrate through paramagnetic resonance will be reported, the preliminary part of which has reported elsewhere.⁷⁾

§2. Samples

Single crystals of this substance can be obtained by slow vaporization from aqueous solution of the reagent.

The sample is very stable both in crystalline state and in solution with slightly excess propionic acid. The colour of this solution is dark emerald green. Seed crystals were at first placed at the bottom of a glass vessel containing the solution. More perfect crystals were prepared by hanging a seed crystal with nylon filament in the middle part of a vessel filled with saturated solution of about 500 cc. Some of these vessels were placed in a rough air-thermostat or in a shady room. Single crystals thus obtained have a linear dimension of about 10 mm.

In order to determine the hydration number of these crystals, some of them were crashed

and kept in a branched glass tube.⁸⁾ This vessel was then evacuated, sealed off and warmed moderately at one end of the branch in which the sample was contained. Water which condensed at the other end was measured showing that this crystal is monohydrate.

The colour of this crystal is dark green. Crystallographic data observed by an optical method showed that the well-developed surfaces in our crystals are in good agreement with those described by Groth.⁹⁾ The symmetry is monoclinic with parameters $a:b:c=0.874:1:0.886$ and $\beta=94^\circ 22'$. They do not show twinning character while in copper acetate all the crystals examined were twins. The $\{110\}$ plane develops easily to show frequently an external form like a prism as shown in Fig. 2. It is softer and has a more wax-like touch than the copper acetate. Thus it is rather easy to cut and grind large single crystals to obtain suitable specimens of disk-shape.

Fig. 2. Typical crystal form of the copper propionate monohydrate.

§3. Experimental Apparatus

i) General arrangement of the measuring apparatus

Measurements described in this article were performed all at room temperature and mainly at wavelength of about 10.35 mm, although some works were later carried out at the other wavelengths to check the results obtained at this wavelength.

The experimental method at each wavelength is essentially the same which is usually called the field modulation method with a

transmission-type cavity.

The block diagram of the measuring apparatus is shown in Fig. 3. Microwave power of a constant frequency and at a constant level is fed through attenuators to a loosely coupled cavity containing the sample crystal and tuned at the frequency used. Completeness of this tuning affects the final results and can be easily obtained by the procedure described in the part iii) of this section. Power coming through the cavity is then detected by a crystal detector.

Fig. 3. Block diagram of our spectrometer.

The cavity is placed between pole-pieces of an electromagnet. Modulation field of about 31 cps. is superimposed to the static magnetic field. When the d.c. component of the magnetic field H comes near to that giving a resonance condition, a part of the output voltage across the crystal detector changes with 31 cps by an amount proportional to dA/dH where A means the magnetic absorption. This a.f. output voltage is amplified and read by a phase-sensitive detector giving the derivative curve of the absorption lines.

ii) Components of the apparatus

a) Microwave source

Microwave powers of $\lambda=16, 10$ and 8 mm were supplied by harmonics multipliers described elsewhere¹⁰⁾ to which the power of fundamental frequency ($\lambda=3$ cm) was fed by a 2K25-type klystron.

The electron beam in the klystron is affected by the stray field from the electromagnet and the associated frequency shift makes the measuring cavity slightly detune, bringing some error in the absorption intensity. In our case, distance of 1.5 m between the klystron and the center of electromagnet makes this

effect negligibly small.

The heater voltage for this klystron is supplied by a storage battery and voltages for cavity and repeller electrodes by an electronically stabilized eliminator source which is mainly aimed at the reduction of voltage changes caused by fluctuation in the a.c. line voltage. Since it was constructed for the use of preceeding works on copper acetate using the d.c. galvanometer method, its stability is enough to the present case of the field-modulation method.

b) Cavity resonator

The sample cavity is made of non-magnetic brass. If it is magnetic from impurities or it contains traces of iron, mechanical deformation of the waveguide system caused by a torque acting on the cavity from the applied magnetic field brings the cavity out of tune. This brings a gradual ghost deflection to the output meter reading, perhaps because of a combined effect of mechanical deformation and vibrations of the cavity synchronized with 31 cps modulation.

This ghost deflection also comes from some other reasons, e.g. leakage of modulation voltage or its induction by an improper earth connection.

This ghost may be, in some cases, taken away by inserting soft pieces of insulating damper in the gaps between cavity and pole-pieces or by rigid setting of the waveguide system accompanied by the appropriate ground at the whole system.

The cavities for measurement are of ordinary rectangular type.¹¹⁾ They have thin side-walls ($1\sim 2$ mm) faced at the pole-pieces in order for the modulation magnetic field to penetrate effectively in it. It is excited either in H_{101} or H_{102} mode and connected to two waveguides through circular coupling windows placed at side-walls other than mentioned above. Adequate coupling is attained by displacement of the plunger with the sample relative to the coupling windows being tuned by adjusting the other (tuning) plunger. Both plunger pistons have quarter wave choke sections. The tuning plunger has a moving mechanism of micrometer screw unit, by which the cavity tuning is roughly performed. Precise adjustment is then carried out by changing the movable part of its "vernier section". This vernier section is built in the tuning

plunger at its central axis and has a shape of cylindrical rod whose cross-area is about $1/10 \sim 1/20$ of that of plunger piston.¹²⁾

c) Electromagnet

The static magnetic field is produced by an electromagnet designed by Prof. Kumagai which has a weight of about one ton. It has pole-pieces of chopped-corn shape inside the frames for the exciting coils.¹⁴⁾ It is excited by a set of storage batteries which is provided only for its use to avoid fluctuations from external origins. As the sample cavity has different dimensions according to its frequency band, gap distance of the electromagnet is varied according to the measuring frequency. By this procedure, the exciting current to observe an absorption at $g=2$ remains $3 \sim 4$ amp, and only about 150 watt is necessary for all frequencies used.

d) Field Modulator

The frequency of field modulation was settled at about 31 cps in order to avoid the interference between signals and hum components of a.c. line voltage ($48 \sim 50$ cps.) at the phase-sensitive detector. Sinusoidal voltage of about 31 cps is generated by an usual a.f. oscillator with an RC feed back linkage. It is fed to a tuned a.f. power amplifier through one stage of buffer and one stage of driver. Final stage is an 807 push-pull amplifier operating at AB_2 -class. Its a.f. power out-put is 120 watts at maximum operation with an out-put transformer tuned in its primary circuit at 31 cps and matched for the modulation coils with its secondary taps.

The modulation coils (each 400 turns) are wound rigidly on a pair of aluminium spools which are placed at the top of pole-pieces. If the setting of these coils is not rigid, they come to vibrate when the magnet produces a high enough static field. The microwave power modulated directly by the mechanical vibration in microwave circuit makes shift the zero point of detector meter. This is one of the origins of fluctuation which decrease the final effective S/N ratio, though the direct leakage, if any, of the modulation voltage to the input circuit of amplifier prevents severely the measurements.

e) Amplifiers

The a.f. component appeared across the detector crystal diode is amplified by a 4-stage

amplifier having low-pass characteristics (upper limit of the pass-band is about 100 cps.) and maximum gain of 120 db at 31 cps. Its output voltage is partly introduced to a monitor C.R.O. and, after amplified by one stage of ordinary amplifier, to a phase-sensitive detector (P.S.D.) of Schuster type¹⁸⁾ with a slight modification.

An electronically tuned high- Q circuit named as "selectoject" was also prepared, having band width of order one cycle at 31 cps. In general, a reduced band-width of amplifier is desirable for a higher S/N ratio in the spectrum. In our present case, however, this narrow-band a.f. circuit was not used in the final measurements because of two reasons. (1) It is not a poor S/N ratio of the spectrometer but the finite width of the absorption lines superimposed on each other to prevent the analysis of experimental results in our crystal. (2) The band width of the whole spectrometer can be reduced, providing the cross modulation from the noise voltage is negligible, by the time constant of the P.S.D., so a simple high-cut amplifier is more favorable and a circuit which is too sensitive to phase is rather ineffective to reserve the stability of the whole system against a drift of the modulation frequency.

iii) *Tuning procedure of the measuring cavity*

In order to determine the correct resonance peak of absorption line with a phase-sensitive detector, it is required that the measuring cavity is just in tune. This is easily attained by the following procedures. Very small portion of 31 cps voltage from the master a.f. oscillator is fed to the repeller electrode taking care of giving as minor change as possible in the static operating condition for the klystron. A small 31 cps component then appears in the monitor C.R.O. whose horizontal axis is swept by the modulation voltage after a proper phase adjustment. The cavity resonator is tuned when the 31 cps Lissajous figure becomes symmetric around the vertical axis. The following procedure is the reduction of the modulation voltage fed to the repeller electrode which may be accompanied by a slight variation in the static operating condition in the klystron bringing a slight change in frequency. The cavity is then retuned to the newly settled frequency by adjusting its vernier piston of

the main plunger of the cavity. The successive retuning procedure can be also attained by changing the repeller voltage by means of a vernier rheostat in the control circuit of the stabilized power supply, which causes a shift in the frequency. By these procedures, the 31 cps. Lissajous in C.R.O. becomes comparable to the noise voltage. The phase-sensitive detector is then used as the monitor to decide the cavity tuning. When these procedures are finished, the part of the circuit branch provided for this 31 cps. source modulation, which is shown by a dotted line in the block diagram, is removed at the beginning of each run, in order to avoid undesired source modulation by stray 31 cps. voltage. If the frequency change is considered to be appreciable after these adjustments, a check in the frequency is required which can be replaced by measuring the resonance field of the marker radical (DPPH).

This method of tuning the cavity is more sensitive and easy than the usual method using a *dc* rectified current of detector as an indicator.

§ 4. Experimental Procedures and Result

i) Preliminary Discussion of Spectra with Copper Acetate as an Example

One of the single crystals is ground to obtain its *ac*-plane from its external form and attached to the rotatable mount by this ground "*ac*-plane" with polystyrene cement. By rotation of the mount, the direction of static magnetic field H may rotate in the "*ac*-plane" of this crystal.

In the first place, let us mention the result of copper acetate as a simpler example. When the static magnetic field H is applied in the *ac*-plane of copper acetate, two absorption peaks are observed at higher values of magnetic field H . Although one more absorption line appears at lower magnetic field which has an apparent g -value of about 4 at shorter wavelengths, it is omitted for the time being from our discussions. When the magnetic field H is rotated in the *ac*-plane, the former two peaks give a pair of lines shown as two thick lines in Fig. 4, which we will call line (a) and (b). They are expressed as functions of angle φ , here φ being the angle between the *c*-axis and the direction of H . This pair of lines gives a extremum at angle $\varphi = \psi$, where

ψ is measured from the *c*-axis towards the *a*-axis.

Then a plane is ground out which intersects perpendicularly the *ac*-plane making an angle with the *bc*-plane. This plane is here called as "perpendicular plane". Then the static field is rotated in this perpendicular plane, the direction of which is expressed by an angle ξ measured from the *ac*-plane as in Fig. 5. Each line observed in the *ac*-plane

Fig. 4. Schematic expression of peak positions of resonance absorption as a function of direction of static magnetic field in a simplest case of one pair per unit cell, e.g., copper acetate.

Fig. 5. Definition of the angles.

splits into two lines as shown in Fig. 4. Two of these four lines give their extreme values at the direction of static field, $\xi = \pm \alpha$.

These behaviours of the spectrum are well explained by an effective spin-Hamiltonian³⁾

$$\mathcal{H} = [g]\beta\vec{S}\vec{H} + DS_z^2 + E(S_x^2 - S_y^2) \quad (2)$$

under the condition of $S=1$. Here x , y and z denote the axes of the crystalline field for

one unit, where z -axis is that of the predominant tetragonal field. Copper acetate contains two inequivalent units. The directions of the z -axes for these units are expressed by $\varphi = \psi$, and $\xi = \pm\alpha$. The y -axis is so chosen that it is within the ac -plane at $\varphi = \psi + 90^\circ$.

Assuming the first term in Eq. (2), the Zeeman energy, is sufficiently predominant compared with the other terms, perturbation treatment gives the following resonance fields in the perpendicular plane which contains the z and x axes.

$$\left. \begin{aligned} h\nu &= \Delta w_{(+1 \rightarrow 0)} \\ &= g\beta H + D/2 \cdot (3p^2 \cos^2 \theta - 1) \\ &\quad + 3E/2 \cdot (q^2 \sin^2 \theta) + \Delta w'' \\ h\nu &= \Delta w_{(0 \rightarrow -1)} \\ &= g\beta H - D/2 \cdot (3p^2 \cos^2 \theta - 1) \\ &\quad - 3E/2 \cdot (q^2 \sin^2 \theta) + \Delta w'' \end{aligned} \right\} \quad (3)$$

where

$$\left. \begin{aligned} p &= g_{\parallel}/g \\ q &= g_{\perp}/g \end{aligned} \right\} \quad (4)$$

Here θ means an angle between the static field H and the z -axis and $\Delta w''$ means a term from the second order perturbation which may be neglected in our present case, because it is estimated to be 180 oer. at its

maximum value which occurs at $\theta \simeq 45^\circ$.

ii) Results in Copper Propionate

a) Observation in the ac -plane

A single crystal of copper propionate is ground to have its ac -plane as in the former case and put under observation. An example of the meter reading of phase sensitive detector is shown in Fig. 6, when H is in the

Fig. 6. Results in the perpendicular plane at $\varphi = 106^\circ$. The arrows indicate the positions of resonance peaks at $\xi = 0^\circ$.

ac -plane and $\varphi = 106^\circ$. The wave-length of the measuring microwave is about 10.35 mm. The arrows in the downward part indicate positions of absorption peaks at $\xi = 0^\circ$ showing that there are six peaks. One more broad

Fig. 7. Peak positions of resonance absorption in the ac -plane of copper propionate as a function of the angle of rotation about the b -axis. The angle φ means direction of the static magnetic field measured from the c -axis towards the a -axis. The solid curves are calculated by equation (2) with the parameters listed in Table I, the circles the experimental points.

Fig. 8. Positions of resonance peaks in the perpendicular plane ($\psi=105.5^\circ$) of the copper propionate monohydrate. Circles indicate the observed values and solid curves the calculated ones using the parameters listed in Table I.

absorption peak, however, appears at lower most magnetic field, as in the case of copper acetate, which has an apparent g -value of about 4 and does not depend approximately on the direction of H . It may be omitted from our present discussion.

These six peaks form three pairs of curves when H is rotated in the ac -plane. One of results is shown in Fig. 7 where plots represent the magnetic fields of measured peaks. We shall label three pairs as pair (1), (2) and (3) as shown in the figure. We shall call the angle φ , at which one of the three pairs of curves shows the extreme resonant field, the angle ψ . ψ were observed to be 105.5° , 158.5° and 176° respectively which are indicated by thick arrows in Fig. 7.

b) Observation in the "Perpendicular Planes"

Single crystals are ground to give one of "Perpendicular planes" which are defined in the case of copper acetate: Planes intersect perpendicularly with the ac -plane at angles ψ . At first, H is rotated in one of the perpendicular planes, e.g., in that of pair (1); $\psi=$

105.5° . Each curve belonging to this pair (1) in the ac -plane splits into two lines as shown in Fig. 8 where plots are the measured values and curves are the calculated ones with equation (2) using parameters in Table I. By the same treatments, results on the pairs (2)

Table I. Parameters for the Hamiltonian (2) as giving the best fit to the observed values.

	Copper Propionate			Copper Acetate

g_z	2.36 ₈	2.36 ₀	2.36 ₈	2.34 ₄
g_x	2.11 ₁	2.10 ₀	2.10 ₂	2.05 ₃
g_y	2.09 ₀	2.08 ₂	2.10 ₀	2.09 ₃
α (degree)	28.5	16.0	54.0	33
ψ (degree)	105.5	158.5	176.0	-34.5 ± 1.5 (145.5 ± 1.5)

Error in the copper propionate is $\pm 0.007 \text{ cm}^{-1}$ in D and ± 0.015 in g 's.

Fig. 9. Positions of resonance peaks in the perpendicular plane ($\psi=158.5^\circ$) of the copper propionate monohydrate. Circles indicate the observed values and solid curves the calculated ones using the parameters listed in Table I.

and (3) are shown in Fig. 9 and Fig. 10. Again the agreements between the calculated curves and the plots of measured values are fairly good. Parameters of the pairs listed in Table I are thus obtained. Using these parameters, resonant fields in the ac -plane can be calculated. Curves in Fig. 7 are thus obtained and their agreements with the plots (the measured values) are again satisfactory. Actually, all the parameters, especially the angle α , are adjusted to give the best fit with the results in these four sorts of planes.

As shown in Fig. 4, the higher and the lower resonance fields at directions of z , x and y axes are called as h^z , h_x , h^z , h_x , h^y and h_y , respectively. The two resonance fields observed when H is in the ac -plane and $\varphi=\psi$ are called h^{ao} and h_{ao} . The observed values of these quantities are listed in Table II. Differences between the observed values and the calculated ones by Eq. (3) using parameters of Table I are also listed in this Table. Maximum difference at axial directions reaches to 60 oer. As shown in Fig. 8, the two curves

belonging to the same "pair" intersect each other at two values of the angle φ in the ac -plane. In other words, at two directions of the applied field H in the ac -plane, the

two resonance fields, $H_{+ \rightarrow 0}$ and $H_{0 \rightarrow -}$, coincide, which are demanded by two transitions between three levels of the same "pair". $\Delta\varphi$ in the Table II means the angle between the two directions described above. This angle difference $\Delta\varphi$ is, in some cases, very sensitive to the determination of angle α . In the pair (3), change of one degree in α brings a change of 7° in $\Delta\varphi$, which is only 55.5° in this pair. $\Delta h_{ao} = |h^{ao} - h_{ao}|$ is also severe check for the angle α . One degree in α , in the pair (3), gives a change of 180 oer in $|h^{ao} - h_{ao}|$ which is only 790 oer in this case.

iii) Experimental Errors

In determination of resonance field, errors may appear from following origins: (1) Cutting of sample crystal, (2) Tuning of the cavity, (3) Reading of exciting current of the electromagnet and its conversion to the strength of magnetic field, (4) Superposition of undesired peaks from the other pair to the peak in question, and (5) Fluctuations of phase-meter from the noise or unstability.

Errors from these origins can be estimated as follows.

(1) In the axial directions of a magnetic unit, the mis-cutting of crystals does not affect appreciably the determination of resonant fields because they change with *cosine* of the angle, around the extremum, as shown by Eq. (2). In our case, change in peak position is only about 7 oer. from an error of 2° in θ which may be considered our maximum value of mis-gridding. So errors in our cutting process does not affect the final results of g and D , since these values are initially determined through resonance fields observed at the directions of the principal axes of a magnetic unit.

Error in h_y or h_{ao} from this origin may be smaller than the linewidth and included in (4), because h_y , h_{ao} etc. are measured in the ac -plane which is a symmetry plane. Large mis-cutting in the ac -plane is easily discovered because a peak in the normal ac -plane splits into peaks. The line width of these peaks is

a very sensitive measure, especially in the case of some peaks belonging to the pair (3), of the correctness in which our "*ac*-plane" is ground, because it shows a tendency to become larger even if the direction of *H* deviates from the *ac*-plane by a fraction of the degree.

(2) If the tuning procedure described in § 3, iii) is adopted, error from the detuned cavity in the field modulation method becomes, in our case, smaller than that of origin (3), so it may be neglected. It is checked by experiments that the detune of cavity from the long time instability brings about 30 oer deviation in peak position with 30 min. Dispersion of the sample does not affect the cavity tuning at the peak position.

(3) The exciting current of the electromagnet is read by a precision type milivoltmeter with a proper shunt resistance. Minimum possible reading is 3 mA at 5A range which corresponds to 9 oer at 10,000 oer. Magnetic field *H* was calibrated by the proton resonance method as a function of exciting current *I*. The calibration curve thus obtained is near to a straight line in the range of magnetic field required for the present work for each frequency. The maximum deviation from the linear relation was about 40 oer., in the range of magnetic field used at $\lambda \simeq 10$ mm. The origin of this deviation may be mainly ascribed to the inhomogeneity in meter scaling, which was concluded by a comparison between calibrations for two shunt resistances.

(4) Since the absorption lines are expected to split into twelve peaks at a general direction of magnetic field and they have widths of 350~450 oer, more than one peak may fall on a same magnetic field. Superposition of undesired peaks belonging to the other "pair" makes the determination of either peak position difficult and inaccurate, and in sometimes makes it impossible. In the "perpendicular" planes, this effect brings sometimes severe difficulties in the determination of peak positions. In Fig. 8~10, in fact, some peak positions are omitted which must belong to the pairs other than that in question, in order to avoid confusions. In all cases, however, of determination of resonance peaks listed in Table II, peaks to be determined are free from this effect of superposition, around the region giving their extremum values.

Then the sum of experimental errors from above-mentioned origins reaches to 0.3~0.6% of *g*-values. As for the six resonance fields appeared in the upper part of Table II, the omission of the second order term $\Delta w''$ in the Equation (2) brings no effect, since this term disappears at the axial directions. In determination of *D*, $\Delta w''$ brings no effect. The observed resonance fields, as shown in Table II, remains in the all cases within the estimated limit of error, 60 oer., from the calculated values.

§ 5. Discussions

The four figures (Figs. 7~10) show that the observed peak positions can be well fitted by three sets of Equation (2) with parameters given by Table I, namely, the paramagnetic resonance spectra observed in the copper propionate monohydrate satisfy eigenvalues of three sets of spin-Hamiltonian of the form of Eq. (2) having parameters shown in Table I.

In the case of copper acetate monohydrate, the results of *x*-ray analysis⁹⁾ show that it is formed by constituents with bimolecular character expressed as $\text{Cu}_2(\text{CH}_3\text{COO})_4 \cdot 2\text{H}_2\text{O}$ in which two copper atoms make direct Cu-Cu contact of 2.6 Å apart. Comparison of the result of paramagnetic resonance spectra with that of *x*-ray analysis has given a knowledge that the axial direction, the *z*-axis of the tetragonal crystalline field, coincides with the direction joining the two copper atoms in pair.

So we can dare to conclude in the present case of copper propionate monohydrate, without the knowledge of the *x*-ray analysis, that this crystal consists of bimolecular constituents which can be expressed as $\text{Cu}_2(\text{CH}_3\text{CH}_2\text{COO})_4 \cdot 2\text{H}_2\text{O}$ from the results of paramagnetic resonance spectra alone. Then, there are six magnetic constituents, from the viewpoint of paramagnetic resonance, in the unit cell of copper propionate which are spatially inequivalent, whereas there are two in the copper acetate. In both cases, the half of them can be derived from the other by reflection in the *ac*-plane. As shown in Table I, the parameters *g*, *D*, and *E* to be used for three pairs well resembles to each other and are similar to those of the copper acetate.

By an analogy to the case of copper acetate, this constituent of magnetic unit in copper propionate may be illustrated as follows;

either of two copper atoms is surrounded by a distorted octahedron of four atoms of oxygen, from four carboxylic acids, one oxygen from molecule of H_2O , and the other copper atom which may be at a distance of order $2.6 \text{ \AA}$.

The direction joining the copper ions may be indicated by angles ψ and α in Table I referred to the crystallographic axes, three others being deduced by mirror reflection with the ac -plane.

The copper atoms in this crystal are influenced by a tetragonal crystalline field within a good approximation since the g tensor has an axial symmetry and E is nearly zero compared with its D value. It can be, therefore, concluded that the atomic configuration of the constituent has a good tetragonal symmetry.

§ 6. Conclusions

Following a plan taken up in 1951, our group has worked out the study of paramagnetic resonance absorption in single crystals of copper salts derived from the series of monocarboxylic acids; copper formate, copper acetate, copper propionate and so on.

Copper formate has its dihydrate $\text{Cu}(\text{HCOO})_2 \cdot 2\text{H}_2\text{O}$ and its tetrahydrate $\text{Cu}(\text{HCOO})_2 \cdot 4\text{H}_2\text{O}$. In both cases, it was observed¹⁶⁾ that single crystals show a single absorption peak given by Eq (1), as in copper Tutton salt or in copper sulfate, which can be explained by an application of ordinary crystalline field theory to the ^3D state of Cu^{++} ions and of exchange interaction.

In copper acetate, the spectra shows an anomalous behaviour. It can be explained not by an ordinary Cu^{++} ion under an influence of crystalline electric field but by cluster of pairs of copper atoms within a bimolecular constituents $\text{Cu}_2(\text{CH}_3\text{COO})_4 \cdot 2\text{H}_2\text{O}$. In a pair, two copper ions have a direct contact in each other located at $2.6 \text{ \AA}$ apart.

In copper propionate, there are six inequivalent magnetic constituents in unit cell, each of which has a bimolecular character similar to that of copper acetate.

We continued experiments beyonds the copper salts of normal butylate. By our preliminary results, the main resonance line of single crystals of this salt appeared to have a large width which can be ascribed to superposition of many absorption lines. At

$\lambda \doteq 3 \text{ cm}$, an absorption peak can be clearly resolved at about zero magnetic field. It may be concluded that the crystal of copper normal butylate consists of, at least contains, bimolecular units, each of which obeying spin-Hamiltonians similar to the Equation (2). The number of inequivalent constituents in unit cell may be larger than the case of copper propionate, which causes the difficulty in analysis of the main line. The preliminary results of x -ray analysis shows that unit cell of this crystal contains 32 formula molecules.

Moreover, paramagnetic resonance of copper monochloroacetate shows that this crystal also consists of bimolecular constituents.

§ 7. Acknowledgements

The author wishes to express his sincere thanks to Professor Hiroo Kumagai for his continuous guidance and encouragement. He is grateful to many of his colleagues for helpful discussions, especially to Mr. J. Shimada and to Profs K. Ôno and I. Hayashi. He also wishes to thank Mr. Osafune of the Nihon Electric Co., Ltd. for a part of silicon wafers and Prof. R. D. Myers for the marker radical.

Variation of Hall Coefficient of Some Non-ferromagnetic Superlattice Alloys

By Kiyoshi YONEMITSU and Takao SATO

Department of Physics, Tokyo Metropolitan University

(Received March 22, 1958)

The temperature dependence of Hall coefficient of five superlattice alloys of Cu_3Pd , CuZn , Ni_3Cr , Au_3Cu and Ag_3Mg was measured to find the effect of order-disorder transformation upon it. At the transition temperature, the Hall coefficient of Cu_3Pd and Ag_3Mg showed a discontinuous change, while the change of Hall coefficient of other three alloys (CuZn , Ni_3Cr , Au_3Cu) are very small. Applying Muto's theory, the qualitative discussion was made, and it was found that the general features of the temperature dependence of CuZn and Ni_3Cr are well understood by the theory. For Au_3Cu , the result of the experiment is explained by adopting the assumption of Schubert that each Au atom affords more than one electrons into the conduction band. The assumption also explains why the temperature dependence of Hall coefficient of Au_3Cu differs from that of Cu_3Au .

It remains unknown why Hall coefficient of Cu_3Pd takes strong minimum at transition temperature, while the abrupt increase of the Hall coefficient with the decreasing temperature below T_c can be explained by the existence of a superzone in the ordered state. In addition, the result Ag_3Mg is contrary with that which Nicholas's theory suggested.

§ 1. Introduction

It was suggested by Slater¹⁾ that the electronic energy plays an important role when some kind of superlattice alloys undergoes the order-disorder transformation. According to Salter, the problem is explained by a rather simple band model; i. e. by considering the suppression of Fermi surface and the lowering of electronic energy in the ordered state. The suggestion was applied to a few superlattice alloys by Nicholas²⁾, who tried to show the effect of suppression of Fermi energy on order-disorder transformation of these alloys. To which extent one can proceed with this rather simple model is not clear, and from this point of view, it will be of some use to know the electrical properties of these alloys.

In 1938, Muto³⁾ predicted that a drastic change in electrical and magnetic properties of these alloys should be expected at the transformation temperature. The prediction was proved to be true by Komar and Sidrov⁴⁾, who had measured Hall coefficient and magneto-resistance coefficient of Cu_3Au . The measurement was held at room temperature, quenching the specimen from high temperatures. The present authors have been measuring Hall coefficient of many superlattice alloys includ-

ing Cu_3Au . The results for Cu_3Au ⁵⁾ and alloys of Mg-Cd system⁶⁾ were previously printed. In the present paper, we will report on the results of measurements on Cu_3Pd , CuZn , Ni_3Cr , Au_3Cu and Ag_3Mg .

§ 2. Preparation of Specimens and Experimental Procedure

Specimens of Cu_3Pd , Au_3Cu , and Ag_3Mg were presented by Mr. M. Hirabayashi and that of Ni_3Cr by Mr. S. Yoshida. To prepare the specimen of CuZn , 99.98% Cu and 99.98% Zn were melted together in a Tammann tube, and then cast into a small plate 2 mm thick.

Table I. Dimension of Specimens

Specimen	Dimension
Cu_3Pd	$18.0 \times 5.5 \times 0.17$ mm
CuZn	$15.0 \times 6.0 \times 0.34$ mm
Au_3Cu	$23.0 \times 6.8 \times 0.087$ mm
Ni_3Cr	$23.0 \times 8.0 \times 0.220$ mm
Ag_3Mg	$22.0 \times 8.1 \times 0.16$ mm

After annealed in the argon vapor for 1 hr at 500°C , the specimen was then polished by sand papers. The dimension of every specimen is shown Table I.

The specimen of Au_3Cu was annealed in the argon vapor for 27 days at 180°C , the next

15 days at 150°C, and the following 30 days at 125°C preceding the measurement. The specimen of Ni₃Cr was annealed for one day at 540°C, the next 6 days at 444°C, and the following 10 days at 390°C in argon vapor preceding the measurement.

In measurements of the Hall coefficient and the electrical resistivity, specimens were set in an electric furnace, which was placed between the pole pieces of an electromagnet. 4 pairs of leads were spot-welded to the specimen; 2 pairs for the Hall potential, a pair for the electrical resistivity, and another pair for primary current. Copper wire 0.2 mm in diameter was used as leads. The temperature of the furnace was controlled by controlling the current of the furnace, and was read by a thermo-couple and a potentiometer. The strength of magnetic field was about 6 kOe. and the Hall potential was measured by a D. C. amplifier and galvanometer, the sensitivity of which was 1.1×10^{-8} volt/ μ A division⁷⁾. The primary current was about 1.5 amp. for Ni₃Cr and about 1 amp. for other alloys.

The measurements of Hall coefficient for Cu₃Pd and Ag₃Mg were carried out while specimens were being cooled from temperature above Curie point, and those for CuZn and Au₃Cu were carried out while they were being heated from room temperature. The measurement of Hall coefficient for Ni₃Cr was held at room temperature for the quenched specimen. This was done so, because on account of high resistivity of Ni₃Cr, Joules heat due to the primary current was apt to disturb the thermal equilibrium of the specimen at high temperature and generate the parasitic thermoelectric potential.

The details of the method of measurements are already described in the preceding paper⁶⁾ and will not be repeated here again.

§ 3. Results

The results are shown in Tabs. II~VI, and in Figs. 1~5. From these figures one can see that fluctuations prevail in the temperature ranges just above and below the Curie point because in these temperature ranges just above and below the Curie point because in these temperature ranges, nucleation and growth or extinction of local orders may occur incessantly, which prevent the specimen from the equilibrium temperature distribution.

The Hall coefficient of Cu₃Pd decreases until the temperature decreases to 470°C, the Curie temperature. Below this temperature the Hall coefficient increases with decreasing temperature, and has a sharp minimum at T_c. The electrical resistivity which was measured simultaneously increases slowly above T_c and decreases abruptly below T_c with temperature decreasing, so that the electrical resistivity

has a slight maximum at T_c . In Fig. 1, two curves are shown, each of which represents the variation of Hall coefficient with different cooling rate. It is desirable to measure the value of Hall coefficient at higher temperature than that which are shown in the figure in order to know the data in perfect disordered state, but this was impossible on account of prevailing fluctuations at higher temperature.

Table IV. Temperature dependence of CuZn . The measurement was done while heating the specimen with the heating rate of

19	7.58 ± 0.11	5.01

At about 180°C, fluctuations increase, and in higher temperature range, Hall coefficient increases toward positive direction with a slight gradient. At room temperature, Hall coefficient of the alloy is -10×10^{-4} e.m.u., and reaches to -8.7×10^{-4} e.m.u. at 350°C. After quenched from 350°C to room temperature, it is nearly equal with that of annealed specimen. However it may be, the variation by temperature of Hall coefficient of Au₃Cu shows a feature much different with that of Cu₃Au; i.e. former shows scarcely any change in transformation, while the latter Hall coefficient is negative in the disordered state and positive in the ordered state.

Fig. 1. Temperature variation of Hall coefficient (a), (b) ((b) after prolonged annealing, see Tab. II) and electrical resistivity (c) of Cu₃Pd.
 $T_0=470^\circ\text{C}$, $\rho_0=28.2 \mu\Omega \text{ cm}$.

Fig. 2. Temperature variation of Hall coefficient (a) and electrical resistivity (b), (c) ((c) after quenched from 352°C to room temperature) of Au₃Cu.
 $T_0=220^\circ\text{C}$, $\rho_0=12.2 \mu\Omega \text{ cm}$.

Fig. 3. Temperature variation of Hall coefficient (a) and electrical resistivity (b) of CuZn.
 $T_0=476^\circ\text{C}$, $\rho_0=15.41 \mu\Omega \text{ cm}$.

The Hall coefficient of CuZn is -0.5×10^{-4} e.m.u. at room temperature, and its absolute value increases quite slowly with the rising temperature. (Fig. 3) There appears a discontinuous change, though very small, at about 440°C , and the absolute value increases about 0.5×10^{-4} e.m.u.. The temperature at which the change occurs in the Hall coefficient, does not agree with that at which a knick occurs in the electrical resistivity measured simultaneously. This was reproducible in repeated experiments.

Fig. 4. Temperature variation of Hall coefficient (a) and electrical resistivity (b) of Ag_3Mg .
 $T_c = 386^\circ\text{C}$, $\rho_0 = 13.5 \mu\Omega \text{ cm}$.

Fig. 5. Hall coefficient (a) and electrical resistivity (b) vs. quenching temperature of Ni_3Cr .
 $\rho_{336^\circ} = 99.0 \mu\Omega \text{ cm}$.

The Curie temperature of Ag_3Mg is 386°C , and just above this, the Hall coefficient is -5.5×10^{-4} e.m.u. (Fig. 4). When the ordering formation begins, the electrical resistivity decreases abruptly, and at the same time, Hall coefficient begins to fall taking a minimum

value, -8.5×10^{-4} e.m.u. at 360°C . Below this temperature, Hall coefficient increases again with the decreasing temperature and at room temperature it reaches to -7.5×10^{-4} e.m.u..

As the experiment was carried out with the quenched specimen of Ni_3Cr , it was impossible to determine the transformation temperature accurately. But as it can be seen from Fig. 5 when the specimen is quenched from 520°C or lower the electrical resistivity is larger than that quenched from 550°C or higher. So, it may be reasonable to think that the order-disorder transformation might take place in the temperature range between 520°C and 550°C . From the figure, it can be shown that the electrical resistivity of Ni_3Cr is larger in ordered than in disordered state like in disordered state like in Au_3Cu . The Hall coefficient is nearly constant, and seems scarcely affected by order-disorder transformation.

§ 4. Consideration

Comparing the above described data with those of Mg-Cd superlattice alloys and Cu_3Au , which have been reported in the preceding reports and by Komar and Sidrov, one will note a distinct difference between them. For the latter, Hall coefficient always increases discontinuously with the ordering formation, while the former shows various feature of changes above and below the transformation temperature.

For instance, Hall coefficient of Cu_3Pd decreases with decreasing temperature, and takes a minimum at that temperature. Below T_c , the Hall coefficient behaves like that of Cu_3Au or Mg-Cd superlattice alloys, though its sign is always negative. Hall coefficient of Ag_3Mg also has a negative sign, but it decreases with the decreasing temperature just below T_c , and has a minimum at the temperature about 30°C below T_c . Other three superlattice alloys show changes that are not so distinct at T_c as others. These variation seems to be explained to some extent by variation of band structure of these alloys.

As Muto predicted, when superlattice alloys transform from random state to ordered state, Brillouin zone splits to form a superzone. If the boundary of the superzone is near the Fermi level, or cross with it, the Fermi surface will be distorted by the superzone, which

must cause some changes in the electrical property associated with the order-disorder transformation.

The change of Hall coefficient of Cu_3Pd below T_c may be interpreted. Since the crystal structure of Cu_3Pd is f.c.c. above Curie temperature, its 1-st Brillouin zone must be like what is shown by the fine line in Fig. 6. Below T_c , it had tetragonally deformed Cu_3Au

Fig. 6. First Brillouin zone of disordered Cu_3Pd and superzone of ordered Cu_3Pd .

type structure, so that its superzone is a distorted dodecahedron which is shown by gross lines in the figure. Of this alloy, the long range order was found by Ogawa, Watanabe and Hirabayashi^{8,9}. The effect of long range order on the superzone is to modify the superzone in a complicated way. It is, however, rather difficult to see the effect of the modification on the electrical property, so that, at present, we will be contented only to examine whether the superzone has any effect on the Fermi surface, and accordingly on the electrical property of the alloy or not.

As palladium is a transition element, it is not clear how many electrons per palladium atom affords into the conduction band. If we assume that it affords 0.6 electrons per atom as nickel, the valency electron concentration (number of conduction electrons per atom) is 0.9. The superzone of the alloy contains electrons nearly equal to one per atom, so that it may be thought that the superzone suppress the Fermi surface, and positive holes must appear in ordered state, thus making Hall coefficient to change in the positive direction. It is not clear why Hall coefficient increases with temperature above T_c . As palladium is a transition element, it is possible that palladium must be contributing to this anomalous behaviour.

The valency electron concentration of CuZn is 1.5, and its 1-st Brillouin zone in random state is a dodecahedron which is surrounded

by $\{110\}$ surfaces and can contain 2 electrons per atom (Fig. 7). The superzone is a cube which is shown in the Fig. 7 by gross lines, and can contain one electron per atom. It is obvious that the superzone has little effect on the Fermi surface, and from this point of view, it is natural that no such drastic change as Cu_3Pd is found at T_c , though there was a small change in Hall coefficient a little below Curie temperature. The reason why such change appears can not yet be explained.

Fig. 7. First Brillouin zone of disordered CuZn and superzone.

It is to be noticed that the temperature dependency of Hall coefficient of Au_3Cu is perfectly different from that of Cu_3Au . If each Au and Cu atom affords one electron into conduction band, it is natural to expect nearly the same behaviour for both alloys, since they have the same crystal structure, though their lattice parameter differ a little. Schubert¹⁰, however, made an interesting assumption that an Au atom affords more than one electrons into conduction band. If we adopt such assumption, the difference between Cu_3Au and Au_3Cu can be easily understood; i.e., if each Au atom affords 1.2 electrons into the conduction band, the valency electron concentration of Au_3Cu is 1.15, while that of Cu_3Au is 1.05. So that, the superzone of Au_3Cu , a dodecahedron that can contain one electron per atom, is nearly filled. The situ-

Fig. 8. Schematic representation of superzone and Fermi surface of ordered Cu_3Au (a) and Au_3Cu (b).

ation for Cu_3Au and Au_3Cu must be such as shown in Fig. 8 schematically. The number of positive holes in Au_3Cu , if they exist in ordered state, may be very small and they give scarcely any effect of the Hall coefficient of Au_3Cu .

The existence of the superlattice structure in Ni_3Cr was ascertained by Taylor and Hinton¹¹. It's resistivity is very high in general and higher in ordered state than in disordered state. Since both Ni and Cr transition elements the valence electron concentration of the alloy can not be determined. If we assume that each Ni atom affords 0.6 electrons and each Cr atom affords one electron into conduction band, the valence electron concentration is 0.7. Since the structure of Ni_3Cr is Cu_3Au type, the superzone of the alloy can contain one electron per atom and will have little effect on the Fermi surface and accordingly on Hall coefficient. Taylor and Hinton attribute the increasing resistivity in ordered state to the $\{110\}$ reflection of the electronic wave, which is in this point of view, rather doubtful.

Fig. 9. First Brillouin zone of disordered Ag_3Mg and superzone suggested by Nicholas.

The change of Hall coefficient of Ag_3Mg is of interest, since it is the only alloy that we have studied, which has Hall coefficient more negative in ordered state than disordered state. The band structure of Ag_3Mg is discussed by Nicholas. According to him, as the alloy has f.c.c. structure in disordered

state, it has the 1-st Brillouin zone which is shown by fine lines in Fig. 9. In ordered state the superzone which is shown by gross lines in the figure appears. The superzone is nearly spherical since the ratio of minimum diameter to maximum one is 1:1.25. The zone can contain 1.32 electrons per atom and the inscribed sphere 1.09. As the valency electron concentration of the alloy is 1.25, Fermi surface must perfectly lie in the superzone. According to Nicholas, the suppression of Fermi level by the superzone results in the lowering of the electronic energy and makes the existence of the superlattice stable in ordered state. If it is so, it is natural to expect Hall coefficient to change in the positive direction when the superlattice is formed. Our result is contrary to the expectation.

Acknowledgements

The authors are indebted to Mr. S. Noguchi for helpful discussion and suggestions. They also express their gratitude to Mr. M. Hirabayashi and Mr. S. Yoshida who have presented specimens to them, and to Mr. H. Nogami for his assistance in measurement.

Study of Metallic Carbides by Electron Diffraction

Part II. Crystal Structure Analysis of Nickel Carbide

By Sigemaro NAGAKURA

Tokyo Institute of Technology, Oh-okayama, Meguro-ku, Tokyo

(Received April 15, 1958)

The crystal structure of nickel carbide, Ni_3C , was studied by the electron diffraction method. The observed intensity showed considerable primary extinction and this was corrected, using Wilson's intensity statistics combined with the theory of primary extinction (S. Nagakura, *Acta Cryst.* **10** (1957) 601). The actual procedure was described in detail and it was concluded that the structure of nickel carbide belongs to the space group $R\bar{3}c$ and nickel atoms occupy $18e$ positions with the parameter $x=1/3$ and carbon atoms $6b$ positions. It was found also that the carbon atoms take a kind of one-dimensionally disordered arrangement in the carbide lattice.

§ 1. Introduction

As a continued work of formation and decomposition of nickel carbide, Ni_3C , reported in Part I¹⁾, the study of crystal structure of the carbide is reported in this paper.

As mentioned in Part I, the electron diffraction method is advantageous in the structure analysis of nickel carbide, since the ratio of the scattering amplitudes of carbon and nickel atoms for electrons is as large as about one-third, while that for X-rays is about one-seventh. However, a serious difficulty in the electron method arises from the effect of dynamical diffraction or primary extinction. The structure proposed in Part I for the carbide seems to be very reasonable from the spacial consideration, but the calculated intensity shows considerable disagreement with the observed intensity, indicating a strong

participation of the primary extinction effect. Recently, Honjo and Kitamura²⁾ gave a method to eliminate the primary extinction effect by extrapolating the observed electron diffraction intensity to zero wave-length. The present author has reported another method to detect and correct the primary extinction effect³⁾. This method is based on Wilson's intensity statistics⁴⁾ and the current theory of primary extinction⁵⁾. The result of its application to nickel carbide showed the proposed structure in Part I to be correct. In the present paper details of the structure analysis are described.

§ 2. Observed Intensity and Proposed Structure

Polycrystalline nickel carbide films were prepared by the method described in Part I.

* Only *M*-reflections are tabulated.

** $\pm$ refer to hkl and hkl , respectively.

Electron diffraction patterns were taken with 40 KV electrons (wave-length $\lambda=0.06 \text{ \AA}$) and the camera length 250 mm. The intensity was measured photometrically up to s ($=2 \sin \theta/\lambda$) $=2.3 \text{ \AA}^{-1}$, utilizing Karle and Karle's method⁶⁾. Fig. 1 shows an example of the intensity curve. The relative intensities of Debye rings were unchanged by inclination of the specimen film against the electron beam, proving that the film had no preferred orientation. The mean particle size of the crystallites, ε , was calculated to be 290 $\text{\AA}$ from the half-breadth of the rings, β ,

Fig. 2. Comparison of P_0 (open circles) and P_e (crosses), which are normalized at (1129) ring.

utilizing the equation $\varepsilon=\lambda/\beta \cos \theta$, where θ is the Bragg angle. Integrated intensities per unit length of the Debye rings, P_0 , were evaluated by measuring the peak area of the intensity curve. The overlapping rings were divided into the components assuming the same half-breadth of each component. The intensities of very weak rings were estimated visually. In Fig. 2, P_0 are plotted by open circles. The square roots of the observed intensities, $\sqrt{I_0}$, are tabulated in Table I.

As mentioned in Part I (§ 3.1), the observed reflections are classified in three groups, M -, s - and f -reflections. The M -reflections are sharp and strong and indexed by the c.p.h. lattice proposed by Jacobson and Westgren⁷⁾ with the lattice constant

$$a_h=2.628 \text{ \AA}, c_h=4.306 \text{ \AA} \text{ and } c_h/a_h=1.638.$$

The s -reflections are weak and broad and

can be indexed, together with the M -reflections, by the hexagonal cell

$$a=\sqrt{3} a_h=4.553 \text{ \AA}, c=3c_h=12.92 \text{ \AA}$$

and

$$c/a=2.837,$$

which is a super-lattice of Jacobson and Westgren's lattice and contains 18 nickel and 6 carbon atoms. From the observation described in Part I (§ 3.1), the f -reflections are concluded to be the forbidden reflections caused by the multiple reflection and are aside from the following consideration.

Indices of the observed reflections based on the super-lattice satisfy the conditions

$$hkil: -h+k+l=3n,$$

$$\bar{h}kil: l=3n,$$

where n is an integer*. The possible space groups satisfying the above conditions are $R3c$ and $\bar{R}3c$. Here, we assume the space group $\bar{R}3c$ having the centre of symmetry. The appropriate atomic positions are as follows:

$$(0, 0, 0; 1/3, 2/3, 2/3; 2/3, 1/3, 1/3) +$$

Ni atoms: $18e, +(x, 0, 1/4; 0, x, 1/4;$

$\bar{x}, \bar{x}, 1/4; \bar{x}, 0, 3/4; 0, \bar{x}, 3/4; x, x, 3/4),$

C atoms: $6b, +(0, 0, 0; 0, 0, 1/2).$

If nickel atoms take the c.p.h. arrangement, the parameter x should be $1/3$. The structure is illustrated

in Fig. 11. The structure amplitudes are given by

$$(i) -h+k=3n, l=2n' \text{ (M-reflection)}$$

$$F_{hkl} = 6f_{Ni} \left\{ \cos \frac{2\pi}{3} h + \cos \frac{2\pi}{3} k + \cos \frac{2\pi}{3} l \right\} \cos \frac{\pi}{2} l + 6f_C, \quad (2.1)$$

$$(ii) -h+k=3n, l=2n'+1 \text{ (M-reflection)}$$

$$F_{hkl} = 6f_{Ni} \left\{ \sin \frac{2\pi}{3} h + \sin \frac{2\pi}{3} k + \sin \frac{2\pi}{3} l \right\} \sin \frac{\pi}{2} l, \quad (2.2)$$

$$(iii) -h+k \approx 3n, l=2n' \text{ (s-reflection)}$$

$$F_{hkl} = 6f_C, \quad (2.3)$$

* The first relation is the rhombohedral condition. The lattice constant referred to the rhombohedral axes are $a_0=5.505 \text{ \AA}$ and $\alpha=53^\circ 39'$. The unit cell contains 12 nickel and 4 carbon atoms.

$$(iv) -h+k \approx 3n, l=2n'+1$$

$$F_{hkl} = 0, \quad (2.4)$$

where, f_{Ni} and f_C are the scattering amplitudes of nickel and carbon atom, respectively. It should be noted here that the s -reflections are contributed only from the carbon atoms. From diffraction patterns of single crystalline carbide films (Part I, Photo 4) it can be proved that the broadening of the s -reflections is due to the elongation of the intensity region along the c^* -axis in reciprocal space. This will be discussed in relation to the stacking order of carbon layers in the crystal at the end this paper (§ 7.2).

§ 3. Preliminary Comparison between Observed and Calculated Intensities

The integrated intensities per unit length of Debye rings

$$P_o = \text{const} \cdot j |F_c|^2 / s^2,$$

where j is the multiplicity factor and F_c is the calculated structure amplitude, were calculated utilizing the equations (2.1)~(2.4)* and compared with P_o . Fig. 2 shows the comparison, where P_o and P_c are represented by open circles and crosses, respectively, being normalized at a medium strong ring (1129). The agreement between P_o and P_c is bad with the reliability factor as large as 45%, though the calculated intensities for some other trial structures showed far larger discrepancies.

Fig. 2 reveals that (i) the magnitudes of P_o and P_c are parallel, (ii) generally speaking, $P_o < P_c$ for lower order reflections while $P_o > P_c$ for higher order reflections, and (iii) the discrepancies are especially remarkable for the reflections having high intensities.

As the atomic scattering amplitude for electrons increases rapidly with decreasing scattering angle, the magnitude of structure amplitude is, on the average, larger at lower angles. Since the effect of primary extinction is stronger for the reflections having larger structure amplitudes, the effect should be, on the average, stronger at the lower order reflections. Thus, the observed relations in Fig. 2 between P_c and P_o are most likely to be due to the primary extinction effect.

* Values of f_{Ni} and f_C were calculated from the equation (4.3) using the values of $f_{X,Ni}$ from James-Brindley's table and $f_{X,C}$ from Mac-Weeny's table.

§ 4. Detection of Primary Extinction by Intensity Statistics

Wilson⁴⁾ pointed out that the local average of X-ray diffraction intensities $\langle I \rangle = \langle |F|^2 \rangle$ is correlated to the atomic scattering amplitudes by the relation

$$\langle I \rangle = \sum_{i=1}^n f_{x,i}^2, \quad (4.1)$$

where $f_{x,i}$ represents the atomic scattering amplitude for i -th atom and n the total number of atoms in a unit cell. When the primary extinction effect participates, the relation (4.1) does not hold, and it should be modified in the form

$$\langle I \rangle < \sum_{i=1}^n f_{x,i}^2. \quad (4.2)$$

This relation can be used to detect the primary extinction.

In the case of electrons, the atomic scattering amplitude is given by

$$f_i = \frac{2me^2}{h^2} \frac{(Z - f_x)_i}{s^2}, \quad (4.3)$$

where Z is the atomic number and m , e and h have usual meanings. f_i decreases very rapidly with s , while the change of $(Z - f_x)_i$ with s is moderate as is the case of $f_{x,i}$. The intensity statistics is, in principle, appropriate for point scatterers which give the angle-independent scattering amplitudes. Therefore, for the case of electron diffraction, it is reasonable to express the relations corresponding to (4.1) and (4.2) in the form

$$K \langle s^4 I \rangle \leq \sum_{i=1}^n (Z - f_x)_i^2, \quad (4.4)$$

$$K = (h^2/2me^2)^2.$$

The plots $\langle s^4 I \rangle$ for the observed intensities I_o are shown in Fig. 3 by open circles, where the values of $\langle s^4 I_o \rangle$ are normalized with the curve $\sum_{i=1}^n (Z - f_x)_i^2$ at the outermost s -value.

It can be seen that the values of $\langle s^4 I_o \rangle$ for the lower angles considerably deviate downward from the curve $\sum_{i=1}^n (Z - f_x)_i^2$, showing evidently the effect of primary extinction.

According to the theory of primary extinction⁵⁾, the diffraction intensity is given by

$$I = f(x) |F|^2. \quad (4.5)$$

The primary extinction coefficient $f(x)$ for the Laue case of electron diffraction from a parallel plate crystal is given by

$$f(x)=\sum_{n=0}^{\infty}J_{2n+1}(2x)/x, \tag{4.6}$$

$$x=(\bar{\rho}\lambda/v)|F| \tag{4.7}$$

where $J_{2n+1}(x)$ is the Bessel function of the odd order and v the unit cell volume.

$$\bar{\rho}=\frac{H}{\sqrt{|\cos\theta_1\cdot\cos\theta_2|}},$$

where H is the thickness of the parallel plate crystal and θ_1, θ_2 are the angles between the normal of the crystal surface and directions of the primary, secondary wave, respectively. $\bar{\rho}$ can be regarded as the effective thickness of the crystal. The variation of $f(x)$ against x is shown in Fig. 4.

Fig. 3. Local averages of the intensity of Ni₃C. Open circles are the plots of the local averages $\langle s^4I_0 \rangle$ and filled squares are $\langle s^4I_0^2 \rangle$. Other plots are the local averages $\langle s^4I_{cor} \rangle$: crosses correspond to $\bar{\rho}=190 \text{ \AA}$, filled circles to $\bar{\rho}=240 \text{ \AA}$ and open squares to $\bar{\rho}=285 \text{ \AA}$.

Fig. 4. Variation of the primary extinction coefficient $f(x)$ against x in the Laue case of electron diffraction. $f'(x)$ and $f''(x)$ represent approximate functions of $f(x)$.

The function $f(x)$ can be approximated by $f'(x)=\exp(-1/3\cdot x^2)$, for $x\lesssim 2.5$ (4.8)

and

$$f''(x)=1/(2x), \text{ for } x\gtrsim 2.0 \tag{4.9}$$

as shown in Fig. 4.

When the approximation (4.9) is allowed,

$$I=\frac{v}{2\bar{\rho}\lambda}|F|, \tag{4.10}$$

i.e. the intensity is proportional to $|F|$. If all reflections satisfy this condition, the local averages of the form $\langle s^4I^2 \rangle$ should coincide with the curve $\sum_{i=1}^n (Z-f_x)^2$. The filled squares in Fig. 3 representing the plots of the local averages $\langle s^4I_0^2 \rangle$ deviate from the curve, showing that the above condition is not satisfied.

§ 5. Modified Patterson Synthesis and Preliminary Fourier Synthesis

In order to obtain the values of the primary extinction coefficient $f(x)$, knowledges of the crystal structure and of the effective thickness of crystallites $\bar{\rho}$ are required at least approximately. In § 2, we proposed that the nickel atoms in Ni₃C take the c.p.h. arrangement. This assumption is verified at least approximately by the methods of modified Patterson synthesis and preliminary Fourier synthesis as follows: The intensity suffering the primary extinction can be expanded into the power series of $|F|^2$

$$I=|F|^2+\left\{-\frac{1}{3}(\bar{\rho}\lambda/v)^2\right\}|F|^4+\left\{\frac{1}{20}(\bar{\rho}\lambda/v)^4\right\}|F|^6+\dots \tag{5.1}$$

Cowley⁸⁾ has shown that the peaks of heavy

Fig. 5. One-dimensional Patterson function along the c -axis formed from I_0 .

atoms in a Patterson diagram are sharpened without any shift in their positions when a power series of $|F|^2$ like (5.1) is used as the coefficient for synthesis. Fig. 5 illustrates the one-dimensional Patterson function along the c -axis obtained from the reflections $(000l)$. The high peaks at 0 and $1/6$, and the low peak at $1/12$ are considered to be the Patterson peaks corresponding to the layer distances between Ni and Ni, and between Ni and C, respectively. Fig. 6 shows a part of the

Fig. 6. Two-dimensional Patterson map formed from I_0 . The map shows a part of the basal plane projection corresponding to Jacobson and Westgren's unit cell. The contours are drawn at arbitrary unit.

Fig. 7. One-dimensional Fourier series along the c -axis formed from (a) $\sqrt{I_0}$ and (b) I_0 .

two-dimensional Patterson function formed by the reflection $(hki0)$ projected on the basal plane. The contours are drawn at arbitrary unit. The high peaks at positions $(1/3, 0)$ and $(1/3, 1/3)$ are considered to represent the interatomic distances between nickel atoms, verifying their c.p.h. arrangement.

Since $f_{Ni} \gg f_C$, signs of the structure amplitudes can be determined without ambiguity. However, magnitude of the structure amplitudes can not be obtained directly from the

observed intensities, since the intensities are proportional to neither $|F|^2$ nor $|F|$ by the effect of primary extinction. Therefore, two kinds of preliminary Fourier syntheses, one by using $\sqrt{I_0}$ and the other by using I_0 as the magnitude of amplitudes, were tried. The curve (a) in Fig. 7, showing the one-dimensional Fourier series formed by $\sqrt{I_0(000l)}$, reveals a high peak at $1/12$ corresponding to a nickel layer. In Fig. 8, the two-dimensional Fourier map formed by $\sqrt{I_0(hki0)}$, high peaks due to nickel atoms are clearly observed at the c.p.h. positions $(1/3, 0)$ and $(1/3, 1/3)$. However, in this map no peak corresponding to carbon atoms is observed.

Fig. 8. Two-dimensional Fourier map formed from $\sqrt{I_0}$. The contours are drawn at arbitrary unit.

Fig. 9. Two-dimensional Fourier map formed from I_0 . The contours are drawn at arbitrary unit.

The curve (b) in Fig. 7, and Fig. 9 are the one- and two-dimensional Fourier maps formed by $I_0(000l)$ and $I_0(hki0)$, respectively. In the former map the low peaks at the positions 0 and $1/6$, and in the latter the low peaks at the positions $(0, 0)$, $(1/3, 2/3)$, $(2/3, 1/3)$ and $(1/3, 1/3)$ corresponding to the carbon positions are clearly appearing besides the high peaks due to the nickel atoms.

Although the above Patterson and Fourier syntheses are of a curde nature, the proposed structure of Ni_3C can be confirmed at least approximately by these trials. It is noteworthy that the use of I_0 rather than $\sqrt{I_0}$ as the magnitude of reflection amplitude gives better result in Fourier synthesis. This is due to the primary extinction which is quite strong in the present case.

§ 6. Refinement of Potential Fourier Map

Now, the refinement of Potential Fourier map will be carried out by correcting the primary extinction effect. Though the approximate structure of Ni_3C is already obtained, a difficulty arises concerning the estimation of the value $\bar{\rho}$ necessary for correcting the primary extinction effect. Though $\bar{\rho}$ is considered to be the same order of magnitude as the mean particle size ε ²⁾, there is only little justification in putting $\bar{\rho}$ equal to ε , since the definitions are not identical, and, moreover, the determination of ε from the Debye rings is inaccurate especially when the mean particle size is larger than 100 Å as in the present case. The most appropriate values of $f(x)$ can be obtained by the following method based on the intensity statistics. The values of $f(x)$ are calculated for various values of $\bar{\rho}$ by assuming F for the approximate crystal structure, and the observed intensities are corrected by these values of $f(x)$ to $I_{\text{cor}} = f(x)I_0$. By comparing the plots of the local averages of the corrected intensities, $\langle s^4 I_{\text{cor}} \rangle$, with the curve $\sum_{i=1}^n (Z - f_x)_i^2$, the case showing the best fit is found out. Six trials for $\bar{\rho} = 190, 210, 230, 240, 250$ and 285 Å were carried out and some of the plots of the local averages are shown in Fig. 3. The local averages for $\bar{\rho} = 240$ Å gave the most satisfactory agreement with the curve $\sum_{i=1}^n (Z - f_x)_i^2$. The values of x , $f(x)$ and $\sqrt{I_{\text{cor}}} = |F_{\text{cor}}|$ for this case are tabulated in Table I. The agreement between $|F_{\text{cor}}|$ and $|F_c|$ is satisfactory. The reliability factor $R = \sum(|F_{\text{cor}}| - |F_c|) / \sum |F_{\text{cor}}|$ was improved to 15%.

Fig. 10 shows the two-dimensional Fourier map calculated from the corrected intensities. The contours are drawn at intervals of 0.5 volt per Å². The mean inner potential

$V(0000)$, which is necessary for determining the level of the map was calculated by Tull's method⁹⁾. It was 18.7 volts. The map shows clearly the peaks of carbon atoms at the reasonable positions. The heights of the carbon and nickel peaks are $V_C(0) = 2.9$ volt/Å² and $V_{\text{Ni}}(0) = 18.1$ volt/Å². They give the ratio $V_C(0)/V_{\text{Ni}}(0) = 0.16$, while the calculated value utilizing Vainstein's formula¹⁰⁾ is $V_C(0)/V_{\text{Ni}}(0) = (2/3)(Z_C/Z_{\text{Ni}})^{\alpha_6} = 0.19$ taking $\alpha_6 = 0.75$,

Fig. 10. Two-dimensional Fourier map formed from the final values of $\sqrt{I_{\text{cor}}}$. The contours are drawn at intervals of 0.5 V Å⁻². The chain lines indicate zero level and the broken lines negative regions. Peak height: $V_{\text{Ni}}(0) = 18.1$, $V_C(0) = 2.9$.

where 2 and 3 are the numbers of overlapped carbon and nickel atoms on the projected plane, respectively. Both values agree approximately*.

§ 7. Crystal Structure of Ni_3C

1. Description of the Structure

The above result shows that the structure proposed in § 2 is appropriate for Ni_3C . Fig. 11 (a) shows the structure schematically, where open circles represent nickel atoms and filled circles, carbon atoms. Fig. 11 (b) shows the basal plane projection of the structure, where A and B represent nickel atoms and (C_1) , (C_2) and (C_3) , the carbon atoms. Nickel atoms occupy the c.p.h. positions and carbon atoms form a rhombohedral lattice occupying one-third of the octahedral interstices of nickel atoms. The structure can be represented by a structural formula $(C_1)A(C_2)B(C_3)A(C_1)B(C_2)A(C_3)B(C_1) \dots$, where ABAB... represents hexagonal layers of nickel atoms stacked with the c.p.h. sequence and $(C_1)(C_2)(C_3) \dots$, the hexagonal layers of

* The ratio $V_C(0)/V_{\text{Ni}}(0)$ in Fig. 9 of I_0 -synthesis is 0.39.

carbon atoms stacked with the rhombohedral sequence. The octahedron formed by nickel atoms is deformed from the regular shape only slightly; six Ni-Ni bond-lengths in the basal plane are 2.628 Å and the other six bond-lengths 2.634 Å. The sequence of the carbon layers forms a rhombohedral lattice with the hexagonal lattice constants $a' = a$

and $c' = (1/2)c$.

2. Stacking of Carbon Layers

As mentioned in §2 the intensity regions of the s -reflections for which $h-k \approx 3n$ elongate along c^* -axis, while those of the M -reflections for which $h-k=3n$ are sharp. The observed half-breadths of $(01\bar{1}2)$ and $(10\bar{1}4)$ rings are tabulated in Table II. The calculation of structure amplitudes shows that the s -reflections are exclusively due to the carbon atoms and that their breadth depends on the sequence of carbon layers, while that of the M -reflections does not. The above observation, therefore, suggests that the $(C_1)(C_2)(C_3)\dots$ stacking of carbon layers in the matrix of nickel lattice $ABAB\dots$ has a certain disorder.

According to Wilson's theory¹¹⁾ the probability α ($\ll 1$) of the mistakes in the rhombohedral stacking order and the half-width, σ , in l' ($=1/2 \cdot l$) are related by

$$\alpha = 2\sigma.$$

The observed widths given in Table II correspond to $\alpha \sim 0.5$. This value, however, is inconsistent with the assumption of the theory that α is small. The situation could not be improved even by the more refined theory taking account of longer 'Reichweite'¹²⁾.

On the other hand, the elongation of the s -reflections can be explained fairly well by a size-effect due to mistakes which take place, on the average, at a regular interval. The observed half-width gives 28 Å (13 carbon layers) for the average value of the interval between the mistakes, δ . It may be worth mentioning that the half-breadth of the s -reflections did not change appreciably up to the decomposition temperature of Ni_3C (Part I, Photo. 7).

§ 8. Discussion

In spite of the optimistic view of Pinsker

and Jamzin¹³⁾ concerning the primary extinction in electron diffraction, the result of the present paper shows that the effect is very significant in practical samples and that the positions of light atoms can not be determined without an appropriate correction of the effect.

Though in the present paper the correction was carried out by assuming an approximate structure, this is not essential. When the approximate structure is unknown, the following procedure can be adopted: By the application of the intensity statistics at a range of larger s -values where the primary extinction is insignificant, we can obtain the absolute scale of intensity. The effective thickness of crystallites are approximately put equal to the mean particle size. These values can be used as starting values of $|F|$ and ρ required for correcting the primary extinction effect. The Fourier map synthesized from the corrected intensities will give the approximate atomic positions. Utilizing this knowledge the values of $f(x)$, therefore, I_0 are recorrected. Then, by the application of intensity statistics for these corrected intensities $\bar{\rho}$ is corrected. Repeating the above procedure the structure analysis can be performed successively until all the plots of the local averages coincide with the curve $\sum_{i=1}^n (Z-f_x)_i^2$. By this procedure the atomic positions and, at the same time, the effective thickness of crystallites can be determined. This method can be applied also to X-ray diffraction, in principle.

In the present structure analysis, the temperature effect was not taken into consideration. However, the Debye temperature of nickel carbide is considered to be higher than that of nickel metal. The temperature effect will not give an appreciable influence on the above analysis. It influences the plots of the local averages oppositely to that of the primary extinction.

The merit of applying the intensity statistics to detect the primary extinction and to justify its correction is that they can be done apart from knowledges of a relevant crystal structure. Concerning its application the following comments may be worth mentioning: In the case of nickel carbide, the M -reflections are sharp and strong and are con-

sidered as being subjected to a considerable effect of primary extinction, while the s -reflections are weak and broad and are considered as being free from the effect. Therefore, the local averages $\langle s^4 I_0 \rangle$ were taken only over the M -reflections and, since the M -reflections are interpreted by the Jacobson and Westgren's structure, they were compared with the curve $\sum_{i=1}^n (Z-f_x)_i^2 = 2(Z-f_x)^2_{Ni} + 2/3 \cdot (Z-f_x)^2_C$, where 2 and 2/3 are the numbers of nickel and carbon atoms in the unit cell, respectively. By this procedure the primary extinction was clearly detected. In the intensity statistics to detect the primary extinction, it is preferable to take the local averages only over reflections subjecting to the primary extinction. In the electron diffraction study of crystals containing heavy and light atoms, we often encounter the situation that a super-lattice formed by a particular distribution of light atoms giving only weak super-lattice reflections. The above remarks are appropriate for such cases, in general.

Fig. 12. Change of the local averages $\langle s^4 I_0 \rangle$ by different averaging ranges. Horizontal bars attached to the plots indicate the averaging ranges and numbers represent the numbers of reciprocal-lattice points in the ranges.

Since in the intensity statistics the random distribution of atoms in a unit cell is assumed, an objection might arise against its application to a simple structure such as nickel carbide. However, the essential requirement in the intensity statistics is that the values of the geometrical structure amplitudes are random in an averaging s -range. An important point of the method is

to find out proper ranges of the local averages so that the plots of $\langle s^4 I_0 \rangle$ give a smooth curve. For example, in Fig. 12 the plots of the local averages represented by open circles do not form a smooth curve owing to the inappropriate choice of the averaging ranges. However, when the averaging ranges are changed appropriately, plots of $\langle s^4 I_0 \rangle$ from the same data give a smooth curve as represented by the filled circles in Fig. 12. Refinement of the averaging ranges should be done successively with the correction of I_0 .

Acknowledgement

Electron Diffraction Study of Evaporated Face-centered Cubic Crystallites

By Hidetake MORIMOTO

Physical Institute, Nagoya University, Nagoya, Japan

(Received June 7, 1958)

Germer and White (Phys. Rev. **60** (1941) 447) found that thin evaporated films of face-centered cubic metals produce electron diffraction patterns with anomalous intensities. Kimoto (J. Phys. Soc. Japan **8** (1953) 762) studied the anomaly by a trial method and attributed it to stacking faults in crystallites. By the radial distribution analysis the present author confirmed Kimoto's conclusion.

Intensities of diffraction patterns from evaporated silver were accurately measured by the sector-microphotometer method and they were turned into radial distribution function. These functions reveal anomalous peaks caused by stacking faults. After a specimen is annealed at 350°C for 3.5 hrs., although crystallites do not grow remarkably, these peaks disappear. The amplitude of thermal vibration is found to be $0.15 \pm 0.02 \text{ \AA}$ which agrees well with that for massive silver crystal. The narrowing of the first neighbor peak is found and is attributed to the correlative thermal vibration.

Gold shows the same anomaly as is observed for silver, but aluminum shows no anomaly. These facts are in accordance with the value of stacking-fault energy.

§ 1. Introduction

Germer and White¹⁾ reported that thin evaporated films of face-centered cubic metals produce electron diffraction patterns with anomalous intensities. The intensity of (200) reflection is especially weak compared with the normal intensity. They tried to explain the anomaly by attributing it to the small size of crystal, but their explanation was not sufficient.

Kimoto²⁾ studied the same phenomenon for silver by using an advanced experimental technique. He confirmed the same anomaly as reported by Germer and White and, moreover, found a slight peak shift of (200) reflection. He explained these anomalies by attributing them to stacking faults³⁾ in crystallites. Since, however, he used a trial method, it is desirable that a direct Fourier analysis be carried out to complete the diffraction study for evaporated crystallites. In this method, the diffracted intensity is accurately measured by the sector-microphotometer⁴⁾ method and the measured intensity is turned by Fourier transformation into the radial distribution function (RDF) which directly indicates the atomic arrangement.

Since the stacking faults produce only a

slight modification of the atomic arrangement, we carried out the experiment and analysis with great care, estimating errors at every stage. For specimens without annealing, RDFs always showed peaks corresponding to the anomalous neighbors caused by stacking faults. These anomalous peaks became lower as the crystal size increased. When the specimen was treated at 350°C for 3.5 hrs., although crystallites did not grow remarkably, the anomalous peaks disappeared.

From the breadth of peaks in RDF the amplitude of thermal vibration is calculated to be $0.15 \pm 0.02 \text{ \AA}$. This value agrees well with the value for massive silver crystal, $0.16 \text{ \AA}$ ⁵⁾. Through a detailed analysis of RDF, we found that the peak corresponding to the nearest neighbor was a little narrower than the other peaks. This narrowing may be attributed to the correlative thermal vibration in crystallites.

While we were carrying out our analysis, much progress was made in the studies of the stacking faults. Paterson⁶⁾ formulated the intensity of X-ray diffraction patterns of f.c.c. crystals with stacking faults. The peak shift of (200) reflection found by Kimoto²⁾ qualitatively agrees with this theory. Following Paterson's theory, Nimura⁷⁾ studied the very

slight peak shifts in electron diffraction patterns from evaporated crystallites of gold and silver and found that they were in accordance with the existence of stacking faults, while Rymer⁸⁾ found that the peak shifts could be explained also by attributing them to the strain due to sessile dislocations in crystallites.

Based on the peak shifts in X-ray diffraction patterns, several authors^{9), 10), 11)} also studied in detail stacking faults in cold-worked f.c.c. metals and concluded that the results agreed well with expected results from the stacking-fault energy.^{12), 13)}

* Estimated by RDF analysis.

** Estimated by Scherrer formula using (111) breadth.

§ 2. Experimental

Experimental procedure in the present work was similar to that used by Kimoto²⁾. By the vacuum evaporation method, silver of mean thickness 3~10 Å was deposited on either Formvar or amorphous carbon film of about 100 Å thick. The thickness of silver was estimated from the mass of silver before evaporation. The deposited silver does not form a uniform film but it coagulates into minute crystallites. Five silver specimens were prepared: Nos. 1 and 3 were deposited simultaneously. Specimen No. 1 was annealed after the diffraction examination and it was then

denoted as No. 2. The diffraction pattern of No. 3 was taken after it had been annealed. The annealing was carried out *in vacuo* at about 1×10^{-3} mmHg. In addition to five silver specimens, one gold and one aluminium specimen were also prepared by vacuum evaporation. Important data of specimens are given in Table I.

Electron diffraction transmission photographs of these specimens were taken by a camera provided with a rotating sector¹⁴⁾. The sector was of the type $\vartheta = \text{const.} \times \rho$, where ϑ was the angle of aperture, ρ the radius, and the constant was 10 deg/mm. The specimen-to-

Fig. 1. Electron diffraction pattern of evaporated silver (Sp. No. 4) with two intensity scales.

Fig. 2. Microphotometer record of Fig. 1 (Sp. No. 4).

plate distance of the camera was 24 cm for the large angle scattering and 45 cm for the small angle scattering. The accelerating voltage was about 40 kv. An example of diffraction patterns is reproduced in Fig. 1. The darkness of photographic plates was measured by Riken B-type microphotometer improved so that a plate could be rotated about the center of diffraction rings¹⁴⁾. The rotation is effective to obtain smooth microphotometer records, eliminating noises due to photographic grains. Fig. 2 is an example of photometer records.

In all procedure of photographing and microphotometering, we have taken care to avoid the distortion of line profile. The incident spot of electron beam on the plate was 0.1 mm in diameter which is so small that the spot size can be neglected in the analysis of intensity profiles. The position of the sector was adjusted so that its center was within 0.1 mm of the incident beam. The error of the centering δ introduces only an error of order $(\delta/\rho)^2$ into the diffraction intensity at the position ρ from the incident beam*.

The stray scattering of the incident beam was almost stopped by two slits and by the specimen holder. The residual stray scattering was very small, the value of which was of the same order as the inelastic scattering in Fig. 3a.

In the microphotometry, the area of irradiation on the photographic plate was 0.1 mm in radial direction and 1 mm in tangential direction of Debye rings. The rotating plate was adjusted so that the deviation of the center of rings from the center of rotation was less than 0.1 mm. Thus the broadening and the shift of peaks in the photometer record were avoided. The deflection of electrometer string of the microphotometer was calibrated each time by applying known voltages. The electrometer and its circuits were adjusted so that the time lag was negligibly small.

Photographic density-exposure relationship, i.e. D-E characteristic curve, was determined

* When the center of sector deviates from the incident beam by δ , through the sector action the intensity at the position ρ from the incident beam is multiplied by $|\rho - \delta|$, but not $|\rho| = \rho$. In the rotating-plate microphotometering, this error becomes

$$\frac{1}{2\pi} \int_0^{2\pi} \left(\frac{|\rho - \delta|}{|\rho|} - 1 \right) d\omega \sim O(\delta^2/\rho^2).$$

for every plate by recording the electron intensity scale on the same plate (Fig. 1). The scale was made according to the method previously reported by Cowley¹⁶⁾. We used Japanese plates "Fuji Process Hard" and developed them by D76d at $20 \pm 0.5^\circ\text{C}$ for 10 minutes. The D-E characteristic curves obtained by Cowley's method were in agreement with each other within 3% for $D < 0.8$, provided the emulsion number of plates was the same. Sometimes, we also determined D-E curve by Bartell-Brockway's method¹⁶⁾. In our experiment, this method also showed D-E curves having 3% fluctuations for $D < 0.8$. The results obtained by these two methods were in agreement within 3%.

The observed intensity is the sum of elastic scattering (I) from the evaporated metal, inelastic scattering (I_i) from the metal, and scattering (I_b) from the supporting film. We assumed the total intensity I_t to be given by $I_t = I + I_i + I_b$, which implies that the multiple scattering in specimen is negligible. This assumption is adequate because the film is thin. To obtain the intensity I (Fig. 3b), we subtracted $I_i + I_b$ from the total intensity curve I_t (Fig. 3a). Intensity curve I_b (Fig. 3a) was obtained from a supporting film bare of metal and was normalized following Kimoto's pro-

Fig. 3. Intensity profiles (Sp. No. 4).

cedure²³. Intensity curve I_i (Fig. 3a) was obtained by Bewilogua's formula¹⁷ which gives the ratio of I_i to the atomic part of the elastic scattering. Errors introduced in this procedure are difficult to estimate. Since, however, they have to be a smooth function of scattering angle, they have little influence on the radial distribution analysis (Sec. 6b).

To estimate the accidental error which arose through all procedures, three pairs of diffraction photographs were taken for specimen No. 4. Intensity was measured independently for each pair. The error in the modified intensity (Eq. (2)) was less than 5% of the (111) peak.

§ 3. Intensity Profiles

In Fig. 3 the anomalously diffuse (200) reflection such as observed by Germer-White¹³ and Kimoto²³ is seen. In Fig. 4 profiles of combined (111) and (200) reflections are shown for all specimens. By an annealing, (200) reflection becomes normal. Gold also shows the anomaly, but aluminum shows no anomaly.

Fig. 4. Intensity profiles of combined (111) and (200) reflections.

Abscissa: $a_0/d = \sqrt{h^2 + k^2 + l^2}$.

As a measure of anomaly, ratio of (200) half breadth to (111) half breadth is given in Table I.

Germer-White and Kimoto reported that the integrated intensity of (200) reflection was

anomalously weak. They separated (200) from (111) by assuming that the peak of the combined (200) and (111) reflection is the peak of (111). According to their method of separation, (200) peak becomes asymmetric as shown by broken curves in Fig. 4. On the other hand, if we assume (111) and (200) are both symmetric, separated (200) reflection is not anomalously weak as shown by dotted curves in Fig. 4. The difference is caused by the different ways of separating two peaks. Based upon his result, Kimoto considered that the anomaly cannot be explained by the external shape effect. According to our result, however, there is a possibility that the anomaly can be explained by the shape effect. Therefore, radial distribution analysis is indispensable to prove the existence of stacking faults in the crystallites.

§ 4. Radial Distribution Analysis

Diffacted intensity from monatomic crystals is given by James¹⁸, taking into account the effect of thermal vibration. If the vibration of each atom is independent, intensity of Debye rings is given by

$$I(s) = |E(s)|^2 \left\{ N + N \cdot \exp\left(-\frac{\bar{u}^2 s^2}{3}\right) \sum_i N_i \frac{\sin sr_i}{sr_i} \right\} \quad (1)$$

where

$$s = 4\pi \sin \frac{\theta}{2} / \lambda$$

and $E(s)$ is the atomic scattering factor for electrons, N the total number of atoms, $\bar{u}^2$ the mean-square amplitude of atoms. r_i and N_i indicate, respectively, the interatomic distance and the number of i th neighbors. In Eq. (1) the first term is the atomic scattering and the second is the so-called molecular scattering. We define modified intensity $J(s)$ by

$$J(s) = I(s) / N |E(s)|^2 \quad (2)$$

and multiply it by a proper artificial temperature factor $\exp(-b^2 s^2)$. Then RDF is calculated by

$$D_\infty(r) = \frac{4}{\sqrt{\pi}} \int_0^\infty s J(s) \cdot \exp(-b^2 s^2) \cdot \sin sr \cdot ds. \quad (3)$$

Substituting Eqs. (1) and (2) into Eq. (3), we obtain

$$D_\infty(r) = D_{1\infty}(r) + D_{2\infty}(r) \quad (4)$$

where

$$D_{1\infty}(r) = \frac{4}{\sqrt{\pi}} \int_0^\infty s \cdot \exp(-b^2 s^2) \cdot \sin sr \cdot ds = \frac{r}{b^3} (-r^2/4b^2) \quad (4a)$$

$$\begin{aligned} D_{2\infty}(r) &= \frac{4}{\sqrt{\pi}} \sum_i \frac{N_i}{r_i} \int_0^\infty \exp(-\beta^2 s^2) \cdot \sin sr_i \cdot \sin sr \cdot ds \\ &= \sum_i \frac{N_i}{r_i \beta} \{ \exp[-(r-r_i)^2/4\beta^2] - \exp[-(r+r_i)^2/4\beta^2] \} \end{aligned} \quad (4b)$$

$$\beta^2 = \frac{\bar{u}^2}{3} + b^2. \quad (4c)$$

Here, $D_{1\infty}$ gives the peak at the origin corresponding to atoms themselves and $D_{2\infty}$ peaks corresponding to neighbor atoms. Since Eq. (4) holds only for positive values of r , the effect of $\exp[-(r+r_i)^2/4\beta^2]$ is negligible and thus the i th term in the summation of $D_{2\infty}$ represents a Gaussian peak corresponding to the i th neighbor. When $D_{2\infty}$ is separated into peaks, the position and the height of the i th peak give the distance r_i and the number N_i of the i th neighbors, respectively. According to Eq. (4b), the breadth 4β of each peak is equal and gives the amplitude of thermal vibration, $\sqrt{\bar{u}^2}$.

If, however, the correlation is taken into account, the intensity formula (1) is modified as*

$$I(s) = |E(s)|^2 \left[N + N \sum_i \frac{N_i}{r_i} \frac{\sin sr_i}{sr_i} \exp \left[-\frac{1}{3} \bar{u}^2 \{1 - \varepsilon(r_i)\} \right] \right] \quad (5)$$

where

$$\varepsilon(r) = \frac{1}{2\pi\tau_m r} \int_0^{2\pi\tau_m r} \frac{\sin u}{u} du \equiv \frac{\text{Si}(2\pi\tau_m r)}{2\pi\tau_m r} \quad (5a)$$

$$2\pi\tau_m r = 2\pi(3r^3/4a_0^3) \simeq 3.9r/a_0$$

where a_0 is the lattice constant.

Thus Eqs. (4b) and (4c) are modified as

$$D_{2\infty} = \sum_i \frac{N_i}{r_i \beta_i} \{ \exp[-(r-r_i)^2/4\beta_i^2] - \exp[-(r+r_i)^2/4\beta_i^2] \} \quad (4b')$$

$$\beta_i^2 = \frac{\bar{u}_i^2}{3} + b^2 \quad (4c')$$

where

$$\bar{u}_i^2 = \bar{u}^2 \{1 - \varepsilon(r_i)\}. \quad (6)$$

Therefore, although each peak is again Gaussian, its breadth $4\beta_i$ should be different for different i . Since $\varepsilon(r)$ has a considerable value for small r (Fig. 5), the narrowing may occur for peaks corresponding to near neighbors. The apparent value of the amplitude $\sqrt{\bar{u}_i^2}$ gives $1 - \frac{1}{2}\varepsilon_i$ times smaller value than the true value, $\sqrt{\bar{u}^2}$.

Fig. 5. Correction term $\varepsilon(r/a_0)$ for simple cubic lattice.

* This equation can be driven from Eq. (5.26) of James' book¹⁸⁾ by taking average over whole directions and by assuming the following conditions:

- (1) Debye's approximation for specific heat problem.
- (2) Longitudinal and transversal waves have the same velocity.
- (3) Temperature is higher than Debye temperature.
- (4) Simple cubic lattice.

In the practical analysis, RDF is calculated by an integration using relative value of modified intensity $kJ(s)$ within a finite integrating region extending from s_m to s_M and is given by

$$kD(r) = \frac{4}{\sqrt{\pi}} \int_{s_m}^{s_M} s \cdot kJ(s) \cdot \exp(-b^2 s^2) \cdot \sin sr \cdot ds. \quad (7)$$

Substituting Eqs. (5) and (2) into Eq. (7) and calculating the above finite integral by the use of complex integral, we obtain, instead of Eq. (4), the expression including the finite region effect as follows:

$$kD(r) = kD_1(r) + kD_2(r) + kD_3(r) \quad (8)$$

where

$$\begin{aligned} D_1(r) &= \frac{4}{\sqrt{\pi}} \int_0^{s_M} s \cdot \exp(-b^2 s^2) \cdot \sin sr \cdot ds \\ &= D_{1\infty} \Phi(r_0) + \frac{2r}{\sqrt{\pi} b^3} \exp(-r_0^2) \left[A\left(\frac{r}{2b}, r_0\right) - \frac{b \sin s_M r}{r} \right] \end{aligned} \quad (8a)$$

$$D_2(r) = D_{2\infty} \Phi(r_i) + \frac{2}{\sqrt{\pi}} \sum_i \frac{N_i}{r_i \beta_i} \exp(-r_i^2) \left[A\left(\frac{r-r_i}{2\beta_i}, r_i\right) - A\left(\frac{r+r_i}{2\beta_i}, r_i\right) \right] \quad (8b)$$

$$D_3(r) = -\frac{4}{\sqrt{\pi}} \int_0^{s_M} s J(s) \cdot \exp(-b^2 s^2) \cdot \sin sr ds \quad (8c)$$

and where

$$\begin{aligned} r_0 &= b s_M, \quad r_i = \beta_i s_M = s_M \sqrt{\frac{u_i^2}{3} + b^2} \\ A(x, r) &= \exp(-x^2) \int_0^{\infty} \exp(t^2) \cdot \sin 2rt \cdot dt \\ \Phi(r) &= \frac{2}{\sqrt{\pi}} \int_0^r \exp(-t^2) dt. \end{aligned} \quad (9)$$

Terms D_1 and D_2 in Eq. (9) correspond to $D_{1\infty}$ and $D_{2\infty}$ in Eq. (4), respectively. Term D_3 in Eq. (8) is caused by the neglecting of the small angle scattering and it forms a smooth background in RDF (Sec. 6e). Since $\Phi(r)$ is almost unity under the usual condition (Table II), the first term in D_1 and that in D_2 are almost equal to $D_{1\infty}$ and $D_{2\infty}$, respectively. They represent true peaks. On the other hand, the second term in D_1 and that in D_2 give rippled ghosts caused by the termination error because $A(x, r)$ is a damped oscillating function. As can be seen from the factor $\exp(-r^2)$, ghosts belonging to D_1 are reduced only by the artificial temperature

factor while those belonging to D_2 are reduced by both natural and artificial temperature factors.

For small x , values of function $A(x, r)$ can be calculated by numerical integration, and the first maximum A_m is given in Table II. For large x , it can be estimated by the asymptotic formula

$$A(x, r) \sim \frac{1}{2x} \sin 2rx - \frac{r}{2x^2} \cos 2rx + O\left(\frac{1}{x^3}\right). \quad (10)$$

Rippled ghosts belonging to a true Gaussian peak in D_2 are illustrated in Fig. 6. The height of ghost peaks is the order of $\frac{1}{2} \exp(-r^2)^*$

* As can be seen by the asymptotic formula

Eq. (10), $A\left(\frac{r+r_i}{2\beta_i}, r_i\right)$ is negligible compared with $A\left(\frac{r-r_i}{2\beta_i}, r_i\right)$ in the neighborhood of peak r_i . Therefore the first maximum of the ghosts is

$$\frac{2}{\sqrt{\pi}} = A_m \exp(-r^2),$$

where A_m is about 0.4 in the usual condition (Table II).

Table II.

r	$\exp(-r^2)$	$\Phi(r)$	A_m	$\frac{2}{\sqrt{\pi}} \exp(-r^2) A_m$
1.0	0.38	0.84	0.41	0.18
1.5	0.11	0.97	0.39	0.05

2.0	0.02	0.995	0.32	0.007

at the first peak and decreases in inverse proportion to $r-r_i$.

Fig. 6. Rippled ghost belonging to Gaussian peak. Peak height is normalized to unity and ghosts are shown magnified ten times.

§ 5. RDF of Silver Crystallites

(a) *Neighbors in normal and disordered f.c.c. crystals.*

In normal f.c.c. crystal of infinite size, each atom has 12 first neighbors, 6 second neighbors, etc. The interatomic distance r_i for the i th neighbor is given by

$$r_i = \frac{a_0}{\sqrt{2}} \sqrt{i} = d_0 \sqrt{i} \tag{11}$$

where a_0 is the lattice constant and d_0 the distance of the nearest neighbor. Interatomic distances in h.c.p. crystal can also be given by Eq. (11). In this case, however, i does not stand for the i th neighbor; it takes fractional values as well as integers. If there are faults in stacking of (111) layers in f.c.c. crystal, i.e. if some stacking sequences of

h.c.p. type are mixed in with sequences of f.c.c. type³⁾, besides the normal neighbors of f.c.c. type the anomalous neighbors with fractional i appear. Interatomic distances r_i for silver ($a_0=4.08\text{\AA}$) and the numbers $N_{i\infty}$ for infinite-size f.c.c. and h.c.p. crystals are tabulated in Table III. From these data it can be expected that, even when there are stacking faults, the numbers of the first and the second normal neighbors remain unchanged but that those of higher orders decrease. The decreased numbers are compensated for by those of the anomalous neighbors.

For comparison with experimental RDF, numbers of neighbors N_i are also given for a few models, some of which are normal and some of which are disordered by stacking faults (Table III). These models are denoted as follows:

- $[l\cdot m \times k]_n$: Parallelepiped model, normal. The parallelepiped denoted by $[\]_n$ is formed by the three edges along $[110]$, $[10\bar{1}]$ and $[01\bar{1}]$ directions. $l\cdot m$ represents the number of atoms on the basal (111) net plane and k the number of stacking (111) net planes (Fig. 7a).
- $[l\cdot m \times k]_t$: Twinned parallelepiped model, disordered by one twin fault (growth fault) at the middle of stacking.

Model denoted by $[\]_t$ consists of two parallelepipeds of similar size, one formed by $[110]$, $[10\bar{1}]$ and $[01\bar{1}]$ directions and the other the mirror image across the twin plane (Fig. 7b).

Ratios N_i/r_i of $[5\cdot 5 \times 8]_n$ and $[5\cdot 5 \times 8]_t$ are shown in Figs. 7a and b. If stacking faults exist in evaporated silver, RDF should show peaks corresponding to the anomalous neigh-

bors, as indicated by dotted lines in Fig. 7b. It is noteworthy that the peak at $r=5.53\text{\AA}$ corresponding to $i=3\frac{2}{3}$ must be the most conspicuous among anomalous peaks because it is expected to be much larger and easily separated from the normal peaks.

(b) *Calculation of RDF from observed intensity.*

RDFs were calculated for all five silver specimens. The modified intensity was first calculated by dividing the observed $I(s)$ by $|E(s)|^2$. We generally used $E(s)$ calculated by Hoerni and Ibers¹⁹⁾, $E_H(s)$. For the purpose of checking (Sec. 6c), we also used $E(s)$ calculated by Born approximation

$$E_B(s) = c\{Z - f(s)\}/s^2,$$

where Z is atomic number, c a numerical constant, and $f(s)$ atomic scattering factor for X-rays²⁰⁾. In the following sections, suffix H is usually omitted except when $E_H(s)$ and $E_B(s)$ are confused.

The modified intensity was multiplied by an artificial temperature factor $\exp(-0.01s^2)$ (Fig. 3c) and then, by using punched cards²¹⁾, the sine transformation was calculated in integrating region $1.4 < s < 14$, by approximating the integral in Eq. (7) by the summation

$$kD(r) = \text{const.} \times \sum_n nJ(n\Delta s) \cdot \exp[-b^2(n\Delta s)^2] \cdot \sin(n\Delta s \cdot r). \quad (12)$$

The interval of the numerical integration was always $(10/\pi)\Delta s = 0.2$. To estimate the error due to the finite interval, we carried out the summation by using a smaller interval $(10/\pi)\Delta s = 0.1$ for a few specimens. We found that RDFs calculated with 0.1 interval and with 0.2 interval did not differ more than 1% in region $r < 10\text{\AA}$, proving that 0.2 interval was small enough. For example, RDF for specimen No. 4 thus calculated is shown in Fig. 7c. This is RDF calculated from the average of three independently measured intensities (Sec. 2).

(c) *General features of observed RDF.*

The observed RDF (Fig. 7c) shows several large peaks which have physical significance. Their positions are in good agreement with normal interatomic distances r_i . Their forms are nearly Gaussian with almost equal breadth, $4\beta \simeq 0.53\text{\AA}$. Since $b = 0.1\text{\AA}$, we obtain $\sqrt{u^2} = 0.15\text{\AA}$; this is in agreement with the value for massive silver crystal⁶⁾. Small anomalous

peaks corresponding to stacking faults cannot be recognized at the first sight because normal peaks are broad.

Besides normal peaks, small rippled peaks are conspicuous near the origin. These peaks can be identified with the termination ghosts accompanying the peak at the origin i.e. the second term of Eq. (8a). It must also be noted that the observed RDF has a smooth background, as shown in Fig. 7c.

(d) *Detailed analysis of RDF.*

To detect anomalous peaks due to stacking faults, we analyzed the observed RDF as fol-

Fig. 7. Analysis of RDF (Sp. No. 4). (a) and (b): Neighbors in normal and disordered model (Sec. 5a). Height of anomalous neighbors (dotted lines) is magnified ten times. (c), (d) and (e) are explained in Sec. 5c-d. Ordinates of (c), (d) and (e) are in the same scale.

lows. First, we drew an arbitrary smooth background of RDF (Fig. 7c) and subtracted it from the total RDF. Secondary, we further subtracted the peak at the origin including the accompanying ghosts, i.e. kD_1 in Eq. (8) (Fig. 7d). In this procedure, D_1 was calculated by a numerical integration of Eq. (8a) and the normalization factor k was determined so that the residual at the position of peak, $r=0.2\text{\AA}$, vanished.

After the subtractions, RDF was separated into peaks under the following assumptions:

- (i) Normal interatomic distances are given strictly by Eq. (11) with $a_0=4.08\text{\AA}$;
- (ii) All the peaks are Gaussian and have the same breadth $4\beta=0.53\text{\AA}$;
- (iii) The height of each peak is determined so that the residual of RDF vanishes at the position of the peak.

Finally the analyzed normal peaks (Fig. 7d) were subtracted from RDF. Thus we obtained a residual part of RDF, denoted by $kR_1(r)$. The residual for specimen No. 4 (Fig. 7e) shows many peaks and valleys.

For further discussion, we denote peaks and valleys for $r>2\text{\AA}$ by a, B, C, d etc., capital letters showing conspicuous peaks or valleys. The largest peak H coincides well with the expected anomalous neighbor $i=3\frac{1}{2}$. Other large peaks G and J also coincide well with the expected anomalous neighbors, $i=2\frac{1}{2}$ and $5\frac{1}{2}$, respectively; and peak K coincides with the composite of $i=6\frac{1}{2}$ and $6\frac{3}{4}$. On the other hand, large valleys B and C have no correspondence to the expected anomalous peaks. They are on both sides of the first normal peak at $r=2.88\text{\AA}$ and they may be caused by the narrowing of the first normal peak by the correlative thermal vibration (Sec. 4). To prove

the results given above, we examine errors in detail in the next section.

§ 6. Examination of Errors

As described in the previous section, the residual was obtained from the observed RDF by subtracting (1) the arbitrarily drawn background, (2) the peak at the origin including accompanying termination ghosts, and (3) the normal peaks. Therefore, the residual may comprise errors of these terms as well as accidental and systematic errors of RDF. In this section we examine all kinds of errors. In Fig. 8 is a collection of errors and residuals calculated under various conditions. In Figs. 8a, b, c, we again show RDF of specimen No. 4 (Fig. 7c), N_i/r_i in $[5.5\times 8]_t$ (Fig. 7b), and residual R_1 of specimen No. 4 (Fig. 7e), respectively. In Table IV is tabulated height of peaks and valleys, together with the calculated anomalous peaks for $[5.5\times 8]_t$.

(a) Accidental error of RDF.

In order to estimate accidental error of RDF, we calculated RDF of specimen No. 4 from each independently measured intensity and from the average intensity. Fig. 7d shows $\Delta_i=D-D^i$ ($i=1, 2, 3$), where D is the RDF derived from the mean intensity, and D^i is that from each measured intensity. We found that the difference is always smaller than dotted curves in Figs. 8c, h and k . As can be seen in Fig. 8c, peaks G, H, J and K , corresponding to the anomalous neighbors, are considerably larger than the error. Valleys B and C also exceed the margin of the error a little. All of the other peaks, viz. a, d, e, f, i and those in $r<2\text{\AA}$, are below the accidental error and they may be ghosts. The order of the error at the position of each peak

Table IV. Peaks and valleys in residual.

									6 3/4	7.45	0.8	

is given in Table IV.

(b) *Errors of RDF caused by misestimating I_b+I_t and by the stray scattering.*

Observed intensity I may include errors caused by misestimating I_b+I_t and by the stray scattering which was always as smooth as I_t and of the same order as I_t (Sec. 2).

Since either of these errors is a smooth function of scattering angle, Fourier transform of either one is considerable only for small r in RDF. If I_b is underestimated by 20%, an error as shown in Fig. 8e appears in RDF. If I_t is misestimated 10 times, an error of the order of 20% I_b -misestimation appears in

Fig. 8. Residuals and errors (Sp. No. 4).
The scale of the ordinate is the same for (a) and (c)-(l).

$r < 2\text{\AA}$ of RDF. Since $I_i(s)$ is a function smoother than $I_b(s)$, in $r > 2\text{\AA}$ the error from I_i was smaller than that from I_b . Thus, small peaks near the origin may be ghosts caused by these errors. Valleys B and C , however, may be too large to be attributed to these errors and peaks G , H , J and K cannot be ghosts caused by them. It is also noteworthy that these errors result in a considerable error in the normalization factor k (Table V).

(c) *Influence of different atomic factors on RDF.*

If we use $E_B(s)$ instead of $E_H(s)$ in the calculation of RDF (Sec. 5b), we obtain an RDF, say $(\text{RDF})_B$, slightly different from that obtained before, $(\text{RDF})_H$. As shown in Fig. 8f, the difference, $\Delta R = (\text{RDF})_B - (\text{RDF})_H$, is a damping wave* the amplitude of which is of the same order as the accidental error. When $(\text{RDF})_B$ is analyzed according to the same conditions as those in Sec. 5d, the heights of normal peaks change considerably (Table V). In the obtained residual R_B , however, large peaks and valleys B , C , H , J and K remain almost unchanged (Fig. 8g). Therefore, even when calculated atomic scattering factors contain an error of the order* ($E_B - E_H$), it has little bearing on the present discussions on the residual.

(d) *Termination ghosts.*

There are ghosts accompanying D_1 of Eq. (8a) and those accompanying D_2 of Eq. (8b). The latter is made small by the artificial temperature factor** while the former cannot be made small, particularly near the origin (Fig. 8h). For this reason, this ghost was subtracted as described in Sec. 5d. Since the

* In Fig. 11, $(E_H/E_B)^2$ of silver atom is nearly constant for $s > 5$ and increases for $s < 5$. Therefore, except for a constant factor, the main difference between J_H and J_B , viz. modified intensity calculated by using $E_H(s)$ or $E_B(s)$, is that (111) intensity of J_B is larger than that of J_H by about 15%. Thus, the sine transform ΔR of $\Delta J = J_B - J_H$ is a wave with the periodicity $2\pi/s_{(111)} \simeq 2.3\text{\AA}$ having maxima at $r \simeq 0.6, 2.9, 5.2, 7.5\text{\AA}$ etc. and minima at $r \simeq 1.7, 4.0, 6.3, 8.6\text{\AA}$ etc.

** Since in our experiment $\gamma_i = \beta_i s_H \simeq 1.9$,

$$\frac{2}{\sqrt{\pi}} \Delta_m \exp(-\gamma_i^2) \simeq 0.01$$

(Table II). The effect of ghosts belonging to all peaks in D_2 can be estimated by the use of the asymptotic formula Eq. (10).

order of magnitude of the former ghost is the same as that of the accidental error for $r > 2\text{\AA}$, the error in estimating this ghost, which mainly arises from the empirical determination of factor k , is negligible.

(e) *Ambiguity of drawing the background of RDF.*

In Sec. 5d, a smooth background was subtracted from RDF. This background can be attributed to the fact that the integral for the region between the origin and s_m was neglected, i.e. D_3 of Eq. (8c). In this region we have only the small angle scattering caused by the external shape of crystallites. The calculation using models proves that the small angle scattering is limited to a very small angle in our experiment and thus curve D_3 gives a smooth background, the periodicity of which is larger than $10\text{\AA}$. For this reason it is certain that the background is not wavy for $r < 10\text{\AA}$. In all other respects, the background is ambiguous. Therefore we tested the effect of different backgrounds. Three different backgrounds, curves (1), (2) and (3) (Fig. 8a), were drawn and the corresponding residuals R_1 , R_2 and R_3 were calculated (Fig. 8c and i).

Through the variation in backgrounds, the residual is changed considerably. With the one exception of peak G , however, large peaks and valleys, B , C , H , J and K , are always conspicuous in R_1 , R_2 and R_3 . Therefore, they cannot be ghosts caused by an arbitrarily drawn background. In addition to these large peaks and valleys, there appear extra valleys in R_2 and extra peaks in R_3 as indicated by arrows in Fig. 8i. Since, however, these extra peaks and valleys appear as being dependent on the background and have no correspondence to any physical origin, they must be ghosts caused by the inadequate background. Therefore, we take background (1) as the most adequate one.

(f) *Three assumptions concerning the normal peaks.*

We further examine how R_1 is reformed by the modification of the three assumptions in Sec. 5d.

Position of normal peaks r_i . We found that if the value of r_i is taken to be 1% smaller than the normal value, peak H in the residual becomes lower (R_4 in Fig. 8j). However, it

is impossible to eliminate peak H perfectly by changing the value of r_4 . Moreover, it is physically impossible that r_4 decreases without changing other r_i . If all interatomic distances are 1% smaller than normal ones, residual has many large ghosts (R_6 in Fig. 8j). We found no variation in lattice parameter even for crystallite so small as 10 Å diameter. This is in agreement with that recently reported by Rymer²²⁾.

Breadth of normal peaks. According to Eqs. (4b') and (4c'), the breadth of near neighbor peaks should be narrower than that of distant neighbor peaks. By taking a smaller breadth for the first peak $4\beta_1=0.49\text{Å}$, valleys B and C can be diminished below the margin of error (R_6 in Fig. 8k). Large peaks in the residual, however, cannot be eliminated by changing the breadth of normal peaks. Therefore, we regard valleys B and C as ghosts caused by the inadequate assumption on breadth. It may be adequate to change assumption (ii) as follows:

(ii') All peaks except the first have the same breadth $4\beta=0.53\text{Å}$. The breadth of the first peak is reduced so that the ghosts in the neighborhood are diminished as

small as possible.

Height of normal peaks. We have proved that the large peaks in R_1 cannot be attributed to any other origins than the anomalous neighbors caused by stacking faults. Therefore, we change assumption (iii) as follows:

(iii') Height of normal peaks is determined so that the residual consists of anomalous peaks at expected positions and of Gaussian form with the same breadth as that of normal peaks.

The solid curve of Fig. 8l (R_7) shows the residual obtained by using the improved assumptions (i), (ii') and (iii'). The dotted curve in this figure shows Gaussian peaks corresponding to the anomalous neighbors. The difference between the solid and the dotted curve is certainly smaller than the margin of error.

§ 7. Result of RDF Analysis

The refined analysis was carried out for five silver specimens given in Table I. The obtained residuals are shown by solid curves in Fig. 9. In this figure, the calculated anomalous peaks for model $[5\cdot5\times8]_t$ is also shown. Anomalous peaks are always remarkable for specimens before annealing (Nos. 1,

Fig. 9. Residuals for each silver specimen.

Dotted curves indicate residuals when the narrowing of the first normal peak is not taken into account.

4 and 5). After annealings, anomalous peaks become very small (No. 2) or vanish (No. 3). All the anomalous peaks correspond to those in the disordered model, i.e. large peak with index $i=3\frac{1}{2}$, middle size peaks with $i=5\frac{1}{2}$, $6\frac{1}{2}$ and $6\frac{3}{4}$, and small peak with $i=2\frac{1}{2}$. Besides these peaks, there is no ghost for $r>1\text{\AA}$. Ghosts near the origin may be caused by the error mentioned in Sec. 6b. The dotted curves in Fig. 9 show the residuals calculated according to assumption (ii). They always have valleys on both sides of the first normal peak. It is evident that the first peak is narrower than the other peaks.

Table V. Result of RDF analysis of specimen No. 4.

i	$\sqrt{u_i^2}$	$\Delta\sqrt{u_i^2}$	Height $N_i/r_i\beta_i$	Error of height		ΔR

7	0.02		14.1	0.4		+0.4
$\Delta k/k$				6%	7%	2%

Apparent value of amplitude of thermal vibration, $\sqrt{u_i^2}$, can be calculated by Eq. (4c') from the observed peak breadth. Apparent amplitudes together with peak heights are summarized in Table V. For all specimens, apparent amplitudes were the same as those for specimen No. 4. The third column of Table V gives the estimated error of the amplitude. Since the effect of changing the peak breadth is small for small peaks, the error of amplitude is large for small peaks, and *vice versa*. It is known that the true value of amplitude is 0.16 $\text{\AA}$ for massive silver crystal⁶⁾. Apparent values, however, are expected to be smaller than the true value by about 20% for the first neighbor, by about 10% for the second and the third neighbor, and by less than 10% for the further neighbors (Eq. (6) and Fig. 5). Therefore, within the experimental error, our result agrees with the theoretical estimation.

Absolute peak height, $N_i/r_i\beta_i$, can be calculated by dividing an observed peak height by

the normalization factor k . Calculated values are given in column 4 of Table V. The same table also gives (1) the error of height caused by the accidental error (column 5); (2) the error by 2% misestimation of I_b or 100% of I_i (column 6), and (3) the difference of height determined by $(RDF)_B$ and that determined by $(RDF)_H$ (column 7). The errors of normalization factor k caused by origins (1), (2) and (3) are given in the lowest line of Table V.

Absolute number of neighbors N_i can be calculated from the absolute peak height $N_i/r_i\beta_i$ and the peak breadth $4\beta_i$. Thus obtained N_i as well as those calculated for models are given in Table III. Since both of the two disordered models given in this table have one fault in 8 layers, the fault probability is $1/8=12.5\%$. For these models the ratio of $\sum_{i\leq 7} N_i$ to $\sum N_i$ is 0.073 while the ratio for specimen No. 4 is 0.14, where $\sum$ indicates the summation over all the normal and anomalous neighbors and $\sum$ that over all the anomalous neighbors. Comparing these values, fault probability of No. 4 is estimated to be 23%. The probabilities estimated in this way for other specimens are given in Tables I and III.

In order to estimate crystal size, we plotted ratio $N_i/N_{i\infty}$ against i in Fig. 10, normalizing $N_1/N_{1\infty}$ to unity because the absolute value includes the error of k . In general, $N_i/N_{i\infty}$ decreases more steeply for smaller crystal. The slope of $N_i/N_{i\infty}$ for every specimen is slower than that for spherical model ($N=180$) and is steeper than that for ($N=54$). This implies that the equivalent diameters of specimens are between 18 $\text{\AA}$ and 12 $\text{\AA}$. Compared with a crystal without stacking faults, a same size crystal with faults has smaller numbers of distant neighbors (Sec. 5a and Table III) and thus shows steeper $N_i/N_{i\infty}$ (Fig. 10b). If the numbers of anomalous neighbors are included, the effect of faults can be corrected in estimating the crystal size. The correction amounted to about 10% for specimen Nos. 1, 4 and 5. The corrected values are given in the parentheses of column 6 in Table I. Other figures in this column show crystal size estimated from (111) half breadth. For all specimens, the latter estimation gives a value larger than that estimated by the former. If, however, the mean value of breadths of (111)

and (200) reflections is used, both estimations give a similar value.

It is also noteworthy that ratio $N_i/N_{i\infty}$ depends on the crystal shape as shown in Fig. 10b. Since, however, a marked relation between $N_i/N_{i\infty}$ and shape could not be found and since the obtained $N_i/N_{i\infty}$ included a considerable error, it was difficult to obtain information on crystal shape.

§ 8. Discussions

(a) Stacking faults.

We confirmed Kimoto's conclusion²⁾ on the existence of stacking faults in evaporated silver crystallites. We found the fault probability of the same order as that found by Kimoto. The faults decrease as crystal size becomes larger and they vanish when the crystallites are annealed.

We estimated fault probability (Table I) by assuming the faults were twin faults. If deformation faults are the case, fault probability turns out to be nearly half because deformation faults cause anomalous neighbors nearly twice those by twin faults. It is impossible to conclude from our RDF which of the faults is actual, because both faults cause a similar type of anomalous neighbors. However, it may be more reasonable to assume that twin faults are dominant in our case.

In the thermal equilibrium state, the prob-

ability of stacking faults is given by

$$\alpha = \exp(-F\Delta E/kT) \tag{13}$$

where F is the area of faulted layer and ΔE the energy of stacking fault per unit area. If we assume $\Delta E=20 \text{ erg/cm}^2$ ^{12), 13)} and $F=15\text{\AA} \times 15\text{\AA}$, α turns out to be less than 0.01% at room temperature. If this were the case, the faults could not have been detected in the present experiment. If, however, we assume that the crystallites are quenched from 1,600°K, the evaporating temperature of silver, to room temperature, α turns out to be 13%. This probability is in agreement with experimental results in the order of magnitude. Since crystallites with high probability of stacking faults are in a meta-stable state at room temperature, faults disappear quickly by an annealing. For aluminum for which ΔE is about 100 erg/cm², faults cannot occur even in meta-stable state. This is in agreement with the experimental result that no anomalous intensity is observed for aluminum. Probability for silver and aluminum are given in Table VI.

Table VI. Fault probability expected from Eq. (13).

Metal	ΔE	F	T	α
Ag	20 (erg/cm ²)	10 Å × 10 Å	1600°K	40%
		15 × 15	300	0.2×10^{-4}
		15 × 15	1600	13%
		20 × 20	1600	3%
Al	100	15 × 15	300	$< 10^{-20}$
		15 × 15	1600	0.5×10^{-4}

In Wagner's experiment¹¹⁾ the crystal size in filings was of the order of 100Å, while in our experiment the crystal size was of the order of 15Å. The difference of annealing temperatures at which stacking faults disappear can be attributed to the difference of crystal sizes. Moreover, in Wagner's experiment the faults were deformation faults. The difference of annealing temperatures may also be due to the difference of energies for deformation and twin faults.

The peak shift such as observed by Nimura⁷⁾ and Rymer⁸⁾ can be explained by either of the following three: (1) Growth faults with about 20% probability⁷⁾, (2) deformation faults with about 2% probability⁹⁾, (3) strain caused by sessile dislocations⁸⁾. In the present experiment, growth faults with about 20% was obtained for crystal size of about 15Å. There-

fore, explanation (1) seems to give too high probability because the crystallites used by Nimura and Rymer were a few ten Å in size. We cannot conclude which explanation is the most adequate. To throw light on this problem, analysis of line profile⁹⁾ may be useful.

(b) *Thermal vibration and strain in crystallites.*

It is emphasized that the observed amplitude of the thermal vibration for very small crystallites is in agreement with that for massive crystal.

On the other hand, Kimoto²³⁾ had to introduce a frozen heat motion corresponding to 600°K; $\sqrt{u^2}=0.24\text{Å}^*$ in order to make the observed intensity agree with the calculated one. He calculated the intensity profile by using E_B in the region between (111) and (311) reflections, i.e. $s=2.67$ and $s=5.11$. By the introduction of frozen heat motion, the damping between (111) and (311) becomes steeper by

$$\exp\{\frac{1}{3}u^2[s_{(311)}^2 - s_{(111)}^2]\}=0.70.$$

However, if E_H is used instead of E_B , the calculated intensity shows a steeper damping by

$$\left\{ \frac{E_H(311)}{E_H(111)} \middle/ \frac{E_B(311)}{E_B(111)} \right\}^2 = 0.85$$

(see Fig. 11). Therefore, the frozen heat motion may be partly due to an inadequate atomic factor. It may also be due to an inadequate background in the intensity curve²³⁾. In our

analysis the same amplitude of thermal vibration was obtained independent of atomic factors. This is due to the fact that the region of s -value in our experiment is so large that $(E_H/E_B)^2$ cannot be expressed by an apparent temperature factor $\exp(-c^2s^2)$ (Fig. 11).

In discussing the frozen heat motion, E_H seems better than E_B . However, it is difficult to conclude which is actually better, because (111) reflection is much stronger than other reflections and thus the photographic measurement is difficult. It must also be noted that for (111) reflections dynamical effect is not negligible even for fairly small crystallites²⁴⁾. The disagreement in data of (111) intensity^{24), 25), 26)} may be due to these causes.

It is interesting that the correlative effect of thermal vibrations was detected in RDF. This effect has often been observed in X-ray patterns of a single crystal as temperature diffuse scattering¹⁸⁾, but has not yet been observed in electron diffraction patterns of polycrystals.

We could not find the gradual increase of peak breadth in RDF. Similarly to liquid, highly distorted crystals give peak breadth which increases in proportion to the square root of distance²⁷⁾: $\Delta \text{breadth} \sim \sqrt{r \cdot a_0} \times \text{strain}$. Since in our experiment the gradual increase of breadth is smaller than $0.02\text{Å}/4\text{Å}$, we conclude that the strain is smaller than 0.01.

Acknowledgement

The author expresses his sincere appreciation to Professor Ryozi Uyeda and Dr. K. Kimoto for their constant encouragement and kind guidance throughout this work. He is indebted to Professor Y. Morino for his courtesy in loaning punched cards and to Dr. K. Kuchitsu for his immeasurable assistance in the calculation of Fourier transformation by punched cards. This experiment was suggested by Dr. K. Kimoto. The present investigation is supported in part by a Scientific Research Grant from the Ministry of Education.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 13, No. 9, SEPTEMBER, 1958

The Electron Distribution and the Location of the Bonded Hydrogen Atom in Crystals

By YUJIRO TOMIIE

*Department of Chemistry, Osaka University,
Nakanoshima, Osaka, Japan*

(Received May 27, 1958)

The electron distribution in a bonded hydrogen in crystals is investigated using mainly the VB method with the Gaussian approximation to the Slater wave functions. This approximation appears to be fairly good if the thermal vibration is considerable. In the present paper is studied the C-H bond as an example. It is concluded that the position of the maximum electron density around the proton is located more or less towards the heavier atom, and hence an apparent bond contraction in the X-ray analysis should occur. This seems to be in accord with experimental results. The apparent bond shortening increases and the peak density decreases with increase in the ionic character of the bond. For a constant value of the ionic character, the magnitude of the apparent bond shortening rapidly reaches a certain constant value when thermal vibration becomes large.

§1. Introduction

Since an ordinary atom other than hydrogen has nonbonded K shell electrons whose density is very sharply distributed and very high at the centre of the atom, the position of the

maximum electron density in it will coincide with that of the nucleus. In the case of the hydrogen atom, however, the K shell electron is at the same time the valence electron and accordingly the electron distribution should

depend more strongly upon bonding. Recent advances in the technique of x-ray crystal structure analysis have enabled us to locate experimentally hydrogen atoms in crystals. For such purpose is required the so-called ($F_o - F_c$)-synthesis which means the difference between the observed and calculated distribution of the electron density, the contribution of the hydrogen atoms being omitted in the later. In Table I are given some of the values of the C-H distances determined by X-ray methods. Although the accuracy of the values is not always very high, it is revealed from Table I that many of the distances are more

stals—the electron distribution is given fairly well by using such approximate AO's.

In our calculation the C-H bond vibration is not particularly considered. However, the bond vibration is usually not so large as the thermal vibration of the whole molecule in crystals. From the electron gas diffraction data of Morino et al.¹⁴, the temperature factor parameter B of the hydrogen atom due to a C-H bond vibration is estimated to be less than 0.5 Å relative to the carbon atom. This value is far smaller than that of the ordinary temperature factor parameter for the molecules in crystals. Therefore, we neglected the bond vibration as a first approximation. Also we consider only the case of the isotropic temperature factor for the molecule as a whole. However, this approximation will be sufficient to be compared with the experimental results as the accuracy of the experiments is not very high at present.

In the present paper are given first the general representations for the electron distribution of a bond by the use of both VB and MO method. Second are derived the mathematical results which give the distribution of the square of an AO, ϕ^2 , and of the product of AO's $\phi_a\phi_b$, both of which are required in our procedure. Finally the application of these results to the bonded hydrogen in the C-H bond is given as an example, calculated values being compared with experimental ones.

§ 2. The Electron Density Distribution in a Bond.

Let Ψ be an approximate wave function for the system, built out of atomic orbitals ϕ_a and ϕ_b , using either molecular orbital or valence bond theory. The electron density is then twice that for just one electron, i.e. $2\int\Psi^2d\tau$, the integral with respect to one electron, and we can write¹⁶,

$$\rho = q_a\phi_a^2 + q_b\phi_b^2 + q_{ab}(\phi_a\phi_b/S_{ab}), \quad (1)$$

where q_a , q_b and q_{ab} are the numbers of electrons distributed according to the normalized density functions ϕ_a^2 , ϕ_b^2 and $\phi_a\phi_b/S_{ab}$, S_{ab} being the overlap integral between the orbitals ϕ_a and ϕ_b . The quantities q_a , q_b and q_{ab} may be called atom and bond "charges"¹⁵ or "populations"¹⁸: their values depend on the approximation used (MO, VB, etc.), but the

* Three-dimensional investigation.

or less shorter than those spectroscopically accepted. This suggests that the maximum electron density around a proton is located somewhat towards the heavier atom. It is the present purpose to investigate theoretically whether the apparent bond shortening should occur in crystals. Since in general the C-H bond is considered not to be significantly affected by an external field, study on the C-H bond will be adequate for our purpose.

The distribution and the peak density of the electron in an atomic hydrogen with thermal vibration have been discussed theoretically by McDonald¹². The present paper treats the case of a bonded hydrogen by using a simple valence bond or molecular orbital method, in which McWeeny's Gaussian approximation¹³ to the Slater atomic orbitals is adopted. We may not expect very accurate electron distributions by using McWeeny's two-term Gaussian AO's. It appears, however, that if the influence of thermal vibration is considerable—and this is the case in most molecular cry-

density always involves the same orbital and overlap charge distributions, ϕ_a^2 , ϕ_b^2 and $\phi_a\phi_b/S_{ab}$.

We have given two approximations: (i) the MO approximation, in which MO's are given as

$$\Psi_j = \sum_r c_{rj} \phi_r, \quad (2)$$

and (ii) the VB approximation, where

$$\Psi = N(\Psi_{\text{cov}} + \lambda \Psi_{\text{ion}}) \quad (3)$$

and Ψ_{ion} describes both electrons on atom a, the more electronegative of the two atoms. λ , the degree of ionic character, is estimated in a later section. The populations are easily evaluated in each case, i.e.,

$$\text{MO:} \quad q_a = 2 \sum_j c_{aj}^2, \quad (4a)$$

$$q_b = 2 \sum_j c_{bj}^2, \quad (4b)$$

$$q_{ab} = 4S_{ab} \sum_j c_{aj}c_{bj}, \quad (4c)$$

$\sum$ being extended over all occupied orbitals,

$$\text{VB:} \quad q_a = 2(N_c^2 + \lambda^2 + 2\lambda S_{ab}N_c)/(1 + \lambda^2 + 4\lambda S_{ab}N_c), \quad (4d)$$

$$q_b = 2N_c^2/(1 + \lambda^2 + 4\lambda S_{ab}N_c), \quad (4e)$$

$$q_{ab} = 4N_c S_{ab}(S_{ab}N_c + \lambda)/(1 + \lambda^2 + 4\lambda S_{ab}N_c), \quad (4f)$$

where $N_c = 2(1 + S_{ab}^2)^{-1/2}$.

It remains to deal with the basic charge distributions.

§ 3. The ϕ^2 Distribution

McDonald¹²⁾ has discussed the influence of the thermal vibration upon the distribution of the electron density in a hydrogen atom three- and two-dimensionally using the square of normalized 1s wave functions. The ϕ^2 distribution with thermal vibration for light atoms could be obtained by applying Fourier transformation numerically to McWeeny's values for Slater type orbital electrons¹⁷⁾. However, since this Fourier transformation is not an easy matter, we shall adopt in the present paper McWeeny's 2-term Gaussian approximation to the AO¹³⁾, which is mathematically more convenient in extending the results to bonded atoms. The general single-term forms of ϕ and ϕ^2 for the 1s, 2s and 2p states are given in Table II.

Following McWeeny's results, terms of the type $r^4 \exp(-2ar^2)$ would be expected in $\phi^2(2s)$. However, since the form shown in Table II

Table II. Types of terms used in approximating ϕ and ϕ^2 .

	ϕ	ϕ^2
(1s)	$\exp(-ar^2)$	$\exp(-2ar^2)$
(2s)	$r^2 \exp(-ar^2)$	$r^2 \exp(-2a'r^2)^*$
(2p)	$r \cdot e \exp(-ar^2)$	$x^2 \exp(-2ar^2)$

e is a unit vector along the 2p orbital

* In the present calculation this form is used instead of the form $r^4 \exp(-2a'r^2)$.

is more convenient and the numerical values for the parameters are easily derived from those in the 2p function, we shall use terms of the type $r^2 \exp(-2ar^2)$ in approximating the $\phi^2(2s)$ function. This will give a more accurate distribution for the 2s electrons than McWeeny's original $\phi^2(2s)$ function, as is clear from the discussion in McWeeny's paper. The resultant ϕ and ϕ^2 for the 1s, 2s and 2p cases are given in Table III, where the atomic unit is chosen as the unit of length.

(2p)	$4.109 \times 10^{-2} \cdot Z^{3/2} \rho \cdot e \{\exp(-0.1512\rho^2) + 0.392 \exp(-0.03287\rho^2)\}$
	ϕ^2
(1s)	$5.886 \times 10^{-2} \cdot Z^3 \exp(-2.660\rho^2) + 3.094 \times 10^{-2} \cdot Z^3 \exp(-0.4028\rho^2) + 8.534 \times 10^{-2} \cdot Z^3 \exp(-1.5814\rho^2)$
(2s)	$5.628 \times 10^{-4} \cdot Z^3 \rho^2 \exp(-0.3024\rho^2) + 0.8648 \times 10^{-4} \cdot Z^3 \rho^2 \exp(-0.06574\rho^2) + 4.412 \times 10^{-4} \cdot Z^3 \rho^2 \exp(-0.18407\rho^2)$
(2p)	$16.884 \times 10^{-4} \cdot Z^3 \xi^2 \exp(-0.3024\rho^2) + 2.594 \times 10^{-4} \cdot Z^3 \xi^2 \exp(-0.06574\rho^2) + 13.236 \times 10^{-4} \cdot Z^3 \xi^2 \exp(-0.18407\rho^2)$

Z is the effective nuclear charge same as in the Slater AO's. $\rho = Zr$ and $\xi = Zx$.

The influence of thermal vibration on the density is easily discussed in three-, two-, or one-dimensional case provided the Gaussian approximation to the AO is chosen.

In the first place we consider the three-dimensional case. A function $T(r)$ is defined as follows;

$$T(r) = \int \exp(-\beta S^2) \exp(-2\pi i S \cdot r) dS, \quad (5)$$

where

$$|S| = 2 \sin \theta / \lambda, \quad \beta = 2\pi^2 \bar{u}^2 = \frac{1}{4} B.$$

β is a constant given as the one fourth of the so-called temperature factor parameter B which will be determined experimentally. $\bar{u}^2$ is related to the mean square displacement of a point from the equilibrium position. Assuming isotropic thermal vibration, we obtain

$$T(\mathbf{r}) = \left(\frac{\pi}{\beta} \right)^{3/2} \exp(-t r^2), \quad (5a)$$

where

$$t = \pi^2 / \beta.$$

Since electron density of the system at rest is given as

$$\rho(\mathbf{r}) = \int f(\mathbf{S}) \exp(-2\pi i \mathbf{S} \cdot \mathbf{r}) d\mathbf{S},$$

where $f(\mathbf{S})$ is the scattering factor of the electron distribution, the distribution with thermal vibration becomes,

$$\bar{\rho}(\mathbf{r}) = \int \rho(\mathbf{u}) T(\mathbf{r} - \mathbf{u}) d\mathbf{u}. \quad (6)$$

We are now in a position to obtain the density of the 1s, 2s and 2p electrons by using Gaussian approximation and by Eq. (6). As the three-dimensional $\bar{\rho}(\mathbf{r})$ is given in Gaussian form as given below, the two- or one-dimensional projection is easily obtained by suitable integrations. In the derivation of the distribution for each orbital electron with thermal vibration, the following two formulae are necessary,

$$\int \exp(-p x^2 + 2q x) dx = (\pi/p)^{1/2} \exp(q^2/p), \quad (7)$$

and

$$\int x^2 \exp(-p x^2 + 2q x) dx = 1/(2p) \cdot (\pi/p)^{1/2} (1 + 2q^2/p) \exp(q^2/p). \quad (8)$$

Assuming the general forms of ϕ^2 shown in Table II, the results including the influence of thermal vibration are found to be as follows:

(1s) State.

$$(3-D) \quad \bar{\rho}(r) = K^{3/2} \exp(-2aKr^2), \quad (9)$$

where

$$K = t/(2a+t), \quad t = \pi^2/\beta,$$

$$(2-D) \quad \bar{\rho}(r) = (\pi/2a)^{1/2} K \exp(-2aKr^2), \quad (10)$$

$$(1-D) \quad \bar{\rho}(r) = (\pi/2a) K^{1/2} \exp(-2aKr^2). \quad (11)$$

r^2 means $x^2 + y^2 + z^2$ (3-D), $x^2 + y^2$ (2-D), and x^2 (1-D) respectively.

(2p) State:—The direction of the orbital along the x -axis.

$$(3-D) \quad \bar{\rho}(r) = \frac{1}{2}(2a+t)^{-1} \times K^{3/2}(1+2Ktx^2) \exp(-2aKr^2). \quad (12)$$

$$(2-D) \quad \text{The projection on the } xy\text{-plane,}$$

$$\bar{\rho}(r) = \frac{1}{2}(\pi/2a)^{1/2}(2a+t)^{-1} \times K(1+2Ktx^2) \exp(-2aKr^2). \quad (13)$$

The projection on the xy -plane,

$$\bar{\rho}(r) = \frac{1}{2}(\pi/2a)^{1/2}(1/2a)K \exp(-2aKr^2). \quad (14)$$

(1-D) The projection on the x -axis,

$$\bar{\rho}(r) = \frac{1}{2}(\pi/2a)(2a+t)^{-1} \times K^{1/2}(1+2Ktx^2) \exp(-2aKr^2). \quad (15)$$

The projection on the y -axis,

$$\bar{\rho}(r) = \frac{1}{2}(\pi/2a)K^{1/2} \exp(-2aKr^2). \quad (16)$$

In Eq. (14) $r^2 = y^2 + z^2$, and in Eq. (16) $r^2 = y^2$.

(2s) State.

$$(3-D) \quad \bar{\rho}(r) = \frac{1}{2}(2a+t)^{-1} \times K^{3/2}(3+2Ktr^2) \exp(-2aKr^2), \quad (17)$$

$$(2-D) \quad \bar{\rho}(r) = \frac{1}{2}(\pi/2a)^{1/2}(2a+t)^{-1} \times K(3+t/2a+2Ktr^2) \exp(-2aKr^2), \quad (18)$$

$$(1-D) \quad \bar{\rho}(r) = \frac{1}{2}(\pi/2a)(2a+t)^{-1} \times K^{1/2}(3+t/a+2Ktr^2) \exp(-2aKr^2), \quad (19)$$

§ 4. $\phi_a \phi_b$ Distribution

Assuming the Gaussian approximation shown in Table II, the vibrational modification of the overlap distribution, $\phi_a \phi_b$, can be obtained. For the sake of convenience, $\exp(-ar_a^2) \times \exp(-br_b^2)$, for instance, is defined as $(1s)_a(1s)_b$. The notation for the coordinates is shown in Fig. 1.

Fig. 1 Vector notation of coordinates.

(1s)_a(1s)_b Distribution.

Considering the following relations, which are obvious from Fig. 1,

$$r_a^2 = r^2 - 2r \cdot A + A^2, \quad r_b^2 = r^2 - 2r \cdot B + B^2,$$

and using Eqs. (7) and (8), the (1s)_a(1s)_b distribution is given as follows,

$$(3-D) \quad \bar{\rho}(r) = K'^{3/2} \exp \{-abR^2/(a+b+t)\} \exp \{-K'(ar_a^2 + br_b^2)\} \quad (20)$$

where $K' = t(a+b+t)$, $R = B - A$ (see Fig. 1),

$$(2-D) \quad \bar{\rho}(r) = \{\pi/(2+b)\}^{1/2} \exp \{-K'abR_z^2/(a+b)\} \\ \times K' \exp \{-abR^2/(a+b+t)\} \exp \{-K'(ar_a^2 + br_b^2)\}, \quad (21)$$

$$(1-D) \quad \bar{\rho}(r) = \pi/(a+b) \cdot \exp \{-K'ab(R_z^2 + R_y^2)/(a+b)\} \\ \times K'^{1/2} \exp \{-abR^2/(a+b+t)\} \exp \{-K'(ar_a^2 + br_b^2)\}, \quad (22)$$

It is clear that r_a^2 is $x_a^2 + y_a^2 + z_a^2$ (3-D), $x_a^2 + y_a^2$ (2-D) or x_a^2 (1-D), and also $R_z = B_z - A_z$, etc.

(2s)_a(1s)_b Distribution.

If we denote the expressions (20), (21) and (22) by I_3 , I_2 and I_1 respectively, it follows that $-(\partial I_3/\partial a)$, $-(\partial I_2/\partial a)$ and $-(\partial I_1/\partial a)$ give the expressions of the three-, two- and one-dimensional (2s)_a(1s)_b distribution. This is analogous to McWeeny's procedure in obtaining the bond structure factor¹³⁾. The results are as follows:

$$(3-D) \quad \bar{\rho}(r) = (a+b+t)^{-2} K'^{3/2} \{ \frac{3}{2}(a+b+t) + (bR + tr_a)^2 \} \\ \times \exp \{-abR^2/(a+b+t)\} \exp \{-K'(ar_a^2 + br_b^2)\}, \quad (23)$$

$$(2-D) \quad \bar{\rho}(r) = \{\pi/(a+b)\}^{1/2} (a+b+t)^{-2} K' \{ (a+b+t) + \frac{1}{2}(a+b+t)^2/(a+b) \\ + bt(b^2 - a^2 + bt)R_z^2/(a+b)^2 + (bR + tr_a)^2 \} \exp \{-abR^2/(a+b+t)\} \\ \times \exp \{-abtR_z^2/(a+b+t)(a+b)\} \exp \{-K'(ar_a^2 + br_b^2)\}, \quad (24)$$

$$(1-D) \quad \bar{\rho}(r) = \pi(a+b) \cdot (a+b+t)^{-2} K'^{1/2} \{ \frac{1}{2}(a+b+t) + (a+b+t)^2/(a+b) \\ + bt(b^2 - a^2 + bt)(R_z^2 + R_y^2)/(a+b)^2 + (bR + tr_a)^2 \} \exp \{-abR^2/(a+b+t)\} \\ \times \exp \{-abt(R_z^2 + R_y^2)/(a+b+t)(a+b)\} \exp \{-K'(ar_a^2 + br_b^2)\}. \quad (25)$$

(2p)_a(1s)_b Distribution.

In order to deal with the (2p)_a(1s)_b distribution it is convenient to introduce vectors $A' = A + \delta_a$, etc., where $\delta_a = \delta_a e_a$ (e_a being a unit vector) is the vector pointing along the directed (2p) orbitals at A (Fig. 1), and to denote the expressions (20), (21) and (22) by I_3' , I_2' and I_1' in which A and B are replaced by A' and B' respectively. It then follows easily that,

$$\frac{1}{2a}(\partial I_3'/\partial \delta_a), \quad \frac{1}{2a}(\partial I_2''/\partial \delta_a), \quad \text{and} \quad \frac{1}{2a}(\partial I_1'/\partial \delta_a)$$

give the expressions of the three-, two- and one-dimensional (2p)_a(1s)_b distributions. The results are given as follows,

$$(3-D) \quad \bar{\rho}(r) = (a+b+t)^{-1} K'^{3/2} (bR \cdot e_a + tr_a \cdot e_a) \exp \{-abR^2/(a+b+t)\} \exp \{-K'(ar_a^2 + br_b^2)\}, \quad (26)$$

$$(2-D) \quad \bar{\rho}(r) = \{\pi/(a+b)\}^{1/2} (a+b+t)^{-1} K' \{ bR \cdot e_a + btR_z \cdot e_a/(a+b) + tr_a \cdot e_a \} \\ \times \exp \{-abR^2/(a+b+t)\} \exp \{-abtR_z^2/(a+b+t)(a+b)\} \exp \{K'(ar_a^2 + br_b^2)\}, \quad (27)$$

$$(1-D) \quad \bar{\rho}(r) = \pi/(a+b) \cdot (a+b+t)^{-1} K'^{1/2} \{ bR \cdot e_a + bt(R_z + R_y) \cdot e_a/(a+b) + tr_a \cdot e_a \} \\ \times \exp \{-abR^2/(a+b+t)\} \exp \{-abt(R_z^2 + R_y^2)/(a+b+t)(a+b)\} \exp \{-K'(ar_a^2 + br_b^2)\}. \quad (28)$$

Eqs. (21), (22), (24), (25), (27) and (28) become much simpler if the bond lies in a projection

plane or projection line.

§ 5. Applications

In the preceding sections are derived the analytical expressions for ϕ^2 and $\phi_a\phi_b$ with thermal vibration which are useful in obtaining the electron distribution of a bond in which a hydrogen atom is participating. The distribution thus calculated is almost the same as that derived by using Slater AO's in particular cases. For example, in Fig. 2 are shown the curves which give the ratios between the values of the peak density for a hydrogen atom calculated by the Gaussian approximation and the Slater AO as the functions of temperature factor B (in $\text{\AA}^3$ unit). Slater 1s function gives a sharp electron distribution at the centre when the atom is at rest. However, from this figure, it is clear that the Gaussian approximation (two-terms) is fairly good especially in the two-dimensional projection if the thermal vibration is considerable.

Next we shall discuss the distribution of the electron density of a C-H bond. We assume that (a) the distance between carbon nucleus and proton is 2 atomic units (1.058 $\text{\AA}$), (b) $\beta=2.0$ in atomic unit which corresponds to $B=2.332 \text{\AA}$, a value usually found in actual crystals, (c) the valence AO of the carbon atom is sp^2 -hybridized since we have found that the peak position is practically unaffected by the change of carbon hybridization among sp , sp^2 and sp^3 . (Peak height is, however, slightly affected.) From the VB point of view, the electron distribution in the C-H bond is given by Eqs. (1) and (4d, e, f) and the numerical values of the distribution can be obtained if λ is suitably chosen.

Coulson¹⁸⁾ has estimated the value of λ as 0.95 from the theoretical discussion of the C-H

Fig. 2. Ratios of the peak density of 1s electron distribution as the function of temperature factor B . $\rho_m(G)$ and $\rho_m(\text{Slater})$ represent the value of peak density given by Gaussian and Slater respectively.

Fig. 3. The electron distribution in a bonded hydrogen combined with the carbon atom whose valence state is sp^2 . λ is the degree of ionic character. (a) Three-dimensional case. (b) Two-dimensional case. The temperature factor $B=2.232 \text{\AA}^2$ ($\beta=2.0 \text{ a.u.}$).

dipole moment. On the other hand, Hannay and Smyth have proposed a formula¹⁹⁾ relating the percentage ionic character of a bond, i.e., $100\lambda^2/(1+\lambda^2)$, to the Pauling electronegativities of atoms a and b : namely,

Percentage ionic character

$$=16|x_a-x_b|+3.5|x_a-x_b|^2. \quad (29)$$

This leads to a much lower value, $\lambda=0.27$. The disagreement is probably associated with hybridization effects¹⁸⁾. We shall consider three cases corresponding to the three values of λ , 0.00, 0.27 and 0.95. The C-H electron distributions corresponding to the three cases are given as follows,

$$0.658\phi_C^2+0.658\phi_H^2+0.949\phi_C\phi_H, \quad \text{for } \lambda=0.00, \quad (30a)$$

$$0.823\phi_C^2+0.433\phi_H^2+1.032\phi_C\phi_H, \quad \text{for } \lambda=0.27, \quad (30b)$$

$$1.161\phi_C^2+0.189\phi_H^2+0.901\phi_C\phi_H, \quad \text{for } \lambda=0.95, \quad (30c)$$

The information about the position and the electron distribution of a bonded hydrogen is usually obtained from the map of the (F_o-F_c) -synthesis, which corresponds, in the present case, to the distribution obtained by subtracting ϕ_C^2 from the above distribution. Thus the electron distribution around a hydrogen atom attached to a carbon atom is given as,

$$-0.342\phi_C^2+0.658\phi_H^2+0.949\phi_C\phi_H, \quad \text{for } \lambda=0.00, \quad (31a)$$

$$-0.177\phi_C^2+0.433\phi_H^2+1.032\phi_C\phi_H, \quad \text{for } \lambda=0.27, \quad (31b)$$

$$0.161\phi_C^2+0.189\phi_H^2+0.901\phi_C\phi_H, \quad \text{for } \lambda=0.95, \quad (31c)$$

In Figs. 3a and 3b are shown the three- and two-dimensional electron distributions along the C-H line when β is 2.0 ($B=2.232 \text{ \AA}$). Similarly in Figs. 4a and 4b are shown the distributions when β is 7 ($B=7.81 \text{ \AA}$), and in Fig. 5 are shown those when β is zero. From these figures, we conclude the following points.

Fig. 4. The electron distribution in a bonded hydrogen combined with the carbon atom whose valence state is sp^2 . (a) Three-dimensional case. (b) Two-dimensional case. The temperature factor $B=7.81 \text{ \AA}^2$ ($\beta=7.0 \text{ a.u.}$).

Fig. 5. The electron distribution in a bonded hydrogen combined with the carbon atom whose valence state is sp^2 . Two-dimensional case. The temperature factor $B=0$.

(a) The position of the maximum electron density is located more or less towards the carbon atom and hence the apparent bond shortening should occur. (b) This apparent shortening is greater as the λ value increases. (c) Also the peak density decreases when the λ value increases. (d) The magnitude of the apparent bond shortening, at a constant value of λ , reaches rapidly a certain constant value when the thermal vibration becomes large. (e) Even if the temperature factor parameter is zero (this does not occur owing to the zero point vibration), the two-dimensional distribution shows more or less an apparent bond shortening, while it can be seen that the three-dimensional distribution does not give such contraction. In these cases, we adopt the ϕ_H^2 curves obtained by McDonald¹²⁾, at the Gaussian approximation is not good.

It seems likely, from Figs. 3, 4 and 5, that the value of λ is too large if we choose $\lambda=0.95$, because, for instance in Fig. 3, this gives the peak densities $0.61 \text{ e. \AA}^{-3}$ and $0.66 \text{ e. \AA}^{-2}$, which seem to be somewhat too small in comparison with the experimental results, and also the apparent bond distance $0.76 \text{ \AA}$ (in average) derived from these figures gives a minimum value of the experimental results. On the other hand, it seems unlikely that λ is zero because of the difference between the electronegativities of carbon and hydrogen. When λ is 0.27 , the peak densities are $0.76 \text{ e. \AA}^{-3}$ and $0.80 \text{ e. \AA}^{-2}$ and the apparent bond distance is $0.92 \text{ \AA}$ (in average). These values seem to be more reasonable as compared with the experimental ones. However, it is to be remarked that, as is seen from Table I, the reported values for the C-H distance are rather diverse. Therefore, it will be safe to say that the actual λ for the C-H bond may have a value between 0.25 and 0.9 , and probably closer to the former. McDonald¹²⁾ has pointed out that the experimental electron distribution curve around a bonded hydrogen atom is similar to that obtained using the atomic hydrogen wave function, though the peak is displaced more or less towards the heavy atom.

The electron distribution curves shown in Fig. 3 are quite similar to those given by McDonald if peaks are adjusted (private communication).

In the two-dimensional projection, it is found that the inclination of a bond direction to the projection plane gives no practical change upon the above conclusion about the apparent C-H bond contraction if the angle of inclination is not large.

I wish to express my thanks to Professor I. Nitta for his interest and helpful advice, to Dr. R. McWeeny for his kind discussion, and to Mr. K. Sakurai and Mr. T. Yamaguchi for their continued interest and for checking the mathematical derivations. My thanks are also due to Professor C. A. Coulson for reading the manuscript. This research was supported by a grant of the Ministry of Education.

Luminescence and Dichroism of F and M Centers in Potassium Chloride

By Goro KUWABARA and Akira MISU

*Department of Physics, Faculty of Science,
University of Tokyo, Tokyo*

(Received May 6, 1958)

In order to determine the model of the M center, the luminescence and dichroism of additively colored KCl were studied in detail. The polarization factor of luminescence due to M centers excited with polarized light in the F band are $P(\pi/4) = -0.37$ and $P(0) = -0.17$. The F band as well as the M band becomes dichroic by irradiating with polarized light in the M band at room temperature or in the F band at low temperature, and the same quantitative relation exists between the amounts of dichroism in the F and M band for both cases.

Above results do not contradict the hypothesis that the second M band overlaps with the F band, and if this assumption is granted, it is concluded from the experiment that the symmetry type of the M center is not C_{2v} but D_{2h} . The oscillator strengths were found to be 0.65 and 0.53 of that of the F band.

If the emission due to M centers excited with light in the F band is assumed to be caused by the resonance transfer from F to M centers, in order to explain the experimental value of transfer probability, the distance between both centers must be less than the order of 10 Å.

§ 1. Introduction

The color centers of alkali halides and their mutual transformation have been investigated by many authors, and the model of the F center is almost conclusively confirmed by the optical and electron spin resonance experiments. However, the models of other centers, proposed chiefly by Seitz¹⁾, are not so sure.

As to the M center, Ueta²⁾ concluded from experiments on the anisotropic bleaching at room temperature that the M center has the symmetry type of C_{2v} or D_{2h} , whose axis is oriented along a face diagonal.

Inui, Uemura and Toyozawa³⁾ calculated the energy levels of the M center by assuming the model proposed by Seitz, and showed that another absorption band (the second M band) due to the M center might exist on the shorter wavelength side of the ordinary M band (the first M band). Van Doorn⁴⁾ found that, when the crystal containing both F and M centers was irradiated with polarized light in the F band at liquid nitrogen temperature, the F and M bands became dichroic, whose directions of maximum absorption were perpendicular with each other.

It has been found recently that not only F centers but also M and R centers luminesce

under suitable conditions, and the measurement of the polarization of luminescence provides powerful means for determining the symmetry of centers. In order to explain the dichroism induced by light in the F band and the polarized luminescence of M centers, van Doorn⁵⁾ proposed a hypothesis that the second M band overlaps with the F band, and assigned D_{2h} symmetry to the M center. However, his experiment on the polarization of the luminescence by M centers excited with light in the F band was in contradiction with his model. On the other hand, from experiments on the luminescence of crystals colored by β -ray bombardment, Lambe et al⁶⁾ showed that the model of the M center proposed by Seitz can explain the experimental facts and suggested that the luminescence of the M center excited with light in the F band is not caused by direct absorption but by transportation of energy from F to M centers through the crystal.

In order to clarify these points it seems necessary to obtain a quantitative knowledge on the amount of dichroism caused by irradiation with light in the F and M band, polarization, quantum efficiency, and temperature dependence of luminescence.

§ 2. Experimental Procedures

The optical arrangement for measuring the absorption and emission spectra is shown in Fig. 1. For excitation and inducing dichroism with light in the *F* band, the polarized light of λ 546 $m\mu$ from a high pressure mercury lamp of 500 watts isolated by suitable filters and a polaroid was used. The luminescence was focused through a Nicol prism and a infrared filter on a detector or on a slit of a monochromator for measurement of spectral distributions. Aperture of the monochromator was *F*: 1.9 and the focal length of a collimator lens was 20 cm. The width of slits were 0.08 mm, which corresponded to the band width of 9 $m\mu$ at 1000 $m\mu$. The polarization characteristic of luminescence was measured by fixing the Nicol relative to the crystal and rotating the polaroid. For absorption measurements and inducing dichroism with light in the *M* band, the light from a quartz double monochromator passed through a Nicol prism was used.

A Ag-Cs phototube with a D. C. amplifier, a photomultiplier or a PbS cell was used as a detector. In the latter, the light was chopped with the frequency of 800 c/s, and the signal was amplified by a tuned amplifier with the gain of 156 db.

Fig. 1. Optical arrangement.

Crystals of potassium chloride grown by Kyropoulos method was additively colored at about 650°C for about 2 hours. Before experiments, a specimen of about 1 mm in thickness cleaved from a crystal was again heated up to 700°C for a few minutes and quenched in the liquid air. The crystals thus obtained contained almost only *F* centers and remained free from *M* centers at least for a few days even at room temperature in the dark. The density of *F* centers was the order of $10^{17} \sim 10^{18}/\text{cm}^3$.

The sample was clamped to a holder in the

liquid air and attached to a dewar vessel shown in Fig. 2.

In order to grow *M* centers, the crystal was warmed up to above room temperature and irradiated in the *F* band.

Fig. 2. Dewar vessel.

§ 3. The Luminescence of the *F* and *M* Centers Excited with Light in the *F* Band.

Absorption and emission spectra of luminescence excited with light in the *F* band for crystals containing various amounts of *F*, *M* and *R* centers are shown Fig. 3, in which the ordinates for luminescent intensity is in an arbitrary unit common for four cases.

Three emission peaks observed at liquid air temperature, which were situated at about 1.19, 1.12 and 1.02 eV might be attributed to the luminescence of *F*, *M* and *R* centers, respectively. The luminescence due to the *F* center was perceived even

for crystals containing large amount of *M* centers. However, in this case the ratio of the emission and absorption intensities of the *F* center for a crystal containing *M* centers appears to be less than that for a crystal containing only *F* centers.

As shown in Fig. 3, luminescent intensities decreased with the rise of temperature for all cases, and the temperature dependence was the largest for *F* emission and the smallest for *M* emission, which remained even at room temperature.

The temperature dependence of the total

emission excited with light in the F band is shown in Fig. 4. A freshly quenched crystal containing only F centers luminesce below -50°C , and the intensity, increasing with the decrease of temperature, became saturated below -180°C . The intensity of luminescence η was linear to that of the exciting light. Be-

tween -210°C and -50°C , the variation of the intensity with temperature was reversible, and the saturated quantum efficiency at low temperature was about 9 per cent.

Temperature dependence was analysed to the following formula,

$$\eta/\eta_{\text{sat}} = 1/[1 + B \exp(-E/kT)], \quad (1)$$

with $B = 2.5 \times 10^4$ and $E = 0.11$ eV.

Except for the low quantum efficiency, the above values seem to be reasonable, if the luminescence is regarded as a competing process with thermal ionization of excited F centers. However, in order to ascertain this point, the measurement of photoconductivity on a luminescent crystal is desirable.

When the crystal containing only the F center was irradiated with light in the F band at room temperature, the M band gradually increased at the cost of the F band, and with prolonged irradiation R_1 and R_2 bands also grew up, while the M band decreased after passing through the maximum value. The rate of growth was sensitive to the temperature as well as the intensity of illuminating light. During the growth of the M band, the R bands were hardly perceptible.

The luminescent behaviour of the crystal containing large amounts of F centers, more than $10^{18}/\text{cm}^3$ seemed rather peculiar compared with crystals of low concentration. In the latter, the intensity of F emission was almost proportional to the absorption intensity of the F band, while in the former, the decrease of the intensity of F emission was more rapid than the decrease of the absorption intensity of the F band, and in some crystals, during the excitation with intense light, the luminescent intensity decreased to one-tenth of the initial value. This fact seems to show the mutual interaction

Fig. 3. Emission and absorption spectra of a crystal in various states. Absorption spectra were measured at -160°C . Full lines, broken lines and dotted lines show the emission spectra measured at -160°C , -100°C and -50°C , respectively.

between *F* centers.

If the exciting light is polarized along the direction of [011], the luminescence of the *M* center is remarkably polarized. The degree of polarization is expressed by *P* factor defined as

$$P(\alpha) = (I_{//} - I_{\perp}) / (I_{//} + I_{\perp}), \quad (2)$$

where the exciting light travelling along the [100] direction, α is the angle between (010) plane and the polarization plane of an analyzer. $I_{//}$ and $I_{\perp}$ are the intensities of luminescence when a polarizer is set parallel and perpendicular to that of the analyzer, respectively.

Fig. 4. Temperature dependence of luminescent intensity due to *F* centers.

light in the *F* band is shown in Fig. 5. The maximum quantum efficiency of *M* emission at room temperature was about one fourth of the saturated value, which was obtained for the same crystal when it contained only *F* centers.

At room temperature, where only *M* centers might luminesce, the mean values of *P* for the emission excited with light in the *F* band were found to be

$$P(\pi/4) = -0.37 \pm 0.05, \quad P(0) = -0.17 \pm 0.07.$$

Above values were different from those reported by Lambe et al.¹⁰ ($P(\pi/4) = -0.30$) and van Doorn⁶ ($P(\pi/4) = +0.24$). Taking the amount of experimental errors and the theoretical values (cf. Tab. I) into consideration, in the following analysis we used $P(\pi/4) = -0.4$ and $P(0) = -0.2$ as the polarization characteristic of *M* emission.

The absolute value of *P* factor of the total emission decreased with the decrease of temperature, and at low temperature it increased with the increase of *M* center concentration. These facts can be explained as due to the superposition of *F* and *M* emissions, and the intensity of the total emission was decomposed into components due to *F* and *M* centers as shown in the figure. The encircled and cross points are the mean values obtained by using $P(\pi/4)$ and $P(0)$. The broken line is the temperature dependence of *F* emission fitted at -150°C . The temperature dependence of luminescence due to *F* centers was found to be not influenced by the presence of *M* centers.

In Fig. 6, the spectral distribution of *P* factor at liquid air

temperature is shown. The observed emission spectrum in (b) was also the superposition of *F*, *M* and a small amount of *R* emissions. By using *P* values the spectrum was decomposed into its components, which seemed reasonable as shown in the figure.

If it is assumed, in addition to the uniform

Fig. 5. Temperature dependence of luminescent intensity and *P* factor due to *F* and *M* centers.

The luminescence of a freshly quenched crystal containing only *F* centers was entirely unpolarized, i.e. $P=0$ for all angles as well as its absorption. (cf. Fig. 6a)

The temperature dependence of the intensity and *P* factors of the total emission for a crystal containing both *F* and *M* centers excited with

orientation of M centers along six equivalent directions, that the absorption band corresponding to the transition from the ground to the second excited states of the M center overlaps with the F band, and that M centers excited to this state by F -light absorption make radiationless transition to the first excited state

analyzer and the dipoles corresponding to the transitions to the first and second excited states of M centers⁷⁾.

$$P(\alpha) = -(3 - \cos 4\alpha)/10 \text{ for the } D_{2h} \text{ symmetry.}$$

$$P(\alpha) = -(1 - 3 \cos 4\alpha)/6 \text{ for the } C_{2v} \text{ symmetry.}$$

In the above argument and throughout this paper, it is assumed that in the case of C_{2v} the transitions from the ground to the first and to the second excited states are active to the light polarized along face diagonals perpendicular to each other, and that in the case of D_{2h} two higher excited states are nearly degenerate. Because the model of the M center consisted of two negative ion vacancies along a face diagonal is similar to a homonuclear diatomic molecule ($D_{\infty h}$), and the transition which corresponds to the band over lapping with the F band is active to the polarized light, whose electric vector lies in the plane normal to the symmetry axis. The transition to the first excited state is active to the light polarized along the axis. The P factor for various cases are listed in Table I. The present result, especially the negative value of $P(0)$ indicates that the symmetry type of the M center is D_{2h} , under the above assumption, that is, the overlapping of the M with the F band, and the

Fig. 6. Spectral distribution of P factor. (a) emission due to F centers (b) due to F and M centers.

and then luminesce, the symmetry type of the M center can be determined from the polarization characteristic of luminescence. polarization of luminescence excited with light in the M band—the emission spectrum is quite the same as that in case of F -light excitation—has been reported by Lambe et al⁶⁾ as $+0.60$ and $+0.33$ for $\alpha=\pi/4$ and $\alpha=0$, respectively. This can be explained by assuming C_{2v} or D_{2h} for the symmetry type of the M center, and agrees with the results obtained by Ueta. For the C_{2v} symmetry, the polarization of luminescence due to the M center excited with polarized light in the F band should be -0.66 and $+0.33$ for $\alpha=\pi/4$ and $\alpha=0$, and for the D_{2h} symmetry, they might be -0.40 and -0.20 . These theoretical values are given by the following formulas, which can be easily derived by considering the angles between directions of the polarizer or

degeneracy of the second and the third excited states.

Table I. The polarization characteristic (P factor) of liminescence due to the M center excited with the polarized light in the F band.

	$P(\pi/4)$	$P(0)$
Calculated for C_{2v}	-0.66	$+0.33$
for C_{2h}	-0.40	-0.20
van Doorn et al	$+0.235$	$+0.17$
Lambe et al	-0.30 ± 0.04	-0.10 ± 0.04
Present authors	-0.37 ± 0.05	-0.17 ± 0.07

The amounts of components of luminescent intensity excited with light in the F band are expected to be proportional to the amount of absorption for both F and M centers. For F centers the relation appears to be a little unsatisfactory as described before. The intensity

of the total emission excited with light in the *F* band, which might be taken as the intensity of luminescence due to *M* centers at temperature above -50°C , was measured as a function of the concentration of the *M* center. As seen in Fig. 7, the luminescent intensity at room temperature increased almost linearly with the concentration until the *R* bands appeared remarkably. The initial concentration of *F* centers was $1.2 \times 10^{17}/\text{cm}^3$, and the concentrations of *M* centers were calculated from absorption coefficients assuming the oscillator strength of the *M* band to be unity.

Fig. 7. Concentration dependence of luminescent intensity due to *M* centers at room temperature.

If it is assumed that the luminescence of *M* centers by exciting with light in the *F* band is caused by the transportation of energy from *F* to *M* centers through the crystal, the probability of dipole-dipole transfer can be given as follows by putting the experimental values into the formula (Equ. (17)) derived by Dexter⁸⁾,

$$P_{FM} = (12.2/R)^6 / \tau_F, \quad (3)$$

where R is the distance between *F* and *M* centers in Å, and $1/\tau_F$ is the transition probability of the *F* band. In this calculation, the shapes of the emission and absorption spectra due to *F* and *M* centers were assumed to be Gaussian with the observed half widths and the thermal ionization of excited *F* centers was neglected. Overlap of emission and absorption spectra due to the *F* and *M* centers was calculated to be 5.9×10^{-5} ev. In order to have an appreciable transfer probability competing with emission in *F* centers, the condition $P_{FM} \cdot \tau_F \approx 1$ must exist at low temperature.

Let C be the concentration of *M* centers in unit of $10^{16}/\text{cm}^3$, which are assumed to be

uniformly dispersed throughout the crystal. If we neglect the radiationless transition at *M* centers, the quantum efficiency of the luminescence due to the *M* center excited with light in the *F* band is given by

$$\eta_{FM} = \{6.3C - 2 \times 10^{-6}(C)^2\} \times 10^{-4}. \quad (4)$$

The maximum value of η_{FM}/η_{sat} determined experimentally amounts to 0.3 at room temperature. η_{sat} is the saturated quantum efficiency of luminescence due to *F* centers, when the same specimen contained only *F* centers. However, even in the case of neglecting the thermal ionization of excited *F* centers, whose probability far exceeds $1/\tau_F$ at room temperature, the calculated value for $C=2$ attains at most 1.3×10^{-3} . Therefore, as long as the luminescence of *M* centers is regarded as the result of resonance transfer between *F* and *M* centers, it must be assumed that both centers distribute not at random but near with each other within a small distance about 10 Å from a pair.

If the *F* and *M* centers lie within a small distance, the shape of the *F* band might be influenced with the growth of the *M* band. The complicated shift of the *F* and *M* bands during the growth of the *M* band was reported by Kanzaki⁹⁾. However, the definite conclusion has not been obtained concerning the interaction of both centers.

§ 4. Dichroism of the *F* and *M* Bands Induced by Polarized Light

If the second *M* band is assumed to overlap with the *F* band, the *F* band as well as the *M* band should become dichroic, when the *M* centers in certain orientations are preferentially bleached by polarized light in the *M* band at room temperature, and moreover, it is expected that some quantitative relations exist between the amount of dichroism of the *F* band and that of the *M* band irrespective of the amount or the methods of inducing dichroism, that is, by irradiating with polarized light in the *F* band at liquid air temperature or with polarized light in the *M* band at room temperature.

In order to test the above assumption, the crystals containing almost only *F* and *M* centers were irradiated with light in the *F* band polarized along [011] direction at low temperature or light in the *M* band polarized along [011] direction at room temperature, and the

absorptions for the light polarized along $[011]$ and $[0\bar{1}1]$ directions were measured at -160°C for both cases. As shown in Fig. 8b, the F band became also dichroic by preferential bleaching of M centers, and the maximum absorption for the F and M bands occurred along $[0\bar{1}1]$ and $[011]$ direction, respectively.

As shown in Fig. 8a, the dichroism of the F and the M band induced by irradiation in the F band at low temperature was also observed as stated by van Doorn⁴, however, in contrast with his result, the dichroism remained stable even at room temperature for several days just as in the case induced by bleaching of M

Fig. 8. Dichroism induced by polarized light. (a) irradiated in the F band at liquid air temperature (b) in the M band at room temperature.

centers in the dark.

Under the above mentioned assumption, the ratio of the difference between the absorptions in the F band for both directions to that in the M band is expected to be constant for all dichroic crystals, i.e.

$$K = \frac{[h_{F[0\bar{1}1]} - h_{F[011]}]}{[h_{M[0\bar{1}1]} - h_{M[011]}]} = \frac{f_{M2} \cdot \nu_{M1}}{f_{M1} \cdot \nu_{M2}}, \quad (5)$$

where h is the absorption coefficient at the peak of a band, and suffixes show the band and the direction of polarization of measuring light. The mean value of K measured for several crystals and for various degree of dichroism induced by light in the M band at room temperature was 0.50 ± 0.05 , and that by light in the F band at low temperature was 0.55 ± 0.09 . The values of K for both cases can be regarded to agree within the accuracy of our experiment. The measured value scattered considerably. This might be partly due to the effect of measuring light.

The ratio of the oscillator strength of the second M band to that of the first M band was calculated by the equation (5) as

$$f_{M2}/f_{M1} = 0.82.$$

In the equation (5), ν_{M1} and ν_{M2} are the half widths of the first and the second M bands,

respectively, and ν_{M2} was estimated as 0.15 ev at -160°C by plotting the differences between absorption intensities in the F band for the light polarized along $[011]$ and $[0\bar{1}1]$ directions. The peak of the difference shifted somewhat to longer wavelength side than that of the original F band.

There is some remarkable difference between the dichroism caused by irradiation with light in the F band at low temperature and that with light in the M band at room temperature polarized along $[011]$ and $[0\bar{1}1]$ directions, respectively. In the latter case, the dichroism was mainly due to the decrease of absorption coefficients for light polarized along $[0\bar{1}1]$ in the M band, and for light along $[011]$ in the F band. On the other hand in the former case, the absorption coefficients remarkably increased for light along $[011]$ in the M band and for light along $[0\bar{1}1]$ in the F band.

The irradiation in the M band at room temperature is considered to cause ionization and consequently, decrease of M centers in certain directions. In this case, the absorption intensity of the M band for the light polarized along $[011]$ remained almost constant

or a little increased, while that for $[0\bar{1}1]$ decreased remarkably. This result does not accord with that obtained by Ueta²⁾, which showed that the absorption intensity of the *M*

band for both directions decreased. Our result may be explained that some electrons ejected from *M* centers in one direction, e.g. $[0\bar{1}1]$ were trapped by vacancies oriented along another direction, e.g. $[011]$. The experimental results were obtained, which would show the existence of the *M* center-like vacancies for a while after ejection of electrons by light in the *M* band. These results will be reported in another paper.

The irradiation in the *F* band at low temperature, on the other hand, may cause re-orientation of the symmetry axis of the *M* center, and the total number of the centers is expected to remain constant.

We assume that by absorbing light in the *F* band, the *M* centers whose axes point to a direction, e.g. $[011]$, change their orientation to $[101]$, $[10\bar{1}]$, $[110]$ or $[\bar{1}10]$ with equal probability, and that numbers of *F* and *M* centers remain constant. Then, the amount of dichroism and the polarization character of *M* emission can be obtained as a function of the irradiation time by solving the simultaneous differential equations for the numbers of *M* centers lying in each of six direction along face diagonals. The *F* light polarized along $[011]$ direction and travelling along $[100]$ was used for producing dichroism, and the symmetry of the *M* center was assumed to be D_{2h} .

In Fig. 9, the calculated results on the dichroism in the *M* band and *P* factor are compared with experimental values. The second assumption that the numbers of *F* and *M* centers remain constant could be checked by the experiment and proved valid in some cases. When the dichroic crystal was excited with the light polarized along the direction perpendicular to that of the light used for inducing dichroism, the dichroism was unstable and easily decreased even at low temperature. Moreover, at low temperature the experimental values of *P* factor of *M* emission were determined by assuming the amount of contribution from luminescence due to *F* centers. Taking the above uncertainties into consideration, the agreement between

Fig. 9. Calculated curves showing the change of dichroism in the *M* band (a), and *P* factor of *M* emission (b) as a function of irradiation time. Irradiated at low temperature with light in the *F* band polarized along $[011]$. Points in the figure show the experimental values.

Fig. 10. Variation of absorption spectra by irradiation in the *F* band at room temperature.

experimental and calculated results would be regarded satisfactory.

When the crystal containing F centers was irradiated in the F band at room temperature, the intensity of the F band decreased and that of the M band increased as shown in Fig. 10. If the overlapping of F and the second M absorption band is assumed, the apparent absorption intensity of the F band is the sum of contributions from both centers, and the following relation was expected to exist between the amount of decrease of the intensity in the F band, $\Delta h'$, and the amount of increase in the M band, Δh ,

$$L = \frac{3\Delta h}{3K\Delta h - \Delta h'} = \frac{f_{M1} \cdot \nu_F}{f_F \cdot \nu_{M1}} \quad (6)$$

Table II. The oscillator strengths of the first and the second M band.

	Absorption (-160°C)			Emission (-160°C)	
	peak position (ev)	half width (ev)	oscillator strength	peak position (ev)	half width (ev)
F band	2.28	0.24	f	1.19	0.20
first M band	1.52	0.10	$0.65f$	1.12	0.19
second M band	2.26	0.15	$0.53f$	—	—

§ 5. Discussion and Summaries

The analysis of the temperature dependence of luminescence emitted by the crystal containing only F centers shows that the emission may be regarded as the competing process of thermal ionization of the excited F centers. However, to confirm this, it would be necessary to determine whether luminescence, which is found only for specially treated crystals, is the inherent or the accidental character of color centers, and also to know the quantum yield of photoconductivity or of $F-F'$ transformation for a luminescent crystal.

The high quantum efficiency of luminescence due to M centers excited with light in the F band, its polarization characteristic and quantitative relation on the amounts of dichroism in the F and M bands seem to be in favour of the model proposed by van Doorn, that is, the M center having a symmetry type of D_{2h} , whose symmetry axis lies along face diagonals, the ordinary M band corresponds to the transition from the ground state to the first excited state, which is active to the polarized

Accordingly, the oscillator strength of the first M band (f_{M1}) referred to that of the F band (f_F) can be obtained. ν_{M1} and ν_F are the half widths of the M and F bands, respectively. In the above consideration, it is assumed that the symmetry of the M center is D_{2h} , and that one M center is produced at the cost of one F center. The latter assumption seemed valid until the R bands appeared remarkably. The value L , which is expected to be constant, was 1.66 ± 0.11 , and the oscillator strength obtained from Fig. 10 and the half widths used for it were listed in Table II. The oscillator strength of the M band has been also measured by Okura¹⁰⁾, but analysed in a different way.

along the symmetry axis, and the absorption band, which corresponds to the transition to the upper excited state and active to the light polarized perpendicular to the symmetry axis overlaps with the F band. The emission due to the M center corresponds to the transition from the first excited to the ground state. The oscillator strengths for these two bands due to the M center are $f_{M1} = 0.65f_F$, $f_{M2} = 0.53f_F$, respectively. However, as far as our results concern, the most serious weak point for the above assumption is that, in some cases, the amount of the decrease of luminescence due to the F center was large compared with that of the absorption in the F band. In the above assumption, the quantum efficiency of luminescence in the M center must be large, and that of the F center must be constant irrespective of the presence or the amount of M centers. About this point, more detailed experiments are desirable. In our results obtained for crystals containing M centers, the ratios of the intensity of luminescence of F centers to that of M centers at low temperature, which was determined

by using the difference of temperature dependence and *P* factor, is not so reliable; they should be precisely determined by measuring the spectral distributions of luminescence, however, owing to the overlap of the emission bands, it might be difficult.

The second difficulty is the mechanism of luminescence due to *R* centers excited with light in the *F* band. The overlap of three absorption bands, i.e. the *F* band, the second *M* band and the second or third *R* band for various crystals investigated^{5),6)} is hardly to be conceived. The experiment on LiF, in which the lattice constant differs remarkably from those of other alkali halides, may give a clue for this problem.

On the contrary, if the luminescence of *M* centers is regarded as due to the resonance transfer of energy from *F* to *M* centers, in order to explain its probability, which must be large compared with that for luminescence or thermal ionization of *F* centers in the excited state, i.e. $1/\tau_F = 10^8/\text{sec}$ or $10^{12}/\text{sec}$, we must assume that the distance between *F* and *M* centers is less than $10 \text{ \AA}$, and in order to explain the dichroism and the polarization characteristic of the luminescence, there must be also assumed a strong interaction between both centers or another new center which has absorption band overlapping with the *F* band and interacts strongly with the *M* center. They may be explained by the asymmetry of crystalline field at the *F* center caused by the presence of the *M* center. It seems, however, difficult to testify this model from the present results. The measurement of temperature dependence of photoconductivity due to light in the *F* band for crystals with and without the *M* band and the detailed measurement of the absorption during the growth of

the *M* band may give clues for this problem.

As a conclusion, it can not be decided conclusively at present which of the two assumptions is correct, the overlapping of the second *M* band with the *F* band or the resonance transfer between both centers. However, if the former is assumed, we conclude from our experiment that the *M* center has a symmetry type of D_{2h} , and the dipole for the first *M* band lies along a face diagonal, and that for the second *M* band lies in the plane normal to it.

In conclusion the authors wish to express their thanks to Professor Koana for his kindness to offer us facility to using optical instruments, and also to Professor Uemura for his valuable suggestions. The present work was supported partly by the research expenditure of the Ministry of Education.

The Flow with Wake past an Oblique Plate

By Yōichi MIMURA

Department of Physics, Faculty of Science, Hiroshima University

(Received May 20, 1958)

In the case of two-dimensional flow with wake of a perfect fluid past an oblique plate, the pressure distributions on the front surface of the plate as well as on the free streamlines are calculated, together with the shapes of the latter, by applying the method of notched hodograph devised by Roshko. The calculated values are compared with the experimental ones obtained by Fage and Johansen. It is thus found that the calculated and the observed values of the pressure distribution along the front surface of the plate coincide fairly well with each other so far as the observed base pressure is constant, but discrepancies between them increase as the angle of attack decreases.

§ 1. Introduction

Roshko¹⁾ treated the two-dimensional flow of a perfect fluid past bluff bodies by the method of notched hodograph which was devised by himself and obtained excellent results especially for a normal plate. In the present investigation, the writer applies his method to the case of flow with wake past an oblique plate placed at various angles of attack, and the pressure distributions on the front (wetted) surface of the plate as well as on the free streamlines, together with the shapes of the latter, are calculated. The calculated values are compared with the experimental ones obtained by Fage and Johansen²⁾.

In the following lines, we shall use, for the sake of convenience, such scales of length and time that make both the breadth of the plate, d , and the velocity of undisturbed flow, U , equal to unity.

§ 2. Method of Notched Hodograph

In the method of notched hodograph devised by Roshko, the following assumptions are made concerning free streamlines, namely:

(1) The direction of the free streamline at the point of separation is in the tangent plane of the body at that point;

(2) The fluid velocity q on the free streamline remains equal to that at the point of separation, which will be denoted by q_s , until the direction of the free streamline becomes

parallel to the undisturbed flow;

(3) Further downstream the free streamline remains parallel to the undisturbed flow.

Adopting these assumptions we shall here deal with the two-dimensional flow with wake of a perfect fluid past an oblique plate. Then

Fig. 1.

the notched hodograph becomes as shown in Fig. 1 (b), where ω is defined by

$$\omega = dz/dw = q^{-1}e^{i\theta}. \quad (2.1)$$

Here $z = x + iy$ is the complex coordinate, the x -axis being taken parallel to the undisturbed flow, and w is the complex potential, while θ is the direction of flow. The flow in the physical plane (z -plane) is shown schematically in Fig. 1 (a), where C is the stagnation point, S and S' are the points of separation, B and B' are the points where the free streamlines become parallel to the undisturbed flow at infinity I .

Next, we map the ω -plane onto an f -plane by the relation:

$$f = \ln(q_s w) = \ln(q_s/q) + i\theta. \quad (2.2)$$

The f -plane is shown in Fig. 1(c).

The polygon CSBIB'S'C in the f -plane is then mapped onto the upper half of a u -plane by applying the theorem of Schwarz-Christoffel. The transformation function is easily seen to be

$$f(u) = a' \int_{b'}^u \frac{(u-I)du}{\{(u-B)(u-B')(u-S)(u-S')\}^{1/2}} + c', \quad (2.3)$$

where B, B', S, S' and I are the values of u at the corresponding points, and a', b' and c' are certain constants. We choose these constants so as to make I in (2.3) equal to zero (Fig. 1(d)).

Further, we map the upper half of the u -plane onto the upper half of a t -plane by the relation:

$$u = \nu_0 - \nu_1(t + \nu)^{-1}, \quad (2.4)$$

where ν_0, ν_1 and ν are certain (positive) constants, and if we choose suitable values for these constants, we can make the lengths of two sections SB and B'S' in the t -plane equal to each other. Then, values of t corresponding to the points S, B, I, B' and S' become $-k^{-1}, -1, -r, 1$ and k^{-1} respectively, where k and r are constants (Fig. 1(e)).

Thus, taking account of the values of $\ln(q_s/q)$ and θ at the points S, B, I, B' and S', we easily find that the values of f , as a function of t , at these points are given by

$$f(-k^{-1}) = (\pi - \alpha)i, \quad (2.5)$$

$$f(-1) = 0, \quad (2.6)$$

$$f(-r) = \ln q_s, \quad (2.7)$$

$$f(1) = 0, \quad (2.8)$$

$$f(k^{-1}) = -\alpha i. \quad (2.9)$$

Combining (2.3) and (2.4), the value of f , as a function of t , now becomes

$$f(t) = aF(\sin^{-1} t, k) - b\sigma_{-1}(\sin^{-1} t, \nu, k) + c, \quad (2.10)$$

where we have put

$$F(\sin^{-1} t, k) = \int_0^t \frac{dt}{\{(1-t^2)(1-k^2t^2)\}^{1/2}}, \quad (2.11)$$

$$\sigma_{-1}(\sin^{-1} t, \nu, k) = \int_0^t \frac{dt}{(t+\nu)\{(1-t^2)(1-k^2t^2)\}^{1/2}}, \quad (2.12)$$

and

$$\left. \begin{aligned} a &= a' \nu_0 \nu_1^{-1} \sqrt{(\nu^2 - 1)(k^2 \nu^2 - 1)}, \\ b &= a' \sqrt{(\nu^2 - 1)(k^2 \nu^2 - 1)}. \end{aligned} \right\} \quad (2.13)$$

§ 3. The Function f

In order to determine the function $f(t)$ it is first necessary to know the value of the two-valued function $\{(1-t^2)(1-k^2t^2)\}^{1/2}$ in $f(t)$. This can be easily attained by comparing it with the one in the case of a normal plate where $\alpha = \pi/2$. In this case, after some simple calculations Eq. (2.3) is transformed to

$$f(u) = - \int_0^u \frac{k_0 u du}{\{(1-u^2)(1-k_0^2 u^2)\}^{1/2}} + \ln q_s, \quad (3.1)$$

with

$$k_0 = (q_s^2 - 1)/(q_s^2 + 1).$$

Hence in this case Eq. (2.4) becomes $u = t$ so that $\nu_1 = \nu^2$, $\nu_0 = \nu$ and $\nu \rightarrow \infty$ and therefore $a' = 1$. (3.1) can be easily integrated and therefore, by virtue of Eqs. (2.5) ~ (2.9), the value of $\{(1-u^2)(1-k_0^2 u^2)\}^{1/2}$ in (3.1) can be determined as shown in (3.2) below, with k_0 in place of k . Thus, by virtue of continuity, the value of $\{(1-t^2)(1-k^2t^2)\}^{1/2}$ in our case can be determined as:

$$\{(1-t^2)(1-k^2t^2)\}^{1/2} = \begin{cases} \sqrt{(1-t^2)(1-k^2t^2)}, & (0 \leq |t| \leq 1) \\ \mp i \sqrt{(t^2-1)(1-k^2t^2)}, & \begin{cases} (1 \leq t \leq k^{-1}) \\ (-k^{-1} \leq t \leq -1) \end{cases} \\ -\sqrt{(t^2-1)(k^2t^2-1)}, & (k^{-1} \leq |t| \leq \infty). \end{cases} \quad (3.2)$$

(2.11) is the elliptic integral of the first kind. For the evaluation of the integral (2.12), we have used convenient formulae in Byrd and Friedman's handbook^{*3}). Thus, for the calculation of (2.12) we have applied (B. 330.50) which involves the function

$$\Pi(\sin^{-1} t, \nu^{-2}, k).$$

This function can be evaluated as follows under the conditions given in the respective brackets:

$$\begin{aligned} \text{(B. 435.01) in } 0 \leq |t| \leq 1, & \quad (k^2 \nu^2 > 1), \\ \text{(B. 436.01) in } k^{-1} \leq |t| \leq \infty, & \quad (k^2 \nu^2 > 1), \\ \text{(B. 434.01) in } 1 \leq |t| \leq k^{-1}, & \\ & \quad (k'^2 \leq k'^2 \nu^2 (\nu^2 - 1)^{-1} < k'), \end{aligned} \quad (3.3)$$

$$\begin{aligned} \text{(B. 433.01) in } 1 \leq |t| \leq k^{-1}, & \\ & \quad (k' < k'^2 \nu^2 (\nu^2 - 1)^{-1}). \end{aligned} \quad (3.4)$$

* Here as well as in what follows the formulae in this book will be quoted as (B. ...). Thus, for example, (B. 330.50) means the formula (330.50) in the book.

As will be seen from (3.12) below, the condition $k^2\nu^2 > 1$ is satisfied in general. Both the formulae (3.3) and (3.4) are used in practical cases (cf. Table I). Using (3.2) and the above formulae we can evaluate $f(t)$ for all ranges of t .

On the other hand, since the point at infinity I corresponds to $u=0$ in the u -plane and to $t=-r$ in the t -plane, we have from (2.4) $r=-\nu_1\nu_0^{-1}+\nu$ and therefore by (2.13) we have ultimately

$$r = -ba^{-1} + \nu. \quad (3.5)$$

Hence the undetermined (positive) constants involved in $f(t)$ are k (< 1), ν (> 1), a , b and c , which can be determined by the five equations (2.5)~(2.9) when the values of α and q_s are prescribed. The calculation is laborious but straightforward, so that we shall give here the results only.

First, the constants a , b and c can be expressed in terms of k and ν as follows:

$$a = b\nu^{-1} + Z(\beta, k), \quad (3.6)$$

$$b = \sqrt{(\nu^2 - 1)(k^2\nu^2 - 1)}, \quad (3.7)$$

$$c = (1/2) \ln \{D(1)/D(0)\}, \quad (3.8)$$

where Z is the Jacobian zeta function, and β and $D(t)$ are defined by (3.12) and (3.19) below, respectively.

Secondly, k and ν are decided by the use of λ ($=\pi/2-\alpha$) and q_s as follows:

$$2\lambda/\pi = K^{-1}F(\beta, k), \quad (3.9)$$

$$q_s = \sqrt{D(1)/D(r)} \exp \Omega_3(r), \quad (3.10)$$

where

$$K = F(\pi/2, k), \quad (3.11)$$

$$\beta = \sin^{-1}(1/k\nu), \quad (3.12)$$

$$r = \nu Z(\beta, k) \{b\nu^{-1} + Z(\beta, k)\}^{-1}, \quad (3.13)$$

and $\Omega_3(t)$ will be defined by (3.20) below.

Inserting the values of a , b and c as given by (3.6)~(3.8) into (2.10), $f(t)$ can be expressed for each range of t as follows:

On the plate ($k^{-1} \leq |t| \leq \infty$), using a variable defined by

$$\xi = (kt)^{-1}, \quad (-1 \leq \xi \leq 1), \quad (3.14)$$

we have*

$$f(\xi) = i(\pm\pi/2 + \lambda) + \frac{1}{2} \ln \left[\frac{G(\xi) \sin \{\lambda - (\pi/2)K^{-1}F(\sin^{-1}\xi, k)\}}{G(1) \sin \{\lambda + (\pi/2)K^{-1}F(\sin^{-1}\xi, k)\}} \right] - \overline{\Omega}_4(\xi), \quad (3.15)$$

* The symbol f is still used irrespective of the change of variables.

the plus and minus signs corresponding to $k^{-1} \leq t \leq \infty$ and $-\infty \leq t \leq -k^{-1}$ respectively where

$$G(\xi) = (1 - k^2\nu^2\xi^2)^{-1} \{2b^2 + (\nu^2 + \nu^2k^2 - 2)(1 - k^2\nu^2\xi^2) + 2k\nu b\sqrt{(1 - \xi^2)(1 - k^2\xi^2)}\},$$

$$\overline{\Omega}_4(\xi) = \sum_{m=1}^{\infty} \frac{q^m \sin 2mw \sin 2m\nu(\xi)}{m \sinh 2mp},$$

$$\nu(\xi) = (\pi/2)K^{-1}F(\sin^{-1}\xi, k), \quad w = \lambda,$$

$$p = (\pi/2)K'K^{-1}, \quad q = \exp(-2p),$$

$$K' = F(\pi/2, k'), \quad k'^2 = 1 - k^2.$$

On the free streamlines of constant pressure ($1 \leq |t| \leq k^{-1}$), we use a variable μ defined by

$$\mu = \sqrt{t^2 - 1}(k't)^{-1}, \quad (-1 \leq \mu \leq 1). \quad (3.16)$$

There are two cases in which (3.3) or (3.4) is to be used. In the first case we have

$$f(\mu) = -i \tan^{-1} E(\mu)$$

$$\pm i\lambda K'^{-1}F(\sin^{-1}\mu, k') \pm i\overline{\Omega}_6(\mu), \quad (3.17)$$

according as $1 \leq t \leq k^{-1}$ or $-1 \geq t \geq -k^{-1}$, where

$$E(\mu) = \sqrt{(k^2\nu^2 - 1)/(\nu^2 - 1)} \cdot \mu / \sqrt{1 - \mu^2},$$

$$\overline{\Omega}_6(\mu) = \tan^{-1} \left\{ \left(2 \sum_{m=1}^{\infty} q'^m \sinh 2mw' \sin 2mv'(\mu) \right) + \left(1 + 2 \sum_{m=1}^{\infty} q'^m \cosh 2mw' \cos 2mv'(\mu) \right) \right\},$$

$$\nu'(\mu) = (\pi/2)K'^{-1}F(\sin^{-1}\mu, k'), \quad w' = \lambda K'K^{-1},$$

$$p' = (\pi/2)KK'^{-1}, \quad q' = \exp(-2p'),$$

while, in the second case, $\overline{\Omega}_6(\mu)$ in the above formula should be replaced by $\overline{\Omega}_2(\mu)$, which is defined by

$$\overline{\Omega}_2(\mu) = \tan^{-1} \left\{ \left(2 \sum_{m=1}^{\infty} q'^m \sinh 2m(p' - w') \sin 2mv'(\mu) \right) + \left(1 + 2 \sum_{m=1}^{\infty} q'^m \cosh 2m(p' - w') \cos 2mv'(\mu) \right) \right\},$$

with

$$w'' = (\pi/2)K'^{-1}F(\theta, k),$$

$$\theta = \sin^{-1} \sqrt{(\nu^2 - k^{-2})/(\nu^2 - 1)},$$

the other symbols in $\overline{\Omega}_2(\mu)$ being the same as those in $\overline{\Omega}_6(\mu)$.

On the free streamlines parallel to the undisturbed flow ($0 \leq |t| \leq 1$), we have

$$f(t) = -(1/2) \ln \{D(t)/D(1)\} - \Omega_3(t), \quad (3.18)$$

where

$$D(t) = (\nu^2 - t^2)^{-1} \{2b^2 + (1 + k^2 - 2k^2\nu^2)(\nu^2 - t^2) + 2b\sqrt{(1 - t^2)(1 - k^2t^2)}\}, \quad (3.19)$$

$$\Omega_3(t) = \sum_{m=1}^{\infty} \frac{\sin 2mw \sin 2mv(t)}{m \sinh 2mp}, \quad (3.20)$$

symbols used in $\Omega_3(t)$ being the same as in $\bar{\Omega}_4(\xi)$.

§ 4. Solution in the Physical Plane

It was found in the previous paragraph that f and hence q and θ are represented as the functions of t . To determine the flow in the physical plane it is necessary to express the coordinates of this plane as functions of t . For this purpose we map the t -plane onto a g -plane by the relation:

$$g = N_1(t + \nu)(t + r)^{-1}, \quad (4.1)$$

where N_1 is a constant, and the point C is mapped to the origin in the g -plane, while the point I is mapped to the point at infinity. Furthermore the g -plane is mapped onto the w -plane by

$$w = g^2. \quad (4.2)$$

Then the streamlines past the front surface of the body are mapped onto the real axis in the w -plane. Hence the w -plane is the potential plane. Therefore, z is represented by t by the use of (2.1), (4.2) and (4.1) as:

$$z = \int q^{-1} e^{i\theta} \frac{dw}{dg} \frac{dg}{dt} dt. \quad (4.3)$$

Applying this equation to the plate, the length s from the leading edge to any point on the plate is, using ξ in (3.14), given by

$$\begin{aligned} s(\xi) &= \frac{1}{q_s} \int_{-1}^{\xi} \frac{q_s}{q(\xi)} \frac{dw}{dg} \frac{dg}{dt} d\xi \\ &= N \int_{-1}^{\xi} \frac{q_s}{q(\xi)} \frac{1 + k\nu\xi}{(1 + kr\xi)^3} d\xi, \end{aligned} \quad (4.4)$$

where

$$N = N_1^2 2k(\nu - r)/q_s.$$

N is to be determined so as to make $s(1)$ equal to unity, i.e.

$$N = \left\{ \int_{-1}^1 \frac{q_s}{q(\xi)} \frac{1 + k\nu\xi}{(1 + kr\xi)^3} d\xi \right\}^{-1}. \quad (4.5)$$

We next apply (4.3) to the free streamline. The origin of the coordinates $z = x + iy$ is taken as S or S' according as we deal with the upper or the lower free streamline. Then, on the free streamlines of constant pressure, x and y are given as the functions of μ in (3.16) by

$$\begin{aligned} \begin{Bmatrix} x(\mu) \\ y(\mu) \end{Bmatrix} &= -N \frac{k'^2}{k} \int_{\mp 1}^{\mu} \begin{Bmatrix} \cos \mu \\ \sin \mu \end{Bmatrix} \\ &\times \frac{q_s}{q(\mu)} \frac{1 + \nu\sqrt{1 - k'^2\mu^2}}{(1 + r\sqrt{1 - k'^2\mu^2})^3} \frac{\mu}{\sqrt{1 - k'^2\mu^2}} d\mu. \end{aligned} \quad (4.6)$$

On the free streamlines parallel to the undisturbed flow, x as determined by (4.3) takes the simple form:

$$x(t) = -\frac{N}{k} \int_{\mp 1}^t \frac{q_s}{q(t)} \frac{t + \nu}{(t + r)^3} dt. \quad (4.7)$$

§ 5. Results

Calculations have been carried out for the cases in which the angle of attack α of the plate is equal to 70° , 50° , 30° and 15° respectively. The values of q_s used have been determined in such a manner that the values of $1 - q_s^2$ become the same as the observed mean base pressure coefficients obtained by Fage and Johansen³⁾ except the case when $\alpha = 15^\circ$. In this exceptional case q_s has been determined from the observed pressure coefficient at the trailing or the leading edge, and these two cases are distinguished by denoting them as $15^\circ A$ and $15^\circ B$ respectively.

The results are shown in Tables I and II and also in Figs. 2 ~ 4. In case when $\alpha = 90^\circ$, the results obtained by Roshko by using $q_s = 1.54$ are also shown for comparison.

In Table I, the first and second columns show the values of α and q_s used in the calculations. The third and fourth columns show the values of k and ν which have been determined from the given values of α and q_s by

the method mentioned in § 3. The fifth column shows which formula of (3.3) and (3.4) has been used.

The distributions of the pressure coefficient on the front surface, $C_{pw}(s(\xi)) [= 1 - q^2(s(\xi))]$, can be obtained by (3.15) and (4.4) and are shown in Figs. 2 (a)~(d). The black circles in

(a) $\alpha=70^\circ$

(b) $\alpha=50^\circ$

(c) $\alpha=30^\circ$

(d) $\alpha=15^\circ$

Fig. 2. Pressure distributions on the front surface of the oblique plate.

these figures show the experimental results of $C_{pw}(s(\xi))$ in the cases in which $\alpha=69^\circ.85$, $49^\circ.85$, $29^\circ.85$ and $14^\circ.85$ respectively. These observed results were obtained by Fage and Johansen³⁾, but no correction due to the tunnel interference effect was made.

The sixth column in Table I gives the values of $s(\xi)$ at the stagnation point, where $\xi = -(k\nu)^{-1}$ by (3.15), while the seventh column shows the corresponding observed

values read from Fig. 2. Also, the eighth column shows the calculated values of the drag coefficient C_N which is given theoretically by

$$C_N = C_{Nw} - (1 - q_s^2),$$

(5.1)

where

$$C_{Nw} = \int_0^1 C_{pw}(s) ds.$$

(5.2)

The ninth column gives the observed values of C_N due to Fage and Johansen. In case when $\alpha=15^\circ$, the base pressure is not uniform as shown in Fig. 2(d) so that C_{Nw} has been calculated in place of C_N and the value

is shown in the brackets in the eighth column. C_{Nw} has also been estimated from the observed distribution of C_{pw} in Fig. 2(d) and is shown in the brackets in the ninth column.

The shapes of the free streamlines until they become parallel to the undisturbed flow can be obtained by (4.6) and are shown in Fig. 3. The pressure coefficients along the free streamlines parallel to the undisturbed flow can be obtained by (4.7) and (3.18), and are shown in Fig. 4.

Table II shows various data concerning the shapes of the free streamlines. Thus, in the columns from the second to the seventh are given the values of the coordinates x, y of the points S, B and B' with the origin at the centre of the plate. The eighth column shows the values of $d' = y_B - y_{B'}$, while the ninth column gives the values of the ratio d'/d'' , where d'' is equal to $2y_s$. This ratio d'/d'' gives the rate of spreading towards downstream of the distance between the free streamlines. For comparison the longitudinal spacing of Kármán vortex street h is shown in the tenth column, which has been determined from the observed value of the lateral vortex spacing a due to Fage and Johansen, using the well-known Kármán's relation $h = 0.281 a$.

The principal results of our calculations are summarized below:

- [1] The calculated values of the normal force acting on the plate become smaller and smaller than the observed ones as α decreases, but they coincide fairly well with each other in cases when $\alpha=90^\circ, 70^\circ, 50^\circ$ and 30° . In this range of values of α the observed base pressure of the plate is almost uniform.
- [2] The calculated position of the stagnation point on the oblique plate is nearer to the leading edge than the observed one in cases when $\alpha=50^\circ$ and 30° (Table I). From Fig. 2 it is found that the main discrepancy between the calculated and the observed values of C_{pw} appears beyond the observed stagnation point and it becomes

Fig. 3. Shapes of the free streamlines for the oblique plate.

Fig. 4. Pressure distributions on the free streamlines for the oblique plate.

- Pressure coefficient on the upper free streamline, C_{p+} .
- Pressure coefficient on the lower free streamline, C_{p-} .
- $\leftarrow \alpha^0 \rightarrow$ Length of the oblique plate projected in the x -axis.

larger as the angle of attack becomes smaller. This discrepancy disappears near the trailing edge.

[3] Discrepancy of C_{pw} between the cases $15^\circ A$ and $15^\circ B$ exists only near the trailing edge (Fig. 2 (d)).

[4] The smaller the angle of attack becomes, the shorter becomes the portion of the constant pressure on the free streamline (Figs. 3 and 4).

[5] The value of C_p recovers rapidly to zero as it passes the range of constant pressure (Fig. 3). By Eqs. (3.18) and (4.7) it is clear that the behaviour of $C_p(x)$ -curve near the points B and B' is given by $(\partial C_p)^2 \propto \partial x$.

[6] The value of C_p recovers almost to zero at a point whose distance from the leading edge is nearly the same as the breadth of the plate (Fig. 3). When $x \gg 1$, $q-1 \propto x^{-1}$. It can be proved by the fact that $q(t)$ at infinity ($t=-r$) takes the minimum value of unity so that $q(-r \pm \varepsilon) = 1 + O(\varepsilon^2)$ for small value ε and $x(-r \pm \varepsilon) = O(\varepsilon^{-2})$ by (4.7).

§ 6. Discussion

[1] In actual flow, a circulation exists around the plate, so the free streamlines cannot remain parallel to the undisturbed flow as is indicated by the notched hodograph. But the effect of the upper and the lower vortex layers on the front surface of the body may be treated as the crowd of doublets when they are situated far from the body, so that as their distance from the body becomes larger, their effect becomes smaller. The situation is the same when vortex layers change to Kármán vortex street*. Therefore the value of C_{pw} may be almost determined by the values of C_p near the body and the effect of the circulation on the far downstream free streamline may be irrelevant. This conclusion can be ascertained by the fact that the present treatment by the notched hodograph gives a fairly good result.

From the result [6] in § 5 C_{pw} may be determined by the observed data of C_p on the free streamlines in a range from the separation point to a certain point whose length is of the order of the breadth of the plate. This will be verified in the case when $\alpha = 90^\circ$ in a subsequent paper.

[2] As is well known, by the form of Eq. (2.2) θ and $\ln(q_s/q)$ can be interpreted by analogy, e.g. as the displacement and the gradient of a membrane (cf. Woods⁴⁾). Therefore, in the ω -plane in Fig. 1, if $\ln(q_s/q)$ on SB is decreased near S, it affects predominantly only the flow near S, and hence $\ln(q_s/q)$ on SS' decreases predominantly near S. (This relation will be discussed in detail in a later paper). For this reason, in order to make the calculated C_{pw} coincide with the observed one, taking into account the discrepancies discussed in [2] and [3] in § 5, we can deduce the following conclusion about the values, C_{p+} and C_{p-} , of C_p on the upper and the lower free streamlines, namely near the leading edge C_{p+} must recover to zero more rapidly than that given by the notched hodograph, but C_{p-} may have the same character as the calculated one.

[3] When the shape of the free streamlines given in Fig. 3 is modified by this result, it may be stated that the nearer the upper free streamline flows to the back surface of the body, the more rapidly C_{p+} may recover to zero. The recovery of C_{p-} near the trailing edge may result from the strong effect of the already recovered C_{p+} .

In general, the magnitude of the vortex flux $\tilde{\omega}$ passing through the vortex layer in a unit time is given by

$$\tilde{\omega} = \int \zeta \mathbf{v} \cdot d\mathbf{s} = (q_1^2 - q_2^2)/2, \quad (6.1)$$

where $\mathbf{v}$ (u, v) is the mean velocity vector and ζ ($=\partial v/\partial x - \partial u/\partial y$) is the vorticity. The integration is taken along a path with line element $d\mathbf{s}$ which crosses the streamlines perpendicularly. q_1 and q_2 are respectively the magnitudes of velocities at the outer and the inner end points of the vortex layer along the path. Where C_p keeps the constant value C_{ps} along the free streamline as is the case in the notched hodograph, it must be $q_1 = q_s$ and $q_2 = 0$ by (6.1) when $\tilde{\omega}$ remains constant. Where C_p decreases, the vorticity in the vortex layer must dissipate or diffuse. The more strongly these occur, the nearer the separated flow approaches the back of the body.

[4] When C_{p+} is modified by the above result [2], the distance between the two free streamlines may be widened. This may explain to some extent why h in Table II diminishes more slowly than d' does when α

* This phenomenological interpretation is due to Prof. T. Maekawa.

decreases.

[5] When α decreases, d' also decreases (cf. Table II). Moreover C_p may recover more rapidly than the calculated one when α is small. Therefore, even if it is taken into account that the modified distance between the two streamlines is larger than the calculated one, the non-equilibrium of the pressure between the upper and the lower free streamlines becomes more and more violent. Therefore, the condition of the constant base pressure may be destroyed gradually as α decreases. When α decreases further, the non-equilibrium of the pressure near the trailing edge cannot be supported after all and the upper free streamline may be re-attached to the back surface of the plate (cf. e.g. Crabtree⁶⁾). This phenomenon will be treated in later papers.

Acknowledgements

The author expresses his sincere thanks to Professor S. Tomotika for his valuable advice and kind inspection of the manuscript. The author's thanks are also due to Professor T. Maekawa for his helpful advice and to Mr. H. Yamaoka for his help in numerical calculation.

Flow past a Bent Flat Plate with an Unsymmetric Dead Air at Mach Number 1

By Takeo SAKURAI*

Department of Aeronautics, Faculty of Engineering, Kyoto University

(Received May 27, 1958)

The ideal case of the flow past a bent flat plate with an unsymmetric dead air region at Mach number 1, in which a streamline comes tangentially to the plate at its leading edge, is discussed by means of the simple procedure of Imai's WKB method. Numerical results are given for several values of the form parameter.

§1. Introduction

Since von Kármán's pioneer work⁷⁾, the transonic flow problem has been studied by many authors. The mathematical difficulty of the problem, however, still prevents us from arriving at thorough understanding of the flow features. A few typical cases that have hitherto been attacked with success are mostly concerned with wedge profiles symmetric with respect to the chord lines. When

the angle of attack is zero, it suffices to discuss the upper half of the plane of flow. Such a case has been treated by Cole¹⁾, Trilling⁸⁾, Trilling and Walker⁹⁾, and Yoshihara¹²⁾ for the high subsonic case, by Guderley and Yoshihara²⁾ for the sonic case and by Vincenti and Wagoner¹⁰⁾ for the low supersonic case. In the case of the wedge with an angle of attack, we have to deal with the difficult boundary conditions which correspond to the unsymmetric flow pattern. The sonic flow investigated by Guderley seems to be the only case that has been dealt with analytically. He studied with Yoshihara the sonic flow past a wedge profile at an angle of attack³⁾ which

* This work was done at the Department of Physics, Faculty of Science, University of Tokyo. This was presented in partial fulfillment of the requirements for the degree of Doctor of Science at the University of Tokyo.

is small compared with the apex angle. He also discussed the flow past a flat plate with a small angle of attack⁴, which can be regarded as the limiting case in which the apex angle of the wedge becomes small in comparison with the angle of attack.

As already mentioned, the above problems are all concerned with the wedge profiles that are symmetric with respect to the chord lines. The unsymmetry of the flow condition is wholly due to the presence of the angle of attack. In view of the fact that practical profiles are usually unsymmetric, it seems to be desirable to investigate the transonic flow past an unsymmetric profile.

As one of the simplest cases, we shall discuss the ideal case of the flow past a bent flat plate with an unsymmetric dead air region at Mach number 1, in which the zero streamline comes tangentially to the plate at its leading edge.

§2. Basic Equations

According to Imai's WKB method⁵, the exact equation for the two-dimensional steady irrotational flow of an inviscid compressible fluid can be approximated as follows:

$$(\partial^2/\partial\tilde{\tau}^2 + \partial^2/\partial\tilde{\theta}^2)\psi = 0 \quad (2.1)$$

where

$$\tilde{\tau} = -\int_1^{\tilde{q}} (\mu/\tilde{q}) d\tilde{q} \quad (2.2)$$

$$\mu = (1 - M^2)^{1/2} \quad (2.3)$$

$$\Psi = K^{-1/2}\psi \quad (2.4)$$

$$K = (\mu\rho_0/\rho)^2 \quad (2.5)$$

and $(\tilde{q}, \tilde{\theta})$ are the magnitude and the direction of the velocity vector, M is the local Mach number, Ψ is the stream function, ρ is the density and ρ_0 is the stagnation density.

The correspondence between the physical and the hodograph planes is expressed as follows:

$$dx + idy = \tilde{q} - 1e^{i\tilde{\theta}}[d\tilde{\theta} + i(\rho_0/\rho)d\Psi] \quad (2.6)$$

$$\partial\Phi/\partial\tilde{\tau} = K^{1/2}\partial\Psi/\partial\tilde{\theta}, \quad \partial\Phi/\partial\tilde{\theta} = -K^{-1/2}\partial\Psi/\partial\tilde{\tau} \quad (2.7)$$

where (x, y) are the Cartesian coordinates and Φ is the velocity potential.

For the adiabatic gas, we have

$$\mu = \{(1 - \tilde{q}^2)/(1 - a^2\tilde{q}^2)\}^{1/2} \quad (2.8)$$

$$\tilde{\tau} = \tanh^{-1}\mu - a^{-1}\tanh^{-1}a\mu \quad (2.9)$$

$$K = (1 - \tilde{q}^2)/(1 - a^2\tilde{q}^2)^{1/a^2} \quad (2.10)$$

$$a^2 = (r - 1)/(r + 1) \quad (2.11)$$

where r is the ratio of the specific heats, and the unit of the magnitude of the velocity is taken to be the critical velocity c_* , at which the fluid velocity is equal to the local velocity of sound.

§3. The Boundary-Value Problem in the Hodograph Plane

Before discussing the boundary conditions in the hodograph plane, let us introduce the modified hodograph variables (τ, θ) by the following equations,

$$\theta = \tilde{\theta}/\theta_0, \quad \tau = \tilde{\tau}/\theta_0 \quad (3.1)$$

where θ_0 is defined in Fig. 1. Then the basic equation (2.1) remains unchanged:

$$(\partial^2/\partial\tau^2 + \partial^2/\partial\theta^2)\psi = 0 \quad (3.2)$$

In the following, the $\sigma = \tau + i\theta$ plane will be called the hodograph plane.

The corresponding points in the physical and the hodograph planes are denoted by the same letters. The correspondence will be best understood if we consider the streamline (OCDO or OCBAO) on which the boundary condition $\psi = 0$ is prescribed. (This streamline may be denoted as the zero streamline.) The streamline starts at negative infinity O of the physical plane horizontally with the free stream Mach number 1, which corresponds to the singular point O in the hodograph plane $\sigma = \tau + i\theta$. As we proceed along the zero

Fig. 1.

streamline towards the profile the magnitude of the velocity decreases and its inclination increases. The streamline comes in contact with the surfaces of the profile CD and CB. Tangentially at the leading edge C, where the streamline bifurcates into two branches. One of them flows along the upper side of the profile towards the point D where the sonic

velocity is reached and the streamline separates from the profile to form the free streamline DO. The other flows along the lower side of the profile towards the point B where the magnitude of the velocity vanishes and its inclination θ changes from $+1$ to $-\alpha$. Then, it proceeds along the profile towards the trailing edge A, where it separates from the profile to form the free streamline AO, with sonic velocity.

§ 4. The Method of Solution

Our task in this section is to solve the boundary value problem described in the last section for a given parameter α . The basic equation (3.2) governs the incompressible flow in the σ -plane (Fig. 2), so that the problem can

parameter α . Therefore, we can regard α as the form parameter of the profile.

By the mapping function

$$\zeta = \exp \left[-\frac{\pi}{1+\alpha} (\sigma + i\alpha) \right] \quad (4.1)$$

the flow field in the σ -plane is mapped onto the flow field in the ζ -plane. (Fig. 3) The complex velocity potential in the ζ -plane is easily found by superposing the dipole and the quadrupole solutions, as follows,

$$\begin{aligned} w = & A[\zeta\{e^{-i\beta}(\zeta - e^{-i\beta})^{-2} + e^{i\beta}(\zeta - e^{i\beta})^{-2}\} \\ & - iB\{e^{-i\beta}(\zeta - e^{-i\beta})^{-1} - e^{i\beta}(\zeta - e^{i\beta})^{-1}\}] \\ = & 2A \sum_{n=0}^{\infty} \zeta^n \{n \cos(n\beta) - B \sin(n\beta)\} \end{aligned} \quad (4.2)$$

where

$$\beta = \frac{\alpha\pi}{1+\alpha} \quad (4.3)$$

Substituting Eq. (4.1) into Eq. (4.2) and taking its imaginary part, we obtain the stream function.

$$\begin{aligned} \psi = & -2A \sum_{n=0}^{\infty} \exp \left(-\frac{n\tau\beta}{\alpha} \right) \sin \left\{ \beta n \left(1 + \frac{\theta}{\alpha} \right) \right\} \cdot \\ & \{n \cos(n\beta) - B \sin(n\beta)\} \end{aligned} \quad (4.4)$$

The flow field in the physical plane is easily found, if we substitute Eq. (4.4) into Eqs. (2.6) and (2.7). Now, we are interested only in the pressure distribution over the profile where the boundary conditions $\theta=1$ or $-\alpha$ and $\psi=0$ are prescribed. Then Eqs. (2.6) and (2.7) can be simplified, yielding,

$$dl = (K^{1/4}/\tilde{q})(\partial\psi/\partial\theta)_{\theta=\text{const}} d\tau \quad (4.5)$$

where l is the length measured along the profile from some fixed point on it (e.g. the leading edge C). Thus, the correspondence over the front and the rear part of the profile is described as follows,

$$dl_{\theta=1} = -A_1[\{dl_{\theta=1}^{(1)} + dl_{\theta=1}^{(2)}\} + B_1\{dl_{\theta=1}^{(3)} + dl_{\theta=1}^{(4)}\}] \quad (4.6)$$

$$dl_{\theta=-\alpha} = -A_1[dl_{\theta=1}^{(1)} + B_1 dl_{\theta=1}^{(3)}] \quad (4.7)$$

where

$$\begin{aligned} dl_{\theta=1}^{(1)} = & -\frac{1}{2} \sinh \xi \left\{ \frac{\cos \beta}{(\cosh \xi - \cos \beta)^2} \right. \\ & \left. - \frac{2 \sin^2 \beta}{(\cosh \xi - \cos \beta)^3} \right\} \frac{K^{1/4}}{\tilde{q}} d\tau \end{aligned} \quad (4.8)$$

$$\begin{aligned} dl_{\theta=1}^{(2)} = & 2 \sinh(2\xi) \left\{ \frac{2 \cos 2\beta}{(\cosh 2\xi - \cos 2\beta)^2} \right. \\ & \left. - \frac{4 \sin^2 2\beta}{(\cosh 2\xi - \cos 2\beta)^3} \right\} \frac{K^{1/4}}{\tilde{q}} d\tau \end{aligned} \quad (4.9)$$

$$\begin{aligned} dl_{\theta=0}^{(3)} = & -\frac{1}{2} \sinh \xi \sin \beta \cdot \\ & (\cosh \xi - \cos \beta)^{-2} (K^{1/4}/\tilde{q}) d\tau \end{aligned} \quad (4.10)$$

Fig. 2.

Fig. 3.

be solved easily by the usual method of conformal mapping, superposing the dipole and the quadrupole solutions. To determine the ratio of the strengths of these poles we make use of the condition that the lengths of the upper and the lower sides of the profile (CD and CB in Fig. 1) should be equal. Then the ratio of the lengths of the front and the rear parts of the profile (CB and BA in Fig. 1) is determined *a posteriori* for a given

$$dl_{\theta=1}^{(4)} = 2 \sinh(2\xi) \sin(2\beta) \cdot (\cosh 2\xi - \cos 2\beta)^{-2} (K^{1/4}/\tilde{q}) d\tau \quad (4.11)$$

$$A_1 = -\frac{2\pi A}{1+\alpha}, \quad B_1 = -B \quad (4.12)$$

and

$$\xi = \frac{\pi\tau}{1+\alpha} \quad (4.13)$$

Here use has been made of the formula¹¹⁾

$$\sum_{n=1}^{\infty} e^{-n\tau} \sin nx = \frac{1}{2} \frac{\sin x}{\cosh t - \cos x} \quad (4.14)$$

In the above formulae, the factor A_1 represents the length scale in the physical plane and it can be chosen arbitrarily; thus we obtain similar flow with various length scales for various values of A_1 . On the other hand, the factor B_1 is uniquely determined for a given parameter α , by the condition that the lengths of the upper and the lower side of the profile (CD and CB in Fig. 1) should be equal. Using Eq. (4.6), the above condition can be expressed as follows,

$$\int_{\tau_0}^0 dl_{\theta=1} = \int_{\tau_0}^{\infty} dl_{\theta=1} \rightarrow \int_0^{\infty} dl_{\theta=1} = 0 \quad (4.15)$$

Hence the value of B_1 can be determined as

$$B_1 = -\left\{ \int_0^{\infty} (dl_{\theta=1}^{(1)} + dl_{\theta=1}^{(2)}) \right\} / \left\{ \int_0^{\infty} (dl_{\theta=1}^{(3)} + dl_{\theta=1}^{(4)}) \right\} \quad (4.16)$$

The correspondence between the physical and the hodograph planes are given by the integrals:

$$l_u(\tau) = \frac{1}{L} \int_{\tau_0}^{\tau} dl_{\theta=1} \quad (0 < \tau < \tau_0) \quad (4.17)$$

$$l_{lf}(\tau) = \frac{1}{L} \int_{\tau_0}^{\tau} dl_{\theta=1} \quad (\tau_0 < \tau < \infty) \quad (4.18)$$

$$l_{lr}(\tau) = \frac{1}{L} \left\{ \int_{\tau_0}^{\infty} dl_{\theta=1} + \int_{\infty}^{\tau} dl_{\theta=-\alpha} \right\} \quad (0 < \tau < \infty) \quad (4.19)$$

Here the suffixes u , lf and lr signify the upper surface, the front part of the lower surface, and the rear part of the lower surface, respectively. Also, L is the chord of the profile defined as

$$L = \int_{\tau_0}^{\infty} dl_{\theta=1} + \int_{\infty}^0 dl_{\theta=-\alpha} \quad (4.20)$$

Once the factor B_1 is determined by Eq. (4.16), the ratio of the lengths of the front and the rear parts is determined by the above formulae.

Since the pressure is a known function of

τ , the pressure distribution over the profile can be obtained by the use of these τ - l relations.

The modified lift coefficient $\tilde{C}_L$ is

$$\tilde{C}_L = \frac{1}{L} \left\{ \int_0^{\infty} \tilde{C}_p dl_{\theta=1} + \int_{\infty}^0 \tilde{C}_p dl_{\theta=-\alpha} \right\} \quad (4.21)$$

where $\tilde{C}_p$ is the modified pressure coefficient;

$$\begin{aligned} \tilde{C}_p &= (\gamma+1)^{1/3} \theta_0^{-2/3} C_p \\ &= (\gamma+1)^{1/3} \theta_0^{-2/3} \frac{p-p_{\infty}}{\frac{1}{2} \rho_{\infty} q_{\infty}^2} \end{aligned} \quad (4.22)$$

If the velocity is close to sonic, we can make further approximations⁶⁾ for $K^{1/4}/\tilde{q}$ and $\tilde{C}_p$

$$K^{1/4}/\tilde{q} \div \left\{ \frac{3}{2} (\gamma+1) \right\}^{1/6} (\rho_0/\rho_*)^{1/2} \theta_0^{1/6} \tau^{1/6} \quad (4.23)$$

$$\tilde{C}_p \div 2^{1/3} 3^{2/3} \tau^{2/3} \quad (4.24)$$

where ρ_0 is the stagnation density, and ρ_* is the density at the sonic state.

§ 5. Numerical Results

We performed the integrations (4.16)–(4.21) numerically, using Simpson's rule, for the cases $\alpha=1, 2, 3, 4, 5$. The results are shown

$\alpha = 2$
Fig. 4.

Fig. 5.

Fig. 6.

Table I

α	$\frac{\vartheta}{\theta_0}$	$\frac{\kappa}{\theta_0}$	$\frac{L_2}{L_1}$	$\tilde{C}_L$	$\tilde{C}_{L\text{ exact}}$
1	0.76	0.21	7.5	2.32	2.12
2	0.92	0.69	1.8	3.36	2.87
3	0.84	0.99	0.84	3.91	3.17
4	0.70	1.12	0.51	4.17	3.26
5	0.56	1.15	0.35	4.36	3.31

in Figs. 4-6 and in Table I.

ϑ and κ in Table I are the attack angle and the camber of the profile, respectively, as shown in Fig. 7.

If $\theta_0 \ll 1$, κ and ϑ are represented by θ_0 , α , L_1 and L_2 as follows,

$$\begin{aligned} \kappa &= \{1 + (\alpha L_2 - L_1)/(L_1 + L_2)\} L_1 \theta_0 \\ \vartheta &= \{(\alpha L_2 - L_1)/(L_1 + L_2)\} \theta_0 \end{aligned} \quad (5.1)$$

In Table I $\tilde{C}_{L\text{ exact}}$ are calculated by means of (4.21) using the exact value of $\tilde{C}_p$, while $\tilde{C}_L$ are estimated using the approximated value given by (4.24). The applicability of the transonic approximation becomes questionable

Fig. 7.

Fig. 8.1.

Fig. 8.2.

Fig. 8.3.

in the neighbourhood of the stagnation point at middle part of lower side of the profile. The comparison of $\tilde{C}_{L\text{exact}}$ and $\tilde{C}_L$ shows that the approximation is comparatively good for the small value of α but becomes worse as α increases. Since α corresponds to the deflection angle of the rear half of the profile, these results seem to be plausible.

As was mentioned already, our solutions deal with a family of the ideal cases where the zero streamline touches the profile tangentially at its leading edge and ϑ may be considered as a kind of critical angle of attack. Thus, for example, the flow past a bent flat plate corresponding to $\alpha=3$ will change its type in the manner as shown in Fig. 8 as the angle of attack is smaller than, equal to, or greater than the critical value $0.84\theta_0$, respectively.

Acknowledgement

The writer wishes to express his cordial thanks to Professor Isao Imai for his hearty

guidance and continual encouragement. The writer is also indebted to Professor Hidenori Hasimoto for his invaluable advice and discussions in the course of this study.

Observation of the Lateral Photovoltage by Surface Field Effect

By Makoto KIKUCHI

Electrotechnical Laboratory, Tokyo, Japan

(Received June 18, 1958)

It was expected that the lateral photovoltage^{1,2)} could be observed by the surface field effect. In our experiment, apparatus was constructed as shown in Fig. 1. A chopped light is focused on the germanium specimen whose back surface is facing to a metal electrode separated by a mylar spacer.

Fig. 1. Experimental apparatus for the measurement of lateral photovoltage.

Fig. 2. Time dependence of the lateral photovoltage. (*n*-type 25 ohm-cm, thickness 150 microns) The light spot is at the position of 1.0 mm in Fig. 3.

When no high voltage is applied to the metal electrode, no output signal is observed. If, however, high voltage is applied, either plus or minus output signal can be observed depending on the position of the small light spot along on the germanium specimen. The sign of the signal is detected from the pattern on the oscilloscope.

Fig. 2 shows the time dependence of the output signal measured on an *n*-type 25 ohm-cm specimen (150 microns in thickness). The decay of the signal after "on" and "off" of the high voltage is, as

expected, quite similar to the one observed in the ordinary surface field effect. Fig. 3 and 4 show the results of the dependence of the signal (at the instant of the high voltage "on") on the position of the light spot along on the specimen. As shown in the figures, the sign of the signal for the same electrode voltage are opposite for *p*-type and *n*-type samples.

Fig. 3. Dependence of the lateral photovoltage on the position of the light spot. *n*-type 25 ohm-cm.

Fig. 4. Dependence of the lateral photovoltage on the position of the light spot. *p*-type 1 ohm-cm.

The variation of the surface conductance and the surface recombination velocity with the surface field was measured in parallel to determine the surface potential. The results will be presented in the near future.

Study on Annealing of Radiation Induced $1/f$ Noise in Ge $p-n$ Junction

By Ki-ichi KOMASTUBARA

Kobe Kogyo Corporation

and Utaka HASHIMOTO

Miyakozima Technical High School

(Received June 28, 1958)

The $1/f$ noise of Ge $p-n$ junction is strongly enhanced by pre-irradiation of γ ray as was reported by Inuishi¹⁾. We have investigated its annealing process in more detail.

The annealing of the short circuit current noise of the $p-n$ junction with reverse bias voltage after 5×10^6 röntgen preirradiation of γ ray from Co^{60} is shown in Fig. 1 and 3. It is interesting to

Fig. 1. Noise is reverse voltage at different time.

note that the short circuit current noise increases immediately after irradiation and then decrease to the level of before irradiation value. The frequency spectrum reveals that this noise is mainly $1/f$ type. This annealing speed increases with increasing annealing temperature, but the tendency of the noise variation was similar, as shown in Fig. 3. The variation of grounded emitter current gain, α_{eb} , when operated as a transistor, is also shown in Fig. 3, and Fig. 2 shows the changes of the reverse current after γ irradiation during annealing process.

The sample used for this study was the collector junction of $p-n-p$ fused transistor which were sealed in vacuum of 10^{-4} mm Hg in order to keep the surface free from the troubles by unknown factors caused by γ ray irradiation. There may be two types of recovery process of defect. One is the rapid variation of noise level, and of α_{eb} , and the other is a very slow variation of I_s and I_{the}

Fig. 2. Reverse current with different times of annealing.

Fig. 3. Annealing curves of noise at 1 Kc, 5 V, and α_{eb} of 1 mA, 5 Vc.

long time variation of α_{eb} and noise.

The mechanism of the above mentioned annealing process is not clear at present, however, one possible speculation may be as follows. Since interstitial atoms introduced by γ irradiation have larger diffusion constant in comparison with vacancies, the former would diffuse more rapidly and stays at surfaces or dislocations. The Vacancies, on the other hand, remains persistently, and may constitute slow annealing process. So perhaps interstitial diffusion causes some noise and the noise may increase at first step of annealing. The increase of $1/f$ type noise may be mainly caused from increase of surface inversion layer and increased defect under γ ray irradiation. It should be emphasized that the annealing speed of α_{eb} , and reverse current were small in comparison with that of $1/f$ noise, but if we assume the recovery of conductivity of bulk wafer is rapid and surface recombination velocity S is hard to recover from above speculation, we may have some clues. We can estimate 0.59 eV for numerical value of the activation energy for rapid decay of noise curves in Fig. 3.

A Remark on the Chemical Kinetics in Polymers during Irradiation

By Tsutomu WATANABE

Department of Applied Physics, Faculty of Engineering, University of Tokyo, Tokyo

(Received June 20, 1958)

In studying the chemical mechanism of radiation effects of polymers, it has usually been regarded that the radical concentration is stationary constant¹⁾. But it is very questionable on the stand point of the paramagnetic resonance data of irradiated polymers²⁾.

Let us set v the concentration of radical produced by the radiation, r the radiation dose, I the dose rate of irradiation, γI the radical production rate per unit volume per unit time, α' , β' radical reaction constant of unimolecular and bimolecular type respectively, then the equation for v is expressed as follows:

$$\gamma I - \alpha'v - \beta'v^2 = \frac{dv}{dt} = I \frac{dv}{dr} \tag{1}$$

The solution of (1) with $v(r)=0$ at $r=0$ becomes

$$v = \frac{ab[1 - \exp(-\sqrt{\alpha^2 + 4\beta\gamma} \cdot r)]}{b - a \cdot \exp(-\sqrt{\alpha^2 + 4\beta\gamma} \cdot r)} \tag{2}$$

where

$$\alpha = (-\alpha + \sqrt{\alpha^2 + 4\beta\gamma})/2\beta, \quad b = (-\alpha - \sqrt{\alpha^2 + 4\beta\gamma})/2\beta$$
$$\alpha' = \alpha I, \quad \beta' = \beta I.$$

And after irradiation, the tendency of decay of v is

$$v = \frac{\alpha v_0 \exp(-\alpha It)}{\beta v_0 [1 - \exp(-\alpha It)] + \alpha} \tag{3}$$

where v_0 is the concentration at $t=0$. Consequently, the value of v at the irradiation dose r and after a time t , is expressed in the case of $\alpha \ll \beta v$,

$$v = \frac{\sqrt{\gamma/\beta} \tanh(\sqrt{\gamma\beta} \cdot r)}{It \sqrt{\gamma\beta} \tanh(\sqrt{\gamma\beta} \cdot r) + 1} \tag{4}$$

and in the case of $\alpha \gg \beta v$

$$v = \frac{\gamma}{\alpha} e^{-\alpha It} (1 - e^{-\alpha r}). \tag{5}$$

Calculating γ from G value and in comparison with teflon and polymethylmethacrylate data the measured v agrees roughly with the equation (5) as shown in Fig. 1. α' is estimated to be about 2.8×10^{-3} in teflon and of the order of 10^{-4} sec^{-1} in PMMA. In the case of other polymers the data

Fig. 1. Spin concentration dependence on irradiation dose in teflon (after Abe).
----- curve of Eq. (4), ——— of Eq. (5).

is not enough to decide the value of α' and β' , but by assuming (4), or (5), α' or β' is estimated from v , resulting

$\alpha' = 10^{-2} \sim 10^{-4} \text{ sec}^{-1}$ or $\beta' = 10^{-18} \sim 10^{-20} \text{ cm}^3 \text{ sec}^{-1}$ in the cases of polyethylene and polystyrene.

In the case of $\alpha \gg \beta v$, the reaction of radical disappearance can be considered that the reaction like

takes place and the X atom diffuses away, or the cage effect such as

is often occurred.

From these results it may well be said that the life-time of radical is pretty long ($10^2 \sim 10^4 \text{ sec}$) in solid polymers, and it is not good to assume the stationary state. The long life-time is also expected by the facts of graft copolymerization of gas phase monomers to the solid polymer after irradiation. As it has been measured that at 30 minutes after the cease of irradiation the graft copolymerization can take place in polyethylene, nylon and polyvinyl alcohol,³⁾ it is properly said that the above conclusion is reasonable.

The author wishes to express his thanks to Prof. H. Abe for his kind offering of experimental data and giving discussions.

Effects of Impurities and Temperature on the Spectra of Electroluminescence

By Ryoichiro HUZIMURA

*Department of Applied Physics,
Kyoto University, Kyoto*

and Tunahiko SIDEI

*Department of Nuclear Science,
Kyoto University, Kyoto*

(Received April 8, 1958)

The dependence of the electroluminescence spectrum of ZnS on impurity concentration and temperature has been observed. The prepared samples are ZnS; Cu, Pb of powder type imbeded in polystyrene and they were excited by high alternating voltage of 60 c.p.s.. The emitted light was recorded by a combination of a spectrometer of constant deviation type and an E.M.I. type 6262 photomultiplier.

Fig. 1. Effects of composition on *EL* spectra.
Resolution ~ 20 Å

Fig. 1 shows the normalized intensity spectra of five specimens with different impurity concentrations measured at room temperature. The composition of each sample in the figure is tabulated in Table I. They can be resolved into three Gaussian components which are centred at 4600, 5200, 5800 Å. As the shape of the most intense component at 5200 Å, we assumed $C \exp \{-(E_0 - E)^2/0.04\}$, where $E_0 = 2.4$ eV. The relative intensities of the other components were determined as shown in table I. The relative total emission intensities of several samples with different impurity concentrations are also tabulated in Table I where the intensities of sample No. 1 is chosen as the standard.

From the behavior of Pb impurity in these phosphors it may be concluded that Pb intensifies the total emission intensity in proportion to its concentration without affecting the relative intensities of three components in the spectrum in a certain range of concentration. Comparing the intensities of sample No. 1, No. 4 and No. 5 in the table, we see that, with the fixed concentration of Pb, the peak at 4600 Å tends to vanish at lower and higher concentration of Cu, and the peak at 5800 Å tends to grow with decreasing concentration of Cu. Then, the variation of spectrum with Cu concentration is similar to the well known behavior of ordinary photoluminescence. However, when a sample of hexagonal symmetry (No. 6), which has the same initial composition as the sample No. 1, is examined, the peak at 4600 Å is most intense.

Fig. 2. Effects of temperature on *EL* spectra.

Table I. Compositions and Relative Emission Intensities of *EL* Spectra.

Sample No.	Added Impurity (mole ratio)		Firing Temp.	Relative Emission Intensity			
	Cu	Pb		4600 Å	5200 Å	5800 Å	Total
1	0.001	0.001	1000°C	0.35	1	0.45	100
2	0.001	0.0001	"	0.33	1	0.5	10
3	0.001	0.00002	"	—	1	0.5	3.2
4	0.003	0.001	"	—	1	0.3	52
5	0.0004	0.001	"	—	1	0.9	34
6	0.001	0.001	1100°C	2	1	—	14

Fig. 3. Temperature variation of electroluminescence at two emission bands, 4600 Å and 5200 Å.

The emission color of sample No. 1 was blue at low temperature but changed to green at higher temperature. The normalized temperature variation of electroluminescent spectrum is shown in Fig. 2. The ratio of the actual peak height of 5200 Å at -196°C to that at room temperature was 1/10. When the temperature was lowered, each component became sharper and the increase of the relative intensity of the 4600 Å component was remarkable. These tendencies, too, are similar to the well known behavior of ordinary photoluminescence.

From these three similarities mentioned above, we may speculate that the energy scheme of luminescence center in the electroluminescence process of cub. -ZnS type is not so much different from that of the ordinary photoluminescence process, and that the high external electric field has little effect on the emission process, but has an important influence on the excitation process as discussed in many literatures.¹⁾

Furthermore, the temperature variation of electroluminescence²⁾ has been examined with sample No. 1 at 4600 Å and 5200 Å simultaneously to see the difference of the phenomena between different emission bands. Peaks of the two curves in Fig. 3 show a similar change as the function of temperature, so it may be suggested that the contribution of traps to electroluminescence is not so much different with these two emission bands.

Electrical Conductivity in *p*-Type InSb Under Strong Electric Field

By Yasuo KANAI

Electrical Communication Laboratory,
Musashinoshi, Tokyo

(Received June 3, 1958)

Recently we measured the current-voltage characteristics and Hall effects of *n*-type InSb under strong pulsive electric field (up to about 3×10^3 volts/cm) at 90°K , and found that the carrier ionization from full band began to occur at about 2×10^3 volts/cm $v_d \sim 3 \times 10^7$ cm/sec.)¹⁾ In this note we will report the similar experimental results about *p*-type InSb.

Fig. 1 shows a typical example of the current-voltage characteristics and Hall coefficients of *p*-

Fig. 1. The current-voltage characteristics with and without magnetic field, and Hall effect of a *p*-type InSb single crystal at 78°K . The absolute values of Hall coefficient are rather erroneous.

type InSb single crystals at 78°K . This sample had the following character at this temperature; resistivity (ρ) = 2.18 ohm-cm and Hall coefficient (R) = $+2.32 \times 10^3$ cm²/coul.. As is shown in the figure we observed an interesting current-voltage characteristic of *p*-type InSb; i.e. at rather low electric field strength (about 15–20 volts/cm) the Ohm's law ceased to be valid and the current increased very rapidly with increasing electric field. Moreover the Hall coefficient of the crystal changed its sign from *p*-type to *n*-type and the current increase in this region was rather suppressed by the magnetic field of about 1 kG. As the characters mentioned above were independent of the conditions of lead wires-InSb contacts, we could believe that the current increase at low electric field was caused not by the electron-injection but by the ionization process from full band due to the energetic holes in *p*-type InSb. Comparing our results with those

of n -type InSb, in which the similar process occurred at about 2×10^2 volts/cm, we would expect that there were very light holes in p -type InSb and the mobility of them was about ten times larger than that of electrons. These holes probably correspond to the light holes which have been theoretically predicted by several investigators²⁾⁻⁶⁾ but not yet verified experimentally.

Piezo-Effect of Selenium Rectifiers

Tadasi NUMATA

*Nagasaki University, Ohashi-Machi,
Nagasaki*

(Received July 21, 1958)

Two lead wires were soldered one each on the counter electrode and on the base metal plate of a commercial selenium rectifier disk by using a small piece of Wood's metal, and the other ends of the wires were connected to a cathode ray oscilloscope.

Oscillating the rectifier disk by applying a mechanical impulse perpendicularly to the surface of the disk, such an oscillating electromotive force as illustrated in Fig. 1 was observed on the oscillo-

→ time

Fig. 1. Piezo-effect of a commercial selenium rectifier. The large white line in the central part of the photograph is a sweep line.

scope. When a mechanical impulse was applied in the direction parallel to the surface of the disk, the electromotive force was fairly smaller than that in the case of the perpendicular impulse.

The frequency of the oscillating electromotive force is equal to the frequency of the mechanical oscillation of the disk, and the amplitude of the electromotive force damps rapidly with damping of

the oscillation of the disk. The magnitude of the electromotive force in Fig. 1 is about 10 milli-volts.

Rectifier disks having an evaporated nickel film as a counter electrode instead of Wood's metal used in commercial rectifiers had poor rectification and showed very small oscillating electromotive forces as illustrated in Fig. 2. Also for selenium rectifiers showing poor rectifying characteristics, the above-mentioned effects were in general small.

→ time

Fig. 2. Piezo-effect of a disk having an evaporated nickel film as a counter electrode.

The same effect was observed for selenium photo-cells. But in this case, the electromotive forces were considerably smaller than those of the commercial selenium rectifiers, and decreased fairly by an illumination of light.

All the above experiments had been done in a quasi-dark room.

Since bulk metallic selenium consists of micro-crystals whose orientations are at random, and since the piezo-effect is very small for the disks having an evaporated nickel film as a counter electrode as shown above, this effect may not be considered a usual piezo-effect of crystals, but to be a barrier piezo-effect caused by oscillating deformation potential of selenium associated with the oscillation of the rectifier disk.

Finally, the author expresses his sincere thanks to Professor A. Okazaki of Kyushu University for his useful discussions and encouragement.

Structure of the F Band in Potassium Chloride

By Goro KUWABARA and Akira MISU

*Department of Physics, Faculty of Science,
University of Tokyo, Tokyo*

(Received August 2, 1958)

Recent experiments^{1),2),3)} on the luminescence and dichroism of the color centers suggest that between various absorption bands there may exist more intimate relations than expected before.

If the absorption band associated with the M or R band is hidden under the F band, it is expected

that some changes might occur in the *F* band, according to the various states of the crystal or the degree of development of the *R* and *M* bands. In this note, the distinct structure in the *F* band of additively colored potassium chloride observed in the excitation spectrum of luminescence and also in inducing dichroism in the *R* and *M* bands is reported.

Curve (a) in Fig. 1 is the excitation spectrum at

Fig. 1. The excitation spectra of additively colored KCl.

(a) Crystal containing only *F* centers (measured with VR-1 filter). (b) Crystal containing large amounts of *M* and *R* centers (with Si filter) measured at -170°C , (slit width $2\text{ m}\mu$ at $546\text{ m}\mu$).

low temperature when a crystal contained only *F* centers, and the curve (b) shows the spectrum when the large amounts of *R* centers were developed in the same crystal by irradiating with light in the *F* band. For excitation the light from a Xenon-arc-lamp passed through a quartz double monochromator was used, and the luminescence in the near infrared region was measured with a PbS cell. To cut off the exciting light, VR-1 filter or a slice of Si crystal was used. In curve (a) the shape of the excitation spectrum near the *F* band almost coincides with that of the absorption spectrum. However, in curve (b), in which the peaks correspond to the *F*, *R*₁, *R*₂, and *M* bands, two peaks were observed in the *F* band, one of which nearly coincided with that of the absorption and another was displaced towards shorter wavelength side by about $20\text{ m}\mu$.

Fig. 2 shows the absorption spectra of the crystal irradiated at room temperature with two monochromatic lights in the *F* band polarized along [011] direction, one of which lies in the shorter (curve (a), $510\text{ m}\mu$) and another in the longer wave

Fig. 2. Absorption spectra of the crystals irradiated at room temperature with the lights of the wavelength (a) $510\text{ m}\mu$ and (b) $565\text{ m}\mu$ (slit width $4\text{ m}\mu$ at $546\text{ m}\mu$) polarized along [011] direction.

length side (curve (b), $565\text{ m}\mu$) of the absorption peak. The former produced the dichroism mainly in the *R* band (probably, together with the *N* band), and the latter mainly in the *M* band, respectively. If the crystal was irradiated with the polarized light in the *R* (*R*₁ and *R*₂) or *M* band, the dichroism appeared also in the *F* band as well as in the irradiated band. The direction of the maximum absorption in the *F* band lay along [011] direction in both cases, and the maximum amount of dichroism was developed at about $505\text{ m}\mu$ or $545\text{ m}\mu$ corresponding to the *R* or the *M* band. The *R*₁ and *R*₂ bands behaved almost similarly, that is, the dichroism in the same sense and of nearly the same amount appeared, but the *M* band behaved differently.

From the results above mentioned, it might be concluded that the shorter and the longer wave length parts of the *F* band slightly different from the peak are associated with the *R* and the *M* band, respectively. However, the role of impurities in these phenomena, especially that of divalent ions, should be checked more carefully. The details of the experiments on the variation of emission spectra with the exciting light, polarization of luminescence and dichroism in the *N* band will appear in this journal.

Small Angle Scattering of X-rays by Deuteron-irradiated Germanium Crystal

By Francisco Eiichi FUJITA* and Ulrich GONSER**

Department of Physics, University of Illinois,
Urbana, Illinois, U.S.A.

(Received May 31, 1958)

Some recent investigations seem to give evidence for existence of thermal spikes produced by high energy particle bombardment in some materials. For instance, it was thought that the observed volume contraction of the GaSb crystal irradiated by 12 Mev deuterons at liquid nitrogen temperature is due to temperature spike regions in which the crystal is locally melted with about 9% contraction and the liquid lattice configuration is then frozen in at such low temperature.^{1,2,3,4} According to the theory of thermal spike,⁵ their size will be 10–1000 Å in diameter.

J. S. Koehler suggested the application of small angle scattering of x-rays to this problem. Guinier gives a formula for the intensity distribution of the scattering of x-rays at small angles ϕ from N identical spherical particles with random distribution,

$$I = I_e n^2 N \exp(-4\pi^2 R^2 \phi^2 / 3\lambda^2) \quad (1)$$

where n is the number of excess or deficit electrons in one particle, I_e the intensity scattered by one electron, λ the wave length of the incident x-rays, and R the radius of gyration of a particle regarding the electron density.

Single crystalline specimens of germanium (5 × 15 mm) were cut, polished and etched with CP-4 to a final thickness of 0.1 mm. The specimens were kept at about -180°C in a liquid nitrogen cryostat during the deuteron irradiation and the x-ray measurement. 8 Mev deuteron beam from the cyclotron irradiated the specimens perpendicularly, then they were turned to the direction perpendicular to the Cu K α x-ray beam from a bent crystal monochromator. A non-screen Kodack film was placed at the focus of the x-rays, 44 mm distant from the specimen, to record the scattered intensity of x-rays.

In Fig. 1 the angular intensity distribution of scattering from one irradiated crystal and that after annealing at room temperature are plotted in $\log I$ vs ϕ^2 . According to Eq. 1, the size of the

Fig. 1. The angular intensity distribution of scattering of X-rays from an irradiated germanium crystal plotted in $\log I$ vs ϕ^2 . The dotted line is estimated from the scattered experimental values.

small particles which are supposed to be the spiked regions is found to be 35 Å in radius, R being 27 Å. Therefore, one region may contain about 9×10^3 atoms, since the atomic volume in germanium is 22.5 Å³. From the comparison between the intensity of the incident x-ray beam and the scattered intensity, the number of particles N was estimated to be $2 \times 10^{17}/\text{cm}^3$ in a specimen irradiated by deuterons of about $5 \times 10^{16}/\text{cm}^2$ by assuming the density increase of several % in spike regions like that in melting. These results are in good agreement with the theory.^{5,6,7}

Between the liquid nitrogen and room temperatures, the scattered intensity decreased to about 1/5 of the original value in spite of little change in the radius. This would suggest that the frozen lattice configuration with higher density was transformed to the normal lattice structure apart from the crystal orientation in this temperature range, retaining a considerable amount of imperfections which can still produce some scattering effect.

We want to express our gratitude to Prof. J. S. Koehler and Prof. F. Seitz for many valuable discussions and Prof. J. S. Allen of the Illinois Cyclotron for his kind cooperation.

The integral square error is defined as follows:

where $x(t)$ is the deviation of controlled variable from its final value and t is the time.

By using the integration variable x instead of t , the expression (1) is easily transformed as follows:

where x_0 is the initial value of x and the integral on the right hand side, i.e. $\oint dx$, means the integral taken along the demeanour of the system. Therefore, we get the following new form of the integral square error:

$$2 \int_0^{x_0} tx \, dx \quad (2)$$

Table.

[illegible]

for stable system such that

$$\lim_{t \rightarrow \infty} [tx^2] = 0.$$

In a non-oscillatory performance, the expression (2) becomes

$$2 \int_0^{x_0} tx \, dx \quad (3)$$

by ordinary integral expression, but in an oscillatory performance, because there are several values of t corresponding to one value of x , we have to express as follows:

$$2 \int_{x_{\min}}^{x_{\max}} \sum \left\{ \operatorname{sgn} \left(-\frac{dx}{dt} \right) t \right\} x \, dx, \quad (4)$$

where $\sum$ indicates the sum of all t 's corresponding to one value of x and sgn stands for the sign of.

Formulae (3) and (4) are suitable for numerical integration for the reason that the calculation of square of experimental value is not required and, accordingly, this computation is much less complicated than direct numerical integration of expression (1).

We have calculated the value of the integral square error of the indicial response shown by the figure. The procedure of calculation is tabulated, where Newton-Cotes numerical integration formula³⁾ is used.

The main computational error arises from experimental data ambiguously read from the experimental figure. Such kind of error appearing in the calculation of the integral square error by the method stated here is about one-half that appearing in the direct numerical integration of the expression (1) in which the square of experimental data is included.

The author expects this method to be a new step for the application of Lebesgues integral to the theory of automatic control.

Excited States of Pt^{192}

By Mitsuhiro KAWAMURA, Atsushi AOKI and Takeo HAYASHI

Department of Physics, Saikyo University, Kyoto

(Received June 6, 1958)

The directional correlations of the 300 KeV–300 KeV, 468 KeV–316 KeV and 300 KeV–600 KeV gamma-gamma cascades in Pt^{192} have been measured by using the coincidence spectrometer reported previously. It is found that the spins of the 784 KeV and 920 KeV levels are 4 and 3, respectively.

§ 1. Introduction

Iridium-192 decays by electron emission to Pt^{192} and by orbital electron capture to Os^{192} . Extensive studies¹⁻⁶⁾ have been made for the gamma radiations following the decay. The decay scheme⁶⁾ of Pt^{192} proposed recently is shown in Fig. 1. Spins and parities of the excited states of this nucleus have been investigated by the measurement of the internal conversion coefficients and the angular correlation functions.^{5), 7-11)} However, there still remain some uncertainties on the spin values assigned to the third and the fourth excited states. Especially, for the fourth excited state, its spin seems to be even contradictory: $J_B = 4^9), 12)$; $J_B = 3$ or $4^5)$; $J_B = 2$

or 3 or 4 or $5^{11)}$; $J_B = 3^{10)}$. The present investigation was intended to remove the above uncertainties by further measurements of the gamma-gamma angular correlations corrected more precisely for the interference effect caused by the higher energy gamma rays.

§ 2. Experimental Procedure

The detectors were NaI(Tl) crystals, $1\frac{1}{2}$ in. diameter and 1 in. thick, obtained from Harshaw Chemical Corporation, and were coupled to the photo-cathodes of the RCA-5819 photomultiplier tubes. The coincidence spectrometer was the same one as reported in the previous paper¹³⁾, operating at a resolving time of 6×10^{-8} sec. The source material (Na_2IrCl_6 in HCl solution) was produced at Oak Ridge National Laboratory whose radiochemical purity was more than 98 %. For the measurements of the single and coincidence spectra, as well as for the 300 KeV–300 KeV and 468 KeV–316 KeV angular correlation experiments, the source was prepared by enclosing the solution in a thin glass sphere having about 1 mm inner diameter. While, in the case of the 300 KeV–600 KeV angular correlation experiment, linear source, placed symmetrically on the axis of the rotation of the counter system, was used in order to increase the source intensity. The extranuclear interaction was minimized by using the sources in liquid form. Following procedures were taken to get the true correlation function from the measured one. When the measurements were performed with the linear sources, the experimental data were fitted firstly with the theoretical correlation function corrected for both the finite source size and the detector size. This corrected function¹⁴⁾ can be written as

Fig. 1. Decay scheme for Pt^{192} based on Baggerly *et al.* Relative intensities of gamma rays are given in parentheses. Unambiguous spin assignments are indicated.

$$\begin{aligned} \bar{W}(\theta) = & 1 + A_2 \left[G_2 P_2(\cos \theta) + \frac{1}{4} \left(\frac{L}{D} \right)^2 (1 - P_1(\cos \theta)) P_4(\cos \theta) \right] \\ & + A_4 \left[G_4 P_4(\cos \theta) + \frac{1}{4} \left(\frac{L}{D} \right)^2 (1 - P_1(\cos \theta)) \left(P_1(\cos \theta) + \frac{7}{3} P_3(\cos \theta) \right) \right], \quad (1) \end{aligned}$$

where L , D , and G 's denote the length of the linear source, the distance between the source and the front surface of the crystal and the attenuation factors due to the finite detector size, respectively. Then, by using A 's in Eq. (1) thus obtained, the true correlation function is expressed as

$$W(\theta) = 1 + A_2 P_2(\cos \theta) + A_4 P_4(\cos \theta). \quad (2)$$

To get the corrected function for the point source, it is enough to insert $L=0$ in Eq. (1).

§ 3. Measurements and Results

1) Single and coincidence spectra

The result of the gamma ray spectrum measurement is shown in Fig. 2. The 300 KeV

Fig. 2. Gamma ray spectrum of Ir^{192} . The shaded portions represent the windows of the pulse height analyzers in the measurement of the coincidence spectra and the angular correlations.

Fig. 3. Coincidence spectrum of the 300 KeV gamma rays.

and 600 KeV peaks in Fig. 2 correspond to the composite peak of the 296 KeV, 308 KeV and 316 KeV gamma rays, and that of the 589 KeV, 604 KeV and 612 KeV gamma rays, respectively. The peak area ratios of the measured 300 KeV, 468 KeV and 600 KeV gamma rays were consistent with those calculated from the gamma ray intensities reported by Baggerly *et al.*⁵⁾ The spectra of the gamma rays in coincidence with the 300 KeV and 468 KeV gamma rays are also given in Figs. 3-4. In measuring the coincidence spectra, the window of the pulse height analyzer in the fixed channel was set on the shaded portion as shown in Fig. 2, while the sweeping channel had the same window width as in the case of the single spectrum measurement.

Fig. 4. Coincidence spectrum of the 468 KeV gamma ray.

2) Angular correlation measurements

In all cases of angular correlation measurements, the windows of the pulse height analyzers were set on the shaded portions in Fig. 2.

a) The 300 KeV-600 KeV angular correlation

In this case, the distances between the source and the crystal surfaces connected to the photomultiplier tubes for the 300 KeV and the 600 KeV gamma rays were 10 cm and 7 cm, respectively. Further, the lead absorber of 5 mm thick was placed in front of the detector for the 600 KeV gamma ray in order to reduce unnecessary background caused by the 300 KeV gamma ray entering this detector. The measurements were made at angles of 90° ,

112.5°, 135°, 157.5° and 180°, and the true coincidence counting rate was about 200/min. The measured results and the most fitted curve for them are shown in Fig. 5. The most fitted A 's were obtained, as described in Sec. 2, by Eq. (1) using the geometrical mean of 10 cm and 7 cm for D , $L=7$ mm, $G_2=0.937$

Fig. 5. Directional correlation of the 300 KeV-600 KeV gamma rays. The solid curve represents the least-squares fit of the experimental data.

Fig. 6. Directional correlation of the 468 KeV-316 KeV gamma rays. The solid curve represents the least-squares fit of the experimental data.

and $G_4=0.802$. With these A 's, the true correlation function is written as

$$W(\theta) = 1 - (0.200 \pm 0.010)P_2(\cos \theta) - (0.047 \pm 0.015)P_4(\cos \theta). \quad (3)$$

b) The 468 KeV-316 KeV angular correlation

The distance between the point source and the front face of each crystal was 7 cm. The measurements were made at angles of 90°, 105°, 120°, 135°, 150°, 165° and 180° and the true coincidence counting rate amounted to about 600/min. The experimental results and the most fitted curve for them are shown in Fig. 6. The most fitted correlation function can be expressed as

$$W'(\theta) = 1 + (0.080 \pm 0.006)P_2(\cos \theta) + (0.011 \pm 0.007)P_4(\cos \theta). \quad (4)$$

This function is expected to contain the desired 468 KeV-316 KeV angular correlation and some contribution from the 600 KeV-300 KeV angular correlation, because, the 600 KeV gamma rays have its Compton component of about 468 keV energy. Hence, we should subtract from Eq. (4) this contribution which has been estimated by using the single spectrum of the 660 KeV gamma ray in Cs^{137} and the coincidence spectrum of the 300 KeV gamma rays. The subtracted correlation function can be represented as

$$W''(\theta) = 1 + (0.094 \pm 0.006)P_2(\cos \theta) + (0.014 \pm 0.007)P_4(\cos \theta). \quad (5)$$

Since the attenuation factors are $G_2=0.918$ and $G_4=0.747$ for the detector geometry in this case, the true correlation function is given as

$$W(\theta) = 1 + (0.103 \pm 0.006)P_2(\cos \theta) + (0.018 \pm 0.010)P_4(\cos \theta). \quad (6)$$

Fig. 7. Directional correlation of the 300 KeV-300 KeV-gamma rays. The solid curve represents the least-squares fit of the experimental data.

c) The 300 KeV-300 KeV angular correlation

The distance between the point source and the front face of each crystal was 7 cm. The measurements were made at angles of 90°, 105°, 120°, 135°, 150°, 165° and 180°. The true coincidence counting rate was about 1800/min. The experimental results and the most fitted curve for them are shown in Fig. 7. The most fitted correlation function can be written as

$$W'(\theta) = 1 - (0.051 \pm 0.004)P_2(\cos \theta) + (0.076 \pm 0.005)P_4(\cos \theta). \quad (7)$$

In this case, it is also necessary to subtract the effects of the interference caused by the 300 KeV-600 KeV and 468 KeV-316 KeV gamma ray cascades. These interference effects were estimated from the spectral shapes of the

660 KeV gamma ray of Cs^{137} for the 600 KeV gamma rays and the 510 KeV annihilation gamma ray of Na^{22} for the 468 KeV gamma ray respectively, by the same procedure described in the case of 468 KeV–316 KeV angular correlation. The subtracted correlation function is

$$W''(\theta) = 1 - (0.053 \pm 0.005)P_2(\cos \theta) + (0.086 \pm 0.006)P_4(\cos \theta). \quad (8)$$

Thus, the true correlation function, applying $G_2=0.917$ and $G_4=0.744$ for Eq. (8), can be written as

$$W(\theta) = 1 - (0.058 \pm 0.005)P_2(\cos \theta) + (0.116 \pm 0.008)P_4(\cos \theta) \quad (9)$$

§ 4. Analysis and Discussion

The correlation function of the 468 KeV–316 KeV cascade represented by Eq. (6) agrees very well with the theoretical function for the $4(Q)2(Q)O$ sequence. Taylor and Pringle⁹⁾, though obtaining the experimental result similar to us, explained their data by the $3(94.2\% D 5.8\% Q)2(Q)O$ sequence in which δ had negative sign.* They insisted the spin assignment of 3 to the 786 KeV level because of the existence of the crossover transition to the ground level. But according to the internal conversion measurements as reported by Baggerly *et al*⁶⁾, and Kelman *et al*⁷⁾, the 468 KeV gamma ray must be pure electric quadrupole radiation. Therefore it seems better to assign the $4(Q)2(Q)O$ sequence for this cascade.

Next, the results of the 300 KeV–300 KeV and 300 KeV–600 KeV angular correlations were used to determine the spin of the 920 KeV level. Both correlation functions given by Eqs. (9) and (3) are expected to be composed of several elementary angular correlation functions: for instance, as easily seen in Fig. 1, the 300 KeV–300 KeV correlation function is the superposition of the 308 KeV–295 KeV, 295 KeV–316 KeV and 308 KeV–316 KeV correlation functions. Accordingly, the information about the relative weights of these elementary processes are required for the analysis of Eqs. (9) and (3). This information can be obtained from the relative intensities of the gamma rays concerned. Among several propositions

on this subject, we prefer the result reported by Baggerly *et al*⁶⁾, as the peak area ratios observed in our single spectrum measurement are consistent with those calculated from their gamma ray intensities. By use of the relative intensities* shown in Fig. 1, in the case of the 300 KeV–300 KeV measurement, the contribution of each cascade to the coincidence rate was found to be: 38.8% (316 KeV–296 KeV), 30.6% (316 KeV–308 KeV), and 30.6% (308 KeV–296 KeV). For the 300 KeV–600 KeV case, we obtained 20.5 % (308 KeV–612 KeV), 43.5 % (316 KeV–604 KeV), 18.0 % (296 KeV–589 KeV) and 18.0 % (316 KeV–589 KeV). Now as the error of the intensity measurements by Baggerly *et al* is estimated to be $\pm 20\%$, the mixing ratios of the gamma rays obtained from our experiment, have corresponding errors. However, the determination of the spin value for the 920 KeV level may be possible even in such a situation, as the correlation function shows notable changes for various spin assignments to the 920 KeV level. Assuming $J_0=2$ for the 612 KeV level supported by the internal conversion measurement, several possibilities for the spin assignment of the 920 KeV level, J_B , can be examined as follows.

(Case 1) $J_B=4$

As shown in Fig. 8, the experimental curves

Fig. 8. Comparison of the theoretical angular correlation curves for the 300 KeV–300 KeV and the 300 KeV–600 KeV gamma ray cascades with the experimental curves represented by Eq. (9) and Eq. (3), in the case of $J_B=4$. δ_1 , δ_4 denote the mixing ratios in the 296 KeV and the 589 KeV gamma rays, respectively.

* δ is the ratio of the reduced matrix element of the quadrupole transition to that of the dipole transition.

* The relative intensities of gamma rays reported recently by O. I. Sumbaev⁸⁾ agree very well with Baggerly's data.

for the 300 keV-300 keV correlation given by Eq. (9) could be fitted within statistical error with the theoretical curve corresponding to the pure electric quadrupole for the 296 KeV gamma ray. Next, we examined the 300 KeV-600 KeV result. To discuss this result, two cases of spin assignments for the 1200 KeV level should be taken into consideration; namely, $J_\pi=3$ and 4. In the case of $J_\pi=3$, all possible combinations of the multipole mixtures from $\delta_1=\pm\infty$ to $\delta_1=\pm 4$ for the 296 KeV gamma ray and from $\delta_4=\pm\infty$ to $\delta_4=\pm 1.6$ for the 589 KeV gamma ray, were examined to fit the measured data with the theoretical curve. Here, $\delta_1=\pm 4$ and $\delta_4=\pm 1.6$ correspond to the maximum and to the value far beyond the maximum of the dipole admixture reported up to the present, respectively. The theoretical curve for the case of $\delta_1=-4$ and $\delta_4=-1.6$ is given in Fig. 8. This curve shows gross disagreement with the experimental one. For all the other combinations, the theoretical curves deviated more markedly. In the case of $J_\pi=4$, the fit became much worse. Accordingly, we should reject $J_\pi=4$ to the 920 KeV level.

(Case 2) $J_\pi=3$

In the analysis of the 300 KeV-300 KeV angular correlation, we could fit, as shown in Fig. 9, our data with the theoretical curve corresponding to the mixing ratios given by Kelman *et al.*⁷⁾ ($\delta_2=-4$ and $\delta_1=\pm\infty$ for the 308 KeV and 296 KeV gamma rays, respectively).

Fig. 9. Comparison of the theoretical angular correlation curves for the 300 KeV-300 KeV and the 300 KeV-600 KeV gamma ray cascades with the experimental curves represented by Eq. (9) and Eq. (3), in the case of $J_\pi=3$. $\delta_1, \delta_2, \delta_3, \delta_4$ denote the mixing ratios in the 296 KeV, 308 KeV, 604 KeV, and 589 KeV gamma rays, respectively.

Their mixing ratios obtained from the measurement of the internal conversion coefficient by their prism beta ray spectrometer seem to be reliable. For the 300 KeV-600 KeV correlation, two cases of spin assignments to the 1200 KeV level, namely $J_\pi=4$ and 3, were examined. For $J_\pi=4$, the experimental curve agreed well with the theoretical curve which was expected from the mixing ratios supported by Kelman *et al.* for the gamma rays concerned ($\delta_3=3, \delta_2=-4$ and $\delta_1=\pm\infty$ for the 604 KeV, 308 KeV and 296 KeV gamma rays, respectively). For $J_\pi=3$, we could also reproduce the experimental 300 KeV-600 KeV correlation curve, assuming $\delta_4=\pm\infty$ for the 589 KeV gamma ray in addition to the above-mentioned assumption for the other gamma rays.

(Case 3) $J_\pi=2$ or 5

For the case of $J_\pi=2$, the counting rate at 135° expected from the theoretical 300 KeV-600 KeV angular correlation should be smaller than the counting rate at 180° , as the theoretical correlation curve is mainly contributed from $2(Q, D)2(Q, O)$ sequence where the admixture of the dipole radiation is limited to the one permitted by the internal conversion data. This tendency is incompatible with our experimental data. Furthermore, $J_\pi=2$ seems unlikely from the information on the beta transitions. The case of $J_\pi=5$ should also be set aside, since the 308 KeV and 604 KeV gamma rays are predominantly electric quadrupole.

§ 5. Conclusion

Judging from the arguments in the preceding sections, it seems that the spin assignment $J_\pi=4$ is very reasonable, while it is concluded that the spin assignment for the 920 KeV level must be $J_\pi=3$, notwithstanding that $J_\pi=3$ or 4 can not be confirmed without ambiguity. Here, we note that Baggerly *et al.* reported the same result for J_π and, for J_π , the present work agreed with Shiel's result but is not consistent with the assignment $J_\pi=4$ reported by Mráz.

Acknowledgement

The authors express their hearty gratitude to Professor K. Kimura and Professor S. Shimizu of Kyoto University for their sustained interest and encouragement throughout the present work. This work was partly supported by a grant-in-aid for scientific research

of the Ministry of Education.

Sector Type Double Focusing Beta Ray Spectrometer Part I General properties

Mitsuo SAKAI and Hidetsugu IKEGAMI

Institute for Nuclear Study, University of Tokyo

(Received June 28, 1958)

A small scale beta ray spectrometer was built, making use of the double focusing principle applied to sector-field. The fringing field was found to be easily corrected and not to be serious for conventional purposes. The gathering power of 0.3% was obtained for the resolving power of 0.7%. Since the source can be placed outside of the magnetic field, this type of spectrometer might serve as a powerful tool for coincidence and correlation measurements.

§ 1. Introduction

The beta ray spectrometers have been greatly developed during the last decade. The magnetic spectrometer is divided into two types, namely, prismatic beta ray spectrometer and lens type spectrometer. The electrons in the former type are deflected in the right direction to the magnetic field and in the latter type the trajectory makes only a small angle with the axis of symmetry of the magnetic field. It is a well known fact that the inhomogeneous magnetic field produces the best focusing character in both type of spectrometers. The typical spectrometers with inhomogeneous magnetic field are the double focusing spectrometer¹⁾ in the former case and

the intermediate image spectrometer²⁾ in the latter case.

Corresponding to progress of the theory of nuclear structure, it was intended to develop a spectrometer especially suitable for coincidence experiments and for angular correlation measurements which give important informations on the nuclear level. In selecting a type among many types of spectrometers, the lens type spectrometer was first excluded because a diverging electron beam should be used in this type of spectrometer, making it difficult to do the measurements of angular correlation. On the other hand in the double focusing spectrometer the source and the detector should be put in the magnetic field, making

inconvenient for coincidence measurements and especially for correlation measurements.

Under the circumstances, we were led to adopt the sector type double focusing spectrometer. This type of spectrometer is not unusual and it was built in many laboratories for analysing particles produced in nuclear reaction.³⁾ But in this case the solid angle was in general an order of 10^{-3} steradian and the effect of fringing field in the entrance and in

the exit region has a little influence on the focusing properties. Since the beta ray spectrometer should have a large solid angle of order of 10^{-1} steradian, the fringing field above mentioned might have a large effect on the focusing properties as in the case for Kofoed-Hansen's spectrometer.⁴⁾ This fact was considered as a grave disadvantage for this type of spectrometer. However, as is seen in the proceeding section, this effect was found to be not so serious if a suitable correction was made.

§ 2. Design

In order to study the general properties of this type of spectrometer a small scale spectrometer with the mean radius of curvature of 9 cm was built. As is presented schematically in Fig. 1, the electrons were deflected in 180° . This angle was chosen for the practical reason that the pair of pole tips can be made at a time by cutting an iron disk machined by lathe. The inhomogeneous magnetic field between the pole tips chosen in the present apparatus has the following character;

$$B(r) = B(\rho) \left\{ 1 - \frac{1}{2} \frac{(\rho - r)}{\rho} + \frac{1}{4} \frac{(\rho - r)^2}{\rho^2} + \dots \right\}$$

This field distribution was easily obtained by a cone type pole tip⁵⁾ of which the extension of surface intersects on the median plane at ρ as shown in Fig. 2. The periphery of pole tips was empirically modified for keeping the field shape near the end of pole gap. The field distribution actually measured was presented in Fig. 3. After a small adjustment of ρ -value, agreement of the actual field with the theoretical one was satisfactory. The source (or the detector) was placed at S on the pole boundary. The other pole boundary

Fig. 1. Top view of sector type double focusing beta ray spectrometer.

Fig. 2. Side view of sector type double focusing beta ray spectrometer.

was cut as shown in Fig. 1 by taking account of the fringing field. In view of getting the virtual boundary⁶⁾ of the magnetic field at the line $\overline{C_2O}$, the cutting line of exit pole boundary was determined in the first approximation to intersect at S' and $\overline{C_1C_2}$ was chosen to 0.7 pole gap. In the present apparatus the pole gap was taken to be $1/2\rho$.

Fig. 3. Radial distribution of magnetic field.

The first order theory of this type of spectrometer⁷⁾ gives the following characters;

focusing distance: $\overline{C_2D}=1.87$

maximum solid angle:

= $A/2$; for the source at pole boundary

= $A/5.4$; for the source at the point D in Fig. 1.

where $A\rho^2$ is the available cross-sectional area of the electron beam in the spectrometer. In the present apparatus the maximum $A\rho^2$ is limited by $\rho \times \frac{1}{2}\rho$. The electron beam was defined by a baffle system which was designed on the basis of conventional second order calculation.

The focal point was first determined by varying the position of the detector in x and y directions by means of O-ring seal. (see Fig. 1.) and by measuring at each point the conversion spectra of Cs^{137} . This spectrum served as a measure of the focusing properties. The focal point of which the coordinates were

denoted as x_{op} and y_{op} was presented in Table I. The counting rate and resolving power measured at each point were also tabulated. As can be noticed in this figure, the electrons were focused on a rather large focal line with about a same quality of focusing. This fact was already pointed out in the particle analyser⁸⁾ and it suggests one of the advantages for this type of spectrometer. A typical spectrum was presented in Fig. 4.

Table I Optimum point in the image area

x_{op} (cm)	+0.5	0.0	-0.5	-1.0
y_{op} (cm)	11.5	10.0	9.5	7.0
Counting rate (Arbitrary)	170	180	170	180
Resolving power (%)	0.62	0.66	0.65	0.71

The sense of x coordinate is shown in Fig. 1.

Fig. 4. Line spectrum of conversion electrons of 661 KeV gamma ray from Cs^{137} .

The fraction of electrons collected at the peak of line spectrum referred to the total electrons belonging to this line emitted from the source was defined as the gathering power. The gathering power can be obtained practically from the following formula.

$$L = n/n_0\xi$$

where n is the counting rate at the peak point, n_0 the total electrons counted by the same detector and ξ the ratio of the area of the line spectrum to the total area taken by the

spectrometer. By using a source of about 3 mm diameter, a gathering power of 0.3% was obtained for a resolving power of 0.7%.

§ 3. Concluding Remark

This type of spectrometer has the versatile characters because 1) the accessibility to the source or to the detector is very good and 2) the electron beam in pencil form can be used and 3) the good relation of gathering power to resolving power can be obtained easily without any serious consideration for the fringing field. Fig. 5 shows some examples for use of this type of spectrometer.

Fig. 5 (a) shows the coincidence and the angular correlation measurements between gamma and conversion or beta radiations. Coupling two spectrometers as in Fig. 5 (b), we are able to do the coincidence measurements for the genetic relation and the correlation function between conversion electrons and conversion electrons or beta radiations. It is worth noting that the long arm reduces largely the effect of magnetic field resulting from the other spectrometer. Fig. 5 (c) illustrates other possibility of this type of spectrometer. Two spectrometers are coupled as in the case of (b). A slit S' is set at the

Fig. 5. Some typical setting configuration for use of sector type double focusing spectrometer.

detector point in the first spectrometer and this slit serves as the virtual source for the second spectrometer. By this setting one can easily get rid of the false counts resulting from the scattering electrons at the wall or from the electrons having the trochoidal trajectory.⁹⁾ This twin setting is especially suitable for the measurement of the higher weak beta component in the presence of the lower strong beta component as is the case of Cs^{137} , Co^{60} and Sc^{64} . This point will be verified in the succeeding report.¹⁰⁾

Sector Type Double Focusing Beta Ray Spectrometer

Part II. Twin Setting Measurement of the Weak Higher Component of Cs^{137}

Toshimitsu YAMAZAKI, Hidetsugu IKEGAMI and Mitsuo SAKAI

Institute for Nuclear Study, University of Tokyo

(Received June 28, 1958)

A twin setting of two sector type double focusing beta ray spectrometers was used for measurement of the weak higher component of Cs^{137} in order to remove completely the contributions resulting from the secondary causes. The measured spectrum agreed well with those of the previous results, which were therefore confirmed to provide a reliable basis for the analysis of the coupling constants in beta decay.

§ 1. Introduction

Two sets of small scale ($\rho=9$ cm) sector-type double focusing beta ray spectrometers were constructed as models for larger ones. This type of beta ray spectrometers, as described in detail in the preceeding paper¹⁾, is suitable for β - γ , e^- - γ , β - e^- and e^- - e^- angular correlation experiments. In addition to these a special use for the measurements of beta ray spectra was pointed out, which consists in making use of the other spectrometer connected with one spectrometer. Since the second spectrometer selects electron momentum once more, this twin spectrometer setting is especially suitable for getting rid of the secondary effects caused in the measurements of weak higher components.

The usual measurements of the weak higher components of Cs^{137} , Co^{60} , Sc^{46} etc., which may need use of strong sources (perhaps of several

milli-curies), necessarily involve the following disturbing effects resulting from the co-existence of other strong beta and gamma radiations: false counting of 1) multiply scattered electrons from the low energy beta components, 2) Compton electrons from various points of apparatus by the strong gamma rays, and 3) low energy electrons with trochoidal trajectories²⁾. These effects, though they can be much reduced by using good baffle system, may still be possible to make disturbance more or less on the observed spectra. By adopting this twin spectrometer method, however, we can expect to get spectra free from these effects. Since the shapes of the higher-forbidden spectra, such as weak higher components of Cs^{137} , Co^{60} , Sc^{46} , etc., provide important informations about the coupling constants of beta decay, it seems worthwhile to measure these spectra once again by means of this

Fig. 1. Experimental arrangement.

twin setting. The present paper concerns the measurement of the weak higher component of Cs^{137} .

§ 2. Experimental Method

The arrangement of experimental apparatus is shown in Fig. 1. The source was put at the point S in the first spectrometer. Then the electrons were focused at F . If one sets the second spectrometer in such a manner that F serves as a virtual source for the second spectrometer, the electron beam passing through a slit placed at F can be refocused at D under a suitable field of the second spectrometer. Of course, the direction of electron trajectory at F is limited by the first.

When the field of the first spectrometer is fixed at $(B\rho)_1 = p$, then the ideal momentum distribution of electrons passing through the slit F (i.e., of the virtual source) may be as the solid line in Fig. 2 a), with a width corresponding to the resolution of the first spectrometer. But the actual distribution may involve moreover low energy part (broken line). This part, resulting from the disturbing electrons in question, corresponds to the false counts in usual single setting. This momentum distribution is observed at D as a sweeping curve in Fig. 2 b), by sweeping the current of the second spectrometer I_2 . If I_2 is fixed on peak, then the true momentum distribution of electrons incident on the detector may be as in Fig. 2 c). Being analysed by the second spectrometer, the low energy disturbing electrons are completely removed here, so far as secondary electrons produced in the second spectrometer can be regarded as negligible. The area of the peak divided by p is the value of the beta spectrum $n(p)$. In practice, to make measurements easier, we adopted so-called flat-topped method making the detector slit large enough to cover the peak. Then the sweeping curve may be flat and broad as in Fig. 2 d). In this case the over-all resolution is equal to the resolution of the first spectrometer, and we get the momentum spectrum $n(p) = N_p/p$, where N_p is the counting rates on the flat peak at $(B\rho)_1 = p$.

In the present measurement the detector slit of 10 mm was used. Observed sweeping curves are shown in Fig. 3. It has a flat part of 2%. The shape of this curve was found to be independent whether $(B\rho)_1$ was set on

or off a conversion line. No detectable amount of low energy electrons were found by sweeping I_2 .

The present twin spectrometer method can

Fig. 2. Illustration of the principle of twin spectrometer method. a) momentum distribution of electrons passing through F . b) sweeping curve with a detector slit. c) momentum distribution of electrons incident on D . d) sweeping curved without a detector slit.

be compared with the case where in usual single spectrometers measurements the scintillation counter is employed as a detector for discriminating the scattered electrons by making use of the energy sensitive character of this type of detector³⁾. The latter method is simpler than ours, but may be inferior because of the incomplete energy discrimination especially due to back scattering on the surface of scintillator.

Fig. 3. Observed sweeping curves. a) with a detector slit of 10 mm b) with a detector slit of 2 mm width.

7 mm thick aluminum baffles were set as shown in Fig. 1. The slit at F was rectangle of 2 mm width and 5 mm length.

A mica end-window Geiger-Müller counter with window thickness of 3 mg/cm² was used as the detector. No influence of counter efficiency by the magnetic field was recognized.

The source contained about 2 milli-curies of Cs¹³⁷ with high specific activity, which was uniformly spread over a rectangular area of 3 mm width and 7 mm length. The counting rates at energies just above the conversion lines of 662 Kev gamma ray were about 600 counts per minute.

The interference effect of the fringing fields of each spectrometer was first studied. Setting a source of Cs¹³⁷ at F and a detector at S , we measured the internal conversion peak by the first spectrometer by varying the exciting

current of the second spectrometer. A few percent shift of the peak was observed in case of high current. A simple magnetic shielding in the straight arm section reduced this shift to within one percent. In usual correlation experiments, where each field should vary independently, such an interference effect may be serious, but for the present purpose, where each field varies proportionally, it makes no disturbance.

Fig. 4. Observed spectrum of the internal conversion lines of Cs¹³⁷.

The overall resolution and gathering power were found to be 0.7% and 0.3%, from measurement of the internal conversion line of Cs¹³⁷.

The spectrometer field was measured indirectly from the exciting current. Calibration was made by Cs¹³⁷ K -internal conversion line ($B\rho=3381.3$), Cs¹³⁷ L -internal conversion line ($B\rho=3498.2$) and Co⁶⁰ 1.17 Mev K -internal conversion line ($B\rho=5322.5$). The currents were stabilised within 0.1%.

§ 3. Result and Discussion

In the present experiment the efforts were focused on the measurement of the higher component of Cs¹³⁷ above the internal conversion lines (≥ 0.65 Mev). For each $(B\rho)_1 = p$, we measured the sweeping curves as in Fig. 3 and got N_p . This procedure was rather tedious, especially near the end point of the spectrum, because of difficulty in finding peaks.

Usual Kurie plot $\sqrt{n(q)/f}$ of the observed spectrum is shown in Fig. 5 and experimental

correction factor $C=n(p)/(E_0-E)^2f$, which indicates the deviation from allowed type, is plotted in Fig. 6 as a function of electron energy E . The broken curve is the best fitted function: $C=q^2+0.003p^2$. The results are in good agreement with the previous investigators^{4),5)}. This means that in their experiments such disturbing effects, so far as the shape of Kurie plot was concerned, are regarded as negligible.

Fig. 5. Kurie plot of the higher component of Cs^{137} . The previous results are also plotted. These are normalized at $E=2.6$.

It is well known that the weak beta transition from $g_{7/2}$ ground state of Cs^{137} to the $d_{3/2}$ ground state of Ba^{137} exists with branching ratio of 8% and that its spectrum indicates twice-forbidden shape involving no change of parity and a spin change of two. L. M. Langer and R. J. D. Moffat, who studied in detail this beta ray component with a magnetic spectrometer, showed the shape of the spectrum could be adequately described by a twice-forbidden factor, C_{27} , resulting from the tensor form of interaction. Recently the same experimental results were reported by T. Katoh, M. Nozawa, Y. Yoshizawa and Y. Koh, who made analysis of the shape of the spectrum

assuming only a linear combination of the ordinary scalar and tensor interactions and concluded the sign of G_S/G_T was negative. Although these analyses will perhaps have to be corrected in near future from the today's viewpoint⁶⁾, the present experiment confirmed that their experimental data are reliable and can be a good basis for analysis.

The present authors express their sincere thanks to Prof. S. Kikuchi, director of this institute, for his constant encouragement during this research.

Fig. 6. Plot of the experimental correction factor $C=n(p)/(E_0-E)^2f$. Broken line is the best fitted curve: $C=q^2+0.003p^2$.

Temperature Distribution during the Martensite Plate Formation*

By Zenji NISHIYAMA, Akira TSUBAKI

Institute of Scientific and Industrial Research, Osaka University

Hideo SUZUKI and Yasusada YAMADA

Department of Physics, Faculty of Science, Osaka University

(Received January 16, 1958)

With the object of obtaining some basis for the thermodynamical consideration of the martensite formation, the temperature distribution during the transformation has been calculated using Bunshah and Mehl's data for the speed of propagation of the transformation front. From the results of calculation it is concluded that (1) the nucleation may be treated as isothermal and that (2) the growth may also be treated in the same way if the propagation of the transformation is steady, but the treatment must be nearly adiabatic if the propagation is intermittent and its unit is large.

§ 1. Introduction

It has been reported that the martensite transformation** in iron alloys occurs very fast. This fact is of importance, because the speed of the transformation has influence upon the resulting configuration in the alloy, and consequently upon its mechanical properties, etc. Notwithstanding the fast speed of the martensite formation some metallurgists have often tried to interpret several phenomena on the assumption that the martensite is produced isothermally. More than ten years ago, Nishiyama and Shimomura³⁾ proposed the idea*** that the isothermal treatments is not applicable to the thermodynamics of the martensite transformation. As for the temperature distribution during the propagation of the transformation front, they supposed a model as shown in Fig. 1. This model, however, was not on the experimental basis, because any quantitative facts concerning the speed of propagation had not yet been reported in those days.

In 1953, Bunshah and Mehl⁴⁾ found that the period of formation of a martensite plate is

of the order of 10^{-7} sec. From the parallelism between the period and the size of a martensite plate, they could estimate the speed of propagation to be 1.1×10^5 cm/sec.

In the present paper further discussion is to be given using Bunshah and Mehl's data.

Fig. 1. Propagation of transformation (a) and distribution of temperature (b) in a martensite needle, assumed formerly.⁽³⁾

But as it is not yet clear whether nucleation start at the mid-rib or at the end of the plate, and also in what crystallographic direction the plate grows, we adopt a simple model without considering any of these matters. Adopting such a model and assuming the steadiness of the propagation of transformation in a martensite plate, numerical calculations of the temperature distribution and its variation with time are to be carried out. And also some discussions on the result are to be described in connection with the thermodynamical meaning of the martensite formation, extending to the case of the intermittent propagation.

§ 2. The Equation of Heat Conduction

As is well known, the martensite phase

* This paper was read before the annual meeting (1957) of the Phys. Soc. Japan.

** According to Förster-Scheil¹⁾ and Suzuki-Homma²⁾ there are two modes, fast (Umklapp) and slow (Schiebung), in the martensite transformation. Only the former mode is the subject of discussion in this paper.

*** Crussard⁴⁾ noticed the dynamical nature of the martensite transformation.

grows with incessant evolution of heat in the austenite phase. The temperature is, therefore, not uniform in the vicinity of the transformation front.

To simplify the problem, we assume that (1) density ρ , specific heat c , and thermal conductivity κ of the two phases are equal, and that (2) in a very large material the martensite plate nucleates at $x=0$ in the form of a plane, which is a plane of symmetry in the course of growth, so that one dimensional treatment may be permissible. These assumptions do not injure the essential nature of the phenomenon and will be allowable for the estimation of the general aspect of the temperature distribution.

Let v denote the velocity of propagation with which the martensite phase grows in the austenite, and Q_0 the heat of transformation, then the heat evolution during an infinitesimal time, Δt , per unit area is given by $Q_0\rho(v\Delta t)$. Since this heat is generated only in the vicinity of the position $x=vt$, the heat of formation per unit area during Δt may be expressed as follows:

$$Q_0\rho(v\Delta t)\delta(x-vt), \quad (1)$$

where x is the coordinate and $\delta(x)$ is Dirac's δ -function satisfying the following relations:

$$\delta(x) \begin{cases} = 0 & \text{if } x \neq 0 \\ \neq 0 & \text{if } x = 0 \end{cases}$$

and

$$\int_{-\varepsilon}^{\varepsilon} \delta(x) dx = 1 \quad (1 \gg \varepsilon > 0). \quad (2)$$

Then we have the equation of heat conduction

$$\frac{\partial \theta}{\partial t} = a^2 \frac{\partial^2 \theta}{\partial x^2} + b \delta(x-vt), \quad (3)$$

where θ is the temperature, $a^2 = \frac{\kappa}{c\rho}$, and

$$b = \frac{Q_0 v}{c}.$$

§ 3. The Solution of Conduction Equation

In order to solve Eq. (3), we use the method of the Laplace transformation. If $\Theta(x, p)$ is the Laplace transformation of $\theta(x, t)$ such that

$$\int_0^\infty e^{-pt} \theta(x, t) dt = \Theta(x, p), \quad (4)$$

then

$$\int_0^\infty e^{-pt} \frac{\partial \theta(x, t)}{\partial t} dt = p\Theta(x, p) - \theta(x, 0). \quad (5)$$

With (4) and (5), (3) becomes

$$p\Theta(x, p) - \theta(x, 0) - a^2 \frac{\partial^2 \Theta(x, p)}{\partial x^2} - \frac{b}{v} e^{-px/v} = 0. \quad (6)$$

Let us assume that, before the nucleation of the martensite, the temperature is zero throughout the parent austenite, i.e.

$$\theta(x, t) = 0 \quad \text{for } t \leq 0. \quad (7)$$

And as we are considering a case in which a martensite plate nucleates at $x=0$ and then grows in the same manner on both side of $x=0$,

$$\left(\frac{\partial \theta(x, t)}{\partial x} \right)_{x=0} = 0, \quad \theta(\infty, t) = \text{finite}. \quad (8)$$

Substituting (7) into Eq. (6), we have

$$\frac{\partial^2 \Theta}{\partial x^2} - \frac{p}{a^2} \Theta = -\frac{b}{a^2 v} e^{-px/v}. \quad (6')$$

The general solution of this equation is

$$\Theta = -\frac{b}{a^2 v} \frac{e^{-px/v}}{p^2/v^2 - p/a^2} + c_1 e^{\sqrt{p}x/a} + c_2 e^{-\sqrt{p}x/a}.$$

And the condition (8) leads to

$$\Theta = -\frac{b}{a^2 v} \frac{e^{-px/v}}{p^2/v^2 - p/a^2} + \frac{b}{av^2} \frac{e^{-\sqrt{p}x/a}}{(p/v^2 - 1/a^2)\sqrt{p}}. \quad (9)$$

Table I.

$F(x, p)$	$f(x, t)$
$e^{-xp/v/p}$	$u\left(t - \frac{x}{v}\right) \equiv \begin{cases} 0 & \text{for } t < \frac{x}{v} \\ 1 & \text{for } t > \frac{x}{v} \end{cases}$
$e^{-xp/v} / \left(p - \frac{v^2}{a^2}\right)$	$\exp\left[\frac{v^2}{a^2}\left(t - \frac{x}{v}\right)\right] u\left(t - \frac{x}{v}\right)$
$e^{-x\sqrt{p}/a} / \left(\sqrt{p} \pm \frac{v}{a}\right)$	$\exp\left(\pm \frac{vx}{a^2}\right) / (4\sqrt{\pi} t^{3/2}) \int_{x/a}^\infty \mu \exp\left(-\frac{\mu^2}{4t} \mp \frac{v}{a}\mu\right) d\mu$
$e^{-x\sqrt{p}/a} / \sqrt{p}$	$\frac{1}{\sqrt{\pi t}} \exp\left(-\frac{x^2}{4a^2 t}\right)$

Rewriting this for the benefit of inverse transformation, we have

$$\theta = -\frac{b}{v} e^{-vz/v} \left\{ -\frac{1}{p} + \frac{1/v^2}{p/v^2 - 1/a^2} \right\} + \frac{ab}{2v^2} \left\{ \frac{1}{\sqrt{p+v/a}} - \frac{1}{\sqrt{p-v/a}} - \frac{2}{\sqrt{p}} \right\} e^{-\sqrt{pz}/a}. \quad (9')$$

Inverting this equation, we can obtain the temperature distribution θ . Table I shows the relations available for the inversion, which are in the text by Morse and Feshbach⁶⁾ except the one on the second row.*

The results of the inversion are as follows:

(i) In the transformed region, $vt > x$,

$$\theta = \frac{b}{v} \left\{ 1 - \exp \left[\frac{v^2}{a^2} \left(t - \frac{x}{v} \right) \right] \right\} - \frac{b}{\sqrt{\pi} v} \left\{ \exp \left[\frac{v^2}{a^2} \left(t + \frac{x}{v} \right) \right] \int_{\frac{x+vt}{2a\sqrt{t}}}^{\infty} e^{-w^2} dw + \exp \left[\frac{v^2}{a^2} \left(t - \frac{x}{v} \right) \right] \int_{\frac{x-2vt}{2a\sqrt{t}}}^{\infty} e^{-w^2} dw \right\}. \quad (10)$$

For simplicity we use a function $E(x)$ defined by

$$E(x) \equiv \int_{-\infty}^x \frac{1}{\sqrt{2\pi}} e^{-w^2/2} dw, \quad (11)$$

then (10) become

$$\theta = \frac{b}{v} \left\{ 1 - \exp \left[\frac{v^2}{a^2} \left(t - \frac{x}{v} \right) \right] \right\} + \frac{b}{v} \left\{ \exp \left[\frac{v^2}{a^2} \left(t - \frac{x}{v} \right) \right] E \left(\frac{2vt-x}{\sqrt{2ta}} \right) - \exp \left[\frac{v^2}{a^2} \left(t + \frac{x}{v} \right) \right] \left[1 - E \left(\frac{2vt+x}{\sqrt{2ta}} \right) \right] \right\}. \quad (10')$$

(ii) In the austenite region, $vt < x$, those corresponding to (10) and (10)' are

$$\theta = -\frac{b}{v} \frac{1}{\sqrt{\pi}} \left\{ \exp \left[\frac{v^2}{a^2} \left(t - \frac{x}{v} \right) \right] \int_{\frac{x+2vt}{2a\sqrt{t}}}^{\infty} e^{-w^2} dw - \exp \left[\frac{v^2}{a^2} \left(t + \frac{x}{v} \right) \right] \int_{\frac{x-2vt}{2a\sqrt{t}}}^{\infty} e^{-w^2} dw \right\}, \quad (12)$$

* This is obtained in the following way; according to the table of Morse and Feshbach⁶⁾ the Laplace transform of $\begin{cases} f(x, t-\alpha) & \text{for } t > \alpha \\ 0 & \text{for } t < \alpha \end{cases}$ is $e^{-\alpha p} F(x, p)$, where $F(x, p)$ is the Laplace transform of $f(x, t)$. Putting $F(x, p) = \frac{1}{p-\beta}$, we obtain that the inverse transformation of $e^{-\alpha p} \frac{1}{p-\beta}$ is $\begin{cases} e^{\beta(t-\alpha)} & \text{for } t > \alpha \\ 0 & \text{for } t < \alpha \end{cases}$.

and

$$\theta = \frac{b}{v} \left\{ \exp \left[\frac{v^2}{a^2} \left(t + \frac{x}{v} \right) \right] E \left(\frac{2vt-x}{\sqrt{2ta}} \right) - \exp \left[\frac{v^2}{a^2} \left(t - \frac{x}{v} \right) \right] \left[1 - E \left(\frac{x+2vt}{\sqrt{2ta}} \right) \right] \right\} \quad (12)'$$

respectively.

§ 4. Numerical Calculations

Now let us estimate the temperature distribution introducing numerical values of physical constants into (10)' and (12)'. For iron

thermal conductivity $\kappa = 0.11$ cal/cm. sec. deg,

specific heat $c = 0.11$ cal/gr. deg,

density $\rho = 7.9$.

Then we have

$$a^2 = \kappa / c\rho \approx 0.1 \text{ cm}^2/\text{sec}.$$

And since the values

$$Q_0 = 10 \text{ cal/gr}, \quad v = 1.1 \times 10^5 \text{ cm/sec}$$

are given from the result of experiment⁵⁾,

$$b = Q_0 v / c \approx 1.1 \times 10^7 \text{ deg. cm/sec}.$$

(a) The temperature variation at the plane of nucleus $x=0$. The result is shown in Fig. 2. In this figure the rise of temperature near

Fig. 2. Temperature variation at the centre of a martensite plate.

$t=0$ appears to be steep, but this has resulted from δ -function in (1). Actually it must be remembered that the generated heat at the earliest stage is almost absorbed by the surrounding matrix, and $\partial\theta/\partial t$ may be nearly zero at $x=0$ and $t=0$. That is to say, at the nucleation period the temperature of martensite may be not yet raised.

(b) The temperature distribution at the time when half the thickness of a martensite plate has grown to be (1) $10 \text{ \AA}$ ($t=10^{-12}$ sec), (2) $100 \text{ \AA}$ ($t=10^{-11}$ sec), or (3) $1000 \text{ \AA}$ ($t=10^{-10}$ sec).

Fig. 3 shows that the temperature falls steeply in the vicinity of the transformation front, and becomes nearly zero at a distance about 100 Å away from the front. Such a sharp gradient of temperature suggests important problems to be discussed. If the propagation of the transformation is steady, these curves will show the true distribution of temperature. But if it is intermittent, the result of calculation must be regarded to show merely the values smoothed out, because the value of propagation speed adopted here is only the average one.

Fig. 3. Temperature distributions at the time when half the size of a martensite plate becomes, (1) 10 Å, 10 × 10⁻¹³ sec. (2) 100 Å, 100 × 10⁻¹³ sec. (3) 1000 Å, 1000 × 10⁻¹³ sec.

Fig. 4. $\left(\frac{\partial \theta}{\partial t}\right)_f - x$ curve.

(c) $\partial \theta / \partial t$ at the time when the transformation front has travelled a certain distance x . Differentiating (12)' with respect to t , and putting $vt = x$, we have

$$\left(\frac{\partial \theta}{\partial t}\right)_f = \frac{b}{a} \sqrt{\frac{v}{\pi x}} \exp\left(-\frac{vx}{4a^2}\right) + \frac{vb}{a^2} \left\{ E\left(\sqrt{\frac{vx}{2a^2}}\right) - \exp\left(\frac{2vx}{a^2}\right) \left[1 - E\left(\sqrt{\frac{9vx}{2a^2}}\right) \right] \right\}, \quad (13)$$

where suffix f denotes the transformation front

in the austenite side. This relation is shown in Fig. 4. $(\partial \theta / \partial t)_f$ is infinity at $x = 0$, which again has come from the characteristic of δ -function and therefore this does not necessarily mean the adiabatic change.

(d) $\partial \theta / \partial x$ at the time when the transformation front has travelled a certain distance x . Differentiating (12)' with respect to x , and putting $vt = x$, we have

$$\left(\frac{\partial \theta}{\partial x}\right)_f = \frac{b}{a^2} \left\{ E\left(\sqrt{\frac{9vx}{2a^2}}\right) \exp\left(\frac{2vx}{a^2}\right) - E\left(\sqrt{\frac{vx}{2a^2}}\right) - \exp\left(\frac{2vx}{a^2}\right) \right\}. \quad (14)$$

Fig. 5 shows this relation. At $x = 0$, $(\partial \theta / \partial x)_f$ has a finite value -1.1 degree/Å.

Fig. 5. $\left(\frac{\partial \theta}{\partial x}\right)_f - x$ curve.

Fig. 6.

§ 5. The Degree of Heat Removal (γ) at the Transformation Front

In Fig. 6, ABC is the temperature distribution at time t , and A'B'C' at $t + \Delta t$. The forward heat conduction during the transformation of the region between $x = vt$ and $v(t + \Delta t)$ can be measured by the area (S) of the shaded region.

$$S = \int_{v(t+\Delta t)}^{\infty} \{\theta(x, t+\Delta t) - \theta(x, t)\} dx, \quad (15)$$

where $\theta(x, t)$ is given by (12)'

Now we define a parameter γ by

$$\gamma = S/b\Delta t, \quad (16)$$

where $b\Delta t$ is the heat evolution during Δt divided by $c\rho$. Regarding the proportion of the backward (toward the already transformed region) heat conduction, we have

$$\begin{aligned} \frac{S'}{b\Delta t} &= \int_0^{vt} \{\theta(x, t+\Delta t) - \theta(x, t)\} dx / b\Delta t \\ &= -\frac{a^2}{v^2\Delta t} \left\{ \left(1 - \exp\left[-\frac{v^2}{a^2}t\right]\right) + \exp\left[-\frac{v^2}{a^2}t\right] E\left(\frac{2vt}{\sqrt{2}ta}\right) - 3E\left(\frac{vt}{\sqrt{2}ta}\right) \right. \\ &\quad + \left(1 - \exp\left[-\frac{v^2}{a^2}(t+\Delta t)\right]\right) \exp\left[\frac{v^2}{a^2}(t+\Delta t)\right] + 2E\left(\frac{vt}{\sqrt{2}(t+\Delta t)a}\right) \\ &\quad \left. - \exp\left[\frac{v^2}{a^2}(t+\Delta t)\right] \left[E\left(\frac{2v(t+\Delta t)}{\sqrt{2}(t+\Delta t)a}\right) - \exp\left[-\frac{v^2}{a^2}t\right] E\left(\frac{vt+2v\Delta t}{\sqrt{2}(t+\Delta t)a}\right) \right] \right\}. \end{aligned} \quad (17)$$

For $t \rightarrow \text{large}$

$$\frac{S'}{b\Delta t} \rightarrow -\frac{3a^3}{v^3\Delta t} \cdot \frac{1}{\sqrt{\pi}t} \left\{ \frac{1}{2} \exp\left[-\frac{v^2}{a^2}t\right] - \exp\left[-\frac{v^2}{4a^2}t\right] \right\}. \quad (18)$$

this value is very small, and also the temperature gradient is very small in the backward direction. Therefore the parameter γ may be taken as a quantity to measure approximately the proportion of the transformation heat removed by the surrounding regions. If $\gamma=0$, the transformation is adiabatic, and if $\gamma=1$, it is isothermal.

To calculate the area S , substitute (12)' into (15) and integrate it. Then we have

$$\begin{aligned} S &= \frac{a^2b}{v^2} \left[3E\left(\frac{v(t+\Delta t)}{\sqrt{2}(t+\Delta t)a}\right) - 2E\left(\frac{v(t+\Delta t)}{\sqrt{2}ta}\right) + \exp\left(\frac{2v^2}{a^2}\right) \left\{ \exp\left(\frac{2v^2}{a^2}\Delta t\right) \left[1 - E\left(\frac{3v(t+\Delta t)}{\sqrt{2}(t+\Delta t)a}\right) \right] \right. \right. \\ &\quad \left. \left. - \exp\left(\frac{v^2}{a^2}\Delta t\right) \left[1 - E\left(\frac{v(3t+\Delta t)}{\sqrt{2}(t+\Delta t)a}\right) \right] - \exp\left(-\frac{v^2}{a^2}\Delta t\right) E\left(\frac{v(t-\Delta t)}{\sqrt{2}(t+\Delta t)a}\right) \right] \right] \end{aligned} \quad (19)$$

Substituting this in (16) and expanding the formula in the power series of Δt , we have

$$\begin{aligned} \gamma &= \gamma^{(0)} + \gamma^{(1)}\Delta t + \gamma^{(2)}(\Delta t)^2 + \dots; \\ \gamma^{(0)} &= E\left(\frac{v}{\sqrt{2}a}\sqrt{t}\right) + \exp\left(\frac{2v^2}{a^2}t\right) \left[1 - E\left(\frac{3v\sqrt{t}}{\sqrt{2}a}\right) \right], \\ \gamma^{(1)} &= \frac{3v^2}{2a^2} \left[1 - E\left(\frac{3v\sqrt{t}}{\sqrt{2}a}\right) \right] - \frac{v^2}{2a^2} E\left(\frac{v\sqrt{t}}{\sqrt{2}a}\right) + \frac{1}{\sqrt{2}\pi} \exp\left(-\frac{v^2t}{4a^2}\right) \left(\frac{a}{8\sqrt{2}t^3v} - \frac{7v}{2\sqrt{2}ta} \right). \end{aligned} \quad (20)$$

The relation between $\gamma^{(0)}$ and t is plotted in Fig. 7. This curve shows that, if the propagation of the transformation is steady ($\Delta t=0$), the process may be considered nearly isothermal. The deviation of γ from 1.0 is about 10% in the extreme case where the thickness of martensite is thinner than 100 Å.

The ratio γ defined by (16) comes to have a special significance if the small region $v\Delta t$ which is here called the "transformation unit" may be regarded as a physical unit of the

intermittent transformation. The attempt to consider such a transformation unit is suggested from the fact that the martensite has fine lamellar structures, which has been made clear through the electron-microscopic observation.⁷⁾ On this point we will advance some discussions later.

Putting $t \rightarrow \infty$ in (19), we have

$$\gamma_{t \rightarrow \infty} = \left[1 - \exp\left(-\frac{v^2\Delta t}{a^2}\right) \right] / \frac{v^2}{a^2}\Delta t. \quad (21)$$

The relations $\gamma_{t \rightarrow \infty}$ and the transformation

unit $v\Delta t$ for $a^2/v \simeq 9.0$, 0.9 and $0.09 \text{ \AA}$ are shown in Fig. 8. From these curves it is noted that the transformation goes more adiabatically as the transformation unit becomes large. In the state where the martensite has not yet grown large, $t \ll \infty$, the transformation process must be more adiabatic, because those curves lie below the corresponding ones in Fig. 8.

Fig. 7. $\gamma^{(0)}-t$ curve.

Fig. 8. Relation between the degree of heat removal ($\gamma_{t \rightarrow \infty}$) and transformation unit ($v\Delta t$).

For Fe-30 % Ni alloy the value of κ is $0.028 \text{ cal/cm. sec. deg}^8$ which is about $1/5$ of that of pure iron. And so is the value of a^2 . Therefore the behaviour of $\gamma_{t \rightarrow \infty}$ in this case must be similar to that in the case where $a^2 = 0.01$. Fig. 8 makes it clear that if the value of a^2/v is of the order of $0.9 \text{ \AA}$, the transformation process is isothermal for $v\Delta t \simeq 10 \text{ \AA}$ or less, and less isothermal for $100 \text{ \AA}$ or more, and that if the value of a^2/v is of the order of $0.09 \text{ \AA}$, it is isothermal only for a few $\text{\AA}$ or less, but it is nearly adiabatic for $40 \text{ \AA}$ or more.

It must be noticed here that the more rapid the transition in the transformation unit is, the more adiabatic it is.

§ 6. Discussion

In the above treatment we considered the change of γ in terms of the transformation

unit $v\Delta t$. If the transformation goes on intermittently, the unit $v\Delta t$ described above becomes to play an important role in the thermodynamics of the martensite transformation. Strictly speaking it is an open question from the characteristics of the equation of the heat conduction (3) whether such a quantity defined here may have any significance, and it is desirable to solve the equation including the correct term of the heat source. To carry out this evaluation we must know in detail the facts concerning the existence of the discontinuous phenomena. For this transformation, however, we have had no data experimentally ascertained. There will be no objection, however, to the introduction of such a transformation unit $v\Delta t$, so long as it is small, because the solution in the case of steady propagation may be the good approximation to the case where transformation propagates intermittently. Though in the latter case v may vary with time, a good agreement may be expected, provided that the transforming region during Δt is written in the form of $v\Delta t$. The larger $v\Delta t$, the worse this approximation. And it may be a great deal to assume that the treatment in this paper is valid qualitatively at least.

From the results described above an approval may be given to the idea that the martensite nucleates isothermally. But the matter is not so simple for the process of the growth, which is an important question about the martensite formation that we must answer. If the transformation proceeds continuously, e.g., it occurs by every atomic layer, or the thickness of the unit is smaller than a certain magnitude which depends on the value of a^2/v , the isothermal treatment is allowable, provided that an account is taken of the fact that the temperature at the transformation front has already been raised. If the thickness of the transformation unit is large, the process comes to be more adiabatic with the size. In this case the size of the unit would play a very important role, but it is very difficult for the present to give a concrete physical meaning to it, because the present discussion is nothing but a speculative one in view of scanty of experimental data. Recently Nishiyama, Shimizu and Sato⁶⁾ found a lamellar structure of the spacing $200 \text{ \AA}$ in the martensite plate of iron-nickel alloy. If this spacing has some

relation to the transformation unit in question, the existence of the lamellar structure is important for discussing the thermodynamic and the mechanism of the martensite formation. As a consequence of this consideration we feel keenly the need of further study to find supermicroscopical details.

The authors express their sincere thanks to Prof. T. Nagamiya with whom the authors have enjoyed the discussion.

Theory of Thermoelectric Power of Ionic Crystals (I)

By Eijiro HAGA

Department of Physics, Faculty of Science, Niigata University

(Received May 7, 1958)

A theory of the thermoelectric power in AgBr is developed, in which the experimental conditions are properly considered. The gradient of the electrochemical potential of silver ions is calculated, since it is related to the quantity measured by the potentiometer, that is, the difference between the Fermi levels at two free ends of lead wires. An expression for the thermoelectric power is derived, which is applicable to AgBr mixed with CdBr₂ at arbitrary temperatures.

The Peltier and Thomson coefficients in the steady state are independently calculated for this special case, and the result shows that the Kelvin relations are really satisfied in the steady state.

Finally, the theory is compared with the experiments of Patrick and Lawson.

§ 1. Introduction and Conclusions

The thermoelectric power together with the electrical conductivity gives us useful informations for comprehension of the ionic crystals. As for AgBr the electrical conductivity has been measured in detail on pure and Cd doped samples and several important parameters have been estimated by making use of the theory.^{1),2)} The thermoelectromotive force of this substance has been also measured on a sample of AgBr+0.25% CdBr₂ besides the pure one,³⁾ and explained on the basis of the old theory.⁴⁾ According to that theory the

value obtained by subtracting the thermoelectromotive force in the lead wires from the observed one is equal to the difference of the electrostatic potential between two silver electrodes at different temperatures. This, however, is not correct, unless the variation of the band levels of metal with temperatures is negligibly small. In addition, the estimation of the so-called heterogeneous effect is not correct. Considering these points we shall develop a theory which takes into account the experimental conditions in the measurements of the thermoelectromotive force. Here

we restrict the meaning "complex" to a combination of a Cd^{++} ion and an Ag^+ vacancy. In the present case there may be other kinds of complex, for example, a pair of Ag^+ interstitial ion and Ag^+ vacancy, but they will have no effect on the present arguments.

Now, it is known from the measurements of the electrical conductivity of AgBr that the Schottky type disorder can be neglected, except near its melting point.^{2),5)} Hence we shall develop a theory with an assumption that the defects in the pure AgBr are completely the Frenkel type.

Fig. 1. Schematic diagram for measurements of thermoelectromotive forces.

Before developing the theory of the thermoelectromotive force, let us consider an experimental arrangement for its measurement. As shown in Fig. 1, the two silver metals are put in contact with the respective ends of an AgBr sample so as to keep AgBr in the state of thermal equilibrium with Ag at junctions, and the two lead wires of the same substance M are joined with the respective silver electrodes. Keeping two electrode at different temperatures T_1 and T_2 the potential difference $\Theta(T_1, T_2)$ between two free ends of lead wires x_6 and x_1 are measured by the potentiometer method. Denoting the magnitude of electronic charge as e , $e\Theta(T_1, T_2)$ is the difference of the Fermi level between the position x_1 and that at x_6 . Let us denote absolute thermoelectromotive force of the lead wire M as $\Theta^M(T_1, T_2)$. The quantity $e\Theta(T_1, T_2) - e\Theta^M(T_1, T_2)$ represents the difference of the Fermi level rather than that of the electrostatic potential between the silver electrode at T_1 and that at T_2 , and it will be shown in Section 2 that the quantity is related to the difference of the electrochemical potential of a silver ion between two ends of the sample. Then the problem is merely to calculate the gradient of the electrochemical potential of a silver ion in AgBr in the presence of temperature gradient rather than to calculate both the homogeneous and heterogeneous effects.

In Section 3 the thermodynamic relations of Kelvin will be derived, taking the ex-

perimental arrangement shown in Fig. 1 into consideration. Also, the Peltier and Thomson coefficients in the steady state will be derived independently and it will be shown that the Kelvin relations are really satisfied in the steady state. In Section 4 we shall compare our theoretical expressions with the experiment by Patrick and Lawson.

§ 2. Thermoelectric Power

Under the experimental arrangement described in Section 1, the electrochemical potentials of a silver ion and of an electron are continuous at the $\text{Ag}-\text{AgBr}$ and $\text{Ag}-M$ junctions respectively. Taking as positive when the potential at x_6 is higher than that at x_1 , $\Theta(T_1, T_2)$ mentioned in Section I is given by

$$e\Theta(T_1, T_2) = \zeta_e^M(x_1) - \zeta_e^M(x_6), \quad (1)$$

where ζ_e^M is the electrochemical potential of an electron in the lead wire M . We can connect $\Theta(T_1, T_2)$ with the difference of the electrochemical potential between two ends of AgBr sample, x_3 and x_4 , by tracing the electrochemical potential of a silver ion or an electron from x_1 to x_6 :

$$e\Theta(T_1, T_2) = [\text{AgBr}(x_4) - \text{AgBr}(x_3)] + [\mu_{\text{Ag}}^{\text{Ag}}(T_1) - \mu_{\text{Ag}}^{\text{Ag}}(T_2)] + e\Theta^M(T_1, T_2), \quad (2)$$

where $\mu_{\text{Ag}}^{\text{Ag}}$ is the chemical potential of a silver atom in the silver metal. If we denote the thermoelectric power corresponding to Θ as Q Eq. (2) gives

$$eQ = eQ_{\text{AgBr}}^{\text{AgBr}} + s_{\text{Ag}}^{\text{Ag}} + eQ^M. \quad (3)$$

Here, $eQ_{\text{AgBr}}^{\text{AgBr}}$ is the value obtained by subtracting the electrochemical potential of a silver ion at the point at lower temperature from that at higher temperature in the case where two points in AgBr are kept at different temperatures by unity, $s_{\text{Ag}}^{\text{Ag}}$ is the entropy of a silver atom in the silver metal. Hence we need obtain only the gradient of the electrochemical potential of a silver ion in AgBr .

Now the chemical potential of an Ag^+ vacancy, μ_v , is defined as the Gibbs free energy required to take out a silver ion at a normal site into the outside, and the chemical potential of an Ag^+ interstitial ion, μ_i , is defined as the Gibbs free energy required to bring a silver ion from the outside vacuum into an interstitial position in AgBr . We shall

assume, in the present paper, that the concentrations of Ag^+ interstitial ions and vacancies, n_i and n_v , are distributed at random. Then μ_d is given by

$$\mu_v = \mu_v^0 + kT \ln(n_v/N_0), \quad (4)$$

where N_0 is the concentration of the Ag^+ lattice sites. A similar equation is valid for μ_i . The chemical potential of an Ag^+ ion in AgBr , $\mu_{\text{Ag}^+}^{\text{AgBr}}$, is given by

$$\mu_{\text{Ag}^+}^{\text{AgBr}} = -\mu_v = \mu_i. \quad (5)$$

According to the theory of transport phenomena, the electrical current densities in the x -direction owing to the Ag^+ interstitial ions and vacancies, j_i and j_v , are written as^{(4), (6), (7)}

$$j_i = eD_i \left(-\frac{dn_i}{dx} + \frac{en_i E}{kT} - \frac{n_i Q_i^*}{kT^2} \frac{dT}{dx} \right)$$

$$j_v = -eD_v \left(-\frac{dn_v}{dx} - \frac{en_v E}{kT} - \frac{n_v Q_v^*}{kT^2} \frac{dT}{dx} \right), \quad (6)$$

where $D_{i,v}$ and $Q_{i,v}^*$ are the ordinary diffusion coefficient and the heat of transport of the two kind of defects respectively.

From above we can obtain $d\mu_{\text{Ag}^+}^{\text{AgBr}}/dx$ making use of

$$\frac{d\mu_{\text{Ag}^+}^{\text{AgBr}}}{dx} = -eE + \frac{d\mu_{\text{Ag}^+}^{\text{AgBr}}}{dx}. \quad (7)$$

The electric field E is obtained from the condition that the total electrical current densities, $j_i + j_v$, should vanish everywhere, and $d\mu_{\text{Ag}^+}^{\text{AgBr}}/dx$ is obtained making use of Eqs. (4) and (5). In the result we have

$$\frac{d\mu_{\text{Ag}^+}^{\text{AgBr}}}{dx} = -\left[\frac{1}{T} \frac{c_i \varphi (h_F + Q_i^*) - c_v Q_v^*}{c_i \varphi + c_v} + \frac{d\mu_v^0}{dT} + k \ln c_v \right] \frac{dT}{dx}, \quad (8)$$

where c_i and c_v are the mol fractions of Ag^+ interstitial ions and vacancies, h_F is the enthalpy of formation of one pair of Frenkel defect, and φ is the ratio of the mobility of Ag^+ interstitial ions to that of vacancies.

The free energy required to take out a silver ion from a normal lattice site in a perfect crystal of AgBr to the vacuum in the outside of the crystal, μ_v^0 , is estimated by dividing this process into the following two steps. (i) A silver ion occupying a normal lattice site at the surface of the crystal is taken out of the crystal. The Gibbs free energy required for this step is, on the average, $-\mu_P$, where μ_P means the Gibbs free energy of a silver

ion in the interior of a perfect crystal of AgBr . (ii) A silver ion on the lattice site in a perfect crystal of AgBr is brought to a lattice site at the surface of the crystal. The temperature-dependent term of the Gibbs free energy required for this step is $-kT \Sigma \ln(\nu_P/\nu_v)$, where ν_P and ν_v are the frequency of a normal mode of lattice oscillations in a perfect crystal of AgBr and that in a crystal including only an Ag^+ vacancy as defect respectively, and Σ means the summation over all normal modes.⁽⁸⁾ Hence, $d\mu_v^0/dT$ in Eq. (8) becomes, from (i) and (ii),

$$\frac{d\mu_v^0}{dT} = s_P - k \Sigma \ln \frac{\nu_P}{\nu_v} \quad (9)$$

where s_P is the entropy of a silver ion in a perfect crystal of AgBr . Using Eqs. (3), (8) and (9) we find a theoretical expression for the thermoelectric power Q :

$$eQ = -\frac{1}{T} \frac{c_i \varphi (h_F + Q_i^*) - c_v Q_v^*}{c_i \varphi + c_v} - k \ln c_v + \alpha + eQ^M, \quad (10)$$

where

$$\alpha = s_{\text{Ag}^+}^{\text{Ag}} - s_P + k \Sigma \ln \frac{\nu_P}{\nu_v}. \quad (11)$$

As seen above, the theoretical expression (10) is obtained on the conditions that the ionic current should vanish and that the Ag^+ interstitial ions and vacancies are in thermal equilibrium, and so it is valid whether the current of complexes exist or not. Let us consider the process approaching the steady state when a certain temperature gradient is set up in the sample. The concentration distributions of Ag^+ interstitial ions and vacancies will vary with time since the associations of complexes take place at each place in the sample owing to these current. The electric field in the sample depends on dn_i/dx or dn_v/dx as seen from Eqs. (6) and (5), and so varies with time. The gradient of electrochemical potential of silver ions in the sample is, however, independent of dn_i/dx or dn_v/dx and so does not vary with time. Hence, the thermoelectric power does not vary with time.

§ 3. Kelvin Relations

We shall derive the Kelvin relations on the basis of the experimental arrangement shown in Fig. 1, and then the Peltier and Thomson coefficients independently and show that the Kelvin relations are really satisfied.

Let us assume that unit charge is let flow quasi-statically across $x_1x_2x_3x_4x_5x_6$ and back to x_1 through an outside imaginary path in Fig. 1. In such a process, silver ions in the silver electrode enter AgBr at x_3 by unit charge and flow through AgBr and reach x_4 . On the other hand, electrons left at x_3 flow across, x_2x_1 , imaginary pass, x_6x_5 and reach x_4 and recombine with silver ions above mentioned, forming $1/e$ silver atoms at x_4 . Hence, in order to complete the cycle, we must carry $1/e$ silver atoms from the silver electrode at temperature T_2 to that at T_1 , and, in this case, the heat given out to the outside is $1/e \cdot \int_{T_2}^{T_1} c_{\text{Ag}}^{\text{Ag}} dT$, where $c_{\text{Ag}}^{\text{Ag}}$ means the specific heat of a silver atom in the silver metal. We shall denote the Peltier coefficient, that is to say, the heat emitted at the junction when unit current flows from the lead wire M to the silver electrode as $\pi_{M \rightarrow \text{Ag}}$ and the Thomson coefficient in the lead wire M as σ^M . Making use of the first and second laws of thermodynamics we can find the Kelvin relations on the basis of the experimental arrangement shown in Fig. 1:

$$Q = (\pi_{M \rightarrow \text{Ag}} + \pi_{\text{Ag} \rightarrow \text{AgBr}})/T, \quad (12)$$

and

$$\frac{dQ}{dT} = (\sigma^M - \sigma^{\text{AgBr}})/T + c_{\text{Ag}}^{\text{Ag}}/eT. \quad (13)$$

Now we shall calculate the Peltier heat, $J\pi_{\text{Ag} \rightarrow \text{AgBr}}$, when a constant current J flows through a junction of Ag and AgBr in the direction $\text{Ag} \rightarrow \text{AgBr}$. For convenience, let us denote the contacting area in Ag and in AgBr as x_{Ag} and x_{AgBr} respectively. The theoretical expression for this Peltier heat can be obtained by dividing it into following three factors.

(i) J/e electrons per second flow from x_{Ag} to the interior of Ag. The contribution of this factor to the Peltier heat is

$$-J/e \cdot Q_e^{*\text{Ag}}, \quad (14)$$

where $Q_e^{*\text{Ag}}$ means the heat of transport of an electron in Ag.

(ii) Let the transport numbers of Ag^+ interstitial ions and vacancies in AgBr be t_i and t_v respectively. Then $t_i J/e$ Ag^+ interstitial ions per second flow from x_{AgBr} to the interior of AgBr and $t_v J/e$ Ag^+ vacancies per second flow from the interior of AgBr to x_{AgBr} . The

contribution of this second factor is

$$J/e \cdot (-t_i Q_i^* + t_v Q_v^*). \quad (15)$$

(iii) J/e silver ions per second flow from x_{Ag} to x_{AgBr} . Of these silver ions, $t_i J/e$ enter the interstitial sites in AgBr and $t_v J/e$ recombine with Ag^+ vacancies which come from the interior of AgBr to x_{AgBr} . The contribution of this third factor is given by

$$JT/e \cdot \left[t_i \left(\frac{\partial \mu_i}{\partial T} \right)_{c_i, p} - t_v \left(\frac{\partial \mu_v}{\partial T} \right)_{c_v, p} - \left(\frac{\partial \mu_{\text{Ag}}^{\text{Ag}}}{\partial T} \right)_p \right], \quad (16)$$

where p is the pressure.

The Peltier heat is obtained by summing up these factors (14), (15) and (16):

$$\begin{aligned} e\pi_{\text{Ag} \rightarrow \text{AgBr}} = & -\frac{c_i \varphi (h_F + Q_i^*) - c_v Q_v^*}{c_i \varphi + c_v} \\ & + T \left(s_{\text{Ag}}^{\text{Ag}} - \frac{d\mu_v^0}{dT} - k \ln c_v \right) \\ & + T \left(\frac{\partial \mu_e^{\text{Ag}}}{\partial T} \right)_p - Q_e^{*\text{Ag}} \end{aligned} \quad (17)$$

We can see easily that the sum of the last two terms in Eq. (17) is the absolute thermoelectric power of Ag multiplied by eT , which is equal to $e(TQ^M - \pi_{M \rightarrow \text{Ag}})$ from the Kelvin relation for metals. Thus Eq. (17) gives the Kelvin relation (12).

Next, we shall calculate the Thomson heat when an infinitesimal steady current J flows in the x -direction through a crystal of AgBr in the presence of temperature gradient. We shall consider a portion A in AgBr lying between the position x at the temperature T and the position $x+dx$ at the temperature $T+dT$. For convenience, we shall denote two ends in A as x_A and $(x+dx)_A$. Now J/e silver ions per second leave x_A and the same amount of silver ions comes to $(x+dx)_A$. Then the Thomson coefficient σ_{AgBr} will be calculated by using the thermodynamic law that the sum ΔW of the work done and the heat given from the outside of A to A is equal to the increase of internal energy ΔU of A .

First we consider the current of Ag^+ interstitial ions in A . The $t_i(T)J/e$ Ag^+ interstitial ions leave x_A per second. The heat given and the work done from the outside to A owing to this current are $t_i(T)Q_i^*(T)J/e$ and $t_i(T)v_i(T)pJ/e$ per second respectively, where v_i is the increase of volume for forming an Ag^+ interstitial ion. On the other hand the $t_i(T+dT)J/e$ Ag^+ interstitial ions come to the

position $(x+dx)_A$ per second. The heat given and the work done from the outside to A owing to this are $-t_i(T+dT)Q_i^*(T+dT)J/e$ and $-t_i(T+dT)v_i(T+dT)pJ/e$ per second respectively. Next, we shall consider the current of Ag^+ vacancies in A . The $t_v(T+dT)J/e$ Ag^+ vacancies leave $(x+dx)_A$ per second and the $t_v(T)J/e$ Ag^+ vacancies come to x_A per second. The heat given and the work done from the outside of A to A owing to this is obtained similarly. Furthermore, the Thomson heat $\sigma^{\text{AgBr}} J dT$ is given from the outside to A as the current flows in A in the presence of temperature gradient. The transport numbers, t_i and t_v , depend, in general, on the temperature, and so the each current of Ag^+ interstitial ions and vacancies varies with the position though the sum of the two is constant. Hence, the recombination (or generation) between Ag^+ interstitial ions and vacancies takes place at each position. The heat given by this from the outside to A should be included in the Thomson heat. Thus we have

$$\Delta W = J/e \cdot dT \frac{d}{dT} (t_v Q_v^* - t_i Q_i^* + t_v v_v p - t_i v_i p) + \sigma^{\text{AgBr}} J dT. \quad (18)$$

Next, we shall calculate ΔU . If we denote the internal energy of an Ag^+ interstitial ion and an Ag^+ vacancy as u_i and u_v respectively, we have

$$\Delta U = J/e \cdot dT \frac{d}{dT} (t u_i - t u_v), \quad (19)$$

where

$$\left. \begin{aligned} u_i &= -p v_i + \mu_i + e\Phi - T \partial \mu_i / \partial T, \\ u_v &= -p v_v + \mu_v - e\Phi - T \partial \mu_v / \partial T, \end{aligned} \right\} \quad (20)$$

Φ being the electrostatic potential of the vacuum. When (20) and (4) are used Eq. (19) becomes

$$\Delta U = J/e dT \frac{d}{dT} [t_v v_v p - t_i v_i p + T t_v (\partial \mu_v / \partial T)_{c_v} - T t_i (\partial \mu_i / \partial T)_{c_i}] + J/e \cdot dx (d\mu_{\text{AgBr}}^{\text{Ag}} / dx - eE) \quad (21)$$

$d\mu_{\text{AgBr}}^{\text{Ag}} / dx - eE$ in Eq. (21) is the gradient of electrochemical potential of a silver ion when the current J is present. This now is equal to the gradient of electrochemical potential of a silver ion when the current is not present, since J is infinitesimal. Hence we can obtain the Thomson coefficient σ^{AgBr} from the thermo-

dynamic law $\Delta W = \Delta U$:

$$\sigma^{\text{AgBr}} = \frac{T}{e} \frac{d}{dT} \left[\frac{1}{T} \frac{c_i \varphi (h_F + Q_i^*) - c_v Q_v^*}{c_i \varphi + c_v} + k \ln c_v + \frac{d\mu_v^0}{dT} \right]. \quad (22)$$

We can see that the Kelvin relation (13) is really satisfied from Eqs. (10) and (22).

The Kelvin relations apply only to the steady state, where irreversible currents of complexes are not present, as seen from these derivations. We calculated in this Section the Peltier and Thomson coefficients in the steady state, while the expression for the thermoelectric power is valid whether the currents of complexes may exist or not. We now have seen that the thermoelectric power, the Peltier and Thomson coefficients independently derived obey the Kelvin relations in the steady state.

§ 4. Comparisons with Experiments

Thermoelectric power in the experimental arrangement shown in Fig. 1 was measured by Patrick and Lawson for the samples of pure AgBr and $\text{AgBr} + 0.25 \text{ Mol-\% CdBr}_2$. The Chromel wires was used as leads and its absolute thermoelectric power Q^M was taken as $20 \mu\text{V}/^\circ\text{C}$.

We shall compare Eq. (10) with the experimental data of Patrick and Lawson. We obtained the carrier concentration in the pure

Fig. 2. The thermoelectric power of pure and doped AgBr as a function of temperature.

— Theoretical curve with $Q_v^* = -0.52 \text{ ev}$, $Q_i^* + h_F = 1.20 \text{ ev}$ and $\alpha = 320 \mu\text{V}/^\circ\text{C}$.

× Experimental value for pure AgBr .

○ Experimental value for $\text{AgBr} + 0.25\% \text{ CdBr}_2$.

sample by using the interpolation formula of Teltow, and also those in the impure sample by using the interpolation formula and taking the activation energy of complexes as 0.16 eV. Three parameters $Q_i^* + h_F$, Q_v^* and α are assumed to be independent of temperature and their values are taken as 1.20 eV, -0.52 eV and $320 \mu\text{V}/^\circ\text{C}$ respectively so that we may obtain a best fit between Eq. (10) and the experimental data on the pure and impure samples. $Q_i^* + h_F$ is nearly equal to that of h_F and consequently the value of Q_i^* is very small. If we take the value of $s_F - s_{Ag}^{Ag}$ as $130 \mu\text{V}/^\circ\text{C}$ then $k \ln(\nu_F/\nu_v)$ becomes $450 \mu\text{V}/^\circ\text{C}$. The full lines of Fig. 2 show Eq. (10) with these values.

The dependence of the thermoelectric power on the concentration of added Cd over wide temperature range is interesting to the author. Measurements of the thermoelectric power on samples of AgCl doped with CdCl_2 of various concentrations are being carried out at our department of physics, and the theory explains fairly well the behaviors of experimental data. The result will be reported in near future.

The writer wishes to express his cordial thanks to Mr. S. Miyatani and Mr. I. Yokota for their useful discussions and kind advices.

The present work was supported by the Scientific Research Fund of the Ministry of Education.

In preparing the manuscript of this paper the writer has been informed of the work of R. E. Howard and A. B. Lidiard (Discussions Faraday Soc. **23** (1957) 113, Phil. Mag. **2** (1957) 1462). The expression derived by the writer is different from that derived by them by the term $(\partial \mu_e^{Ag}/\partial T)_p$. This is expected to be of the order of $100 \mu\text{V}/^\circ\text{C}$ from thermionic emission experiments.

A Theory of Impurity Conduction I

Tadao KASUYA

Faculty of Science, University of Nagoya

(Received May 19, 1958)

The phenomena of impurity conduction of semiconductors such as G_e and S_i are treated theoretically by deviding into the following three ranges of impurity concentration: (i) The concentration of impurity atom is fairly large and the impurity levels are merged into the conduction bands. Then the impurity atoms play a role of scatterers. (ii) The concentration of impurity atom becomes fairly small and the impurity levels split from the conduction bands. The energy width of this impurity band is, however, determined mainly by the translational energy of electron in this band. (iii) The concentration of impurity atom becomes very small and the width of the impurity band is determined mainly by the fluctuation of the local potential energy. In this paper we treat the first two cases. For this purpose, the general theory of transport phenomena is developed and the condition that the ordinary Boltzman-Bloch equation is applicable is given on this general theory. The result of impurity conduction given by E. M. Conwell is obtained as a limiting case of our formula. However the condition that the Conwell's formula is applicable is not satisfied in actual cases.

§ 1. Introduction

The electron mobility in S_i and G_e is determined by the scattering of electrons by phonons at higher temperatures. At low temperatures, however, the mobility is determined mostly by the presence of impurity atoms. Concerning the mobility at higher temperatures, some peculiarities are observed experimentally. These problems are also interesting from the theoretical point of view, and will be discussed in another paper. In this paper, however, we restrict ourselves only to phenomena at lower temperatures where the mobility is determined by impurity atoms.

It may be possible to classify the concentration of impurity atoms into the following three ranges:

(1) When the concentration of impurity atoms is fairly large and the overlapping between atomic wave functions localizing in each impurity atom is large, impurity levels become very broad and we can not distinguish the impurity band from the conduction band. In this case, only one conduction band exists (the structure of this conduction band may be complicated in general), and impurity atoms play a role of scatterers. Scattering potential of each impurity atom is, however, neither of a short range force nor of a weak force

compared with the translational energy of the electron, because in general the number of conduction electrons is nearly equal to that of impurity atoms and the screening effect of Coulomb field of impurity atoms by conduction electrons is not so large. As well-known, the transport equation of Boltzmann-Bloch is applicable only in the case where the effective range of scattering potential is fairly small compared with the whole space and the energy of thermal fluctuation κT (where κ is the Boltzmann constant and T is the absolute temperature) is larger than the energy uncertainty due to scattering processes $\hbar/\tau$ (where $\hbar$ is Planck's constant and τ is the relaxation time appearing in the definition of conductivity). The above mentioned conditions for the applicability of Boltzmann-Bloch's transport equation are not fulfilled when the temperature becomes lower and mean translational energy of electrons becomes smaller. In this case, we can not use the Boltzmann-Bloch's equation to calculate the conductivity and must consider the transport phenomena from a more general stand point. In § 2, we discuss about this general transport equation first proposed by F. Nakano¹⁾, and in § 3 we calculate the mobility in this range practically.

(2) When the concentration of impurity

atoms becomes smaller, a new band composed mainly by the atomic wave functions localized in each impurity atom splits from the conduction band. We call this band as an impurity band. Main factors to determine the mobility in this impurity band are such that: (i) Correlation energy between electrons induced by Coulomb interaction between them. (ii) Resonance energy induced by overlapping between atomic wave functions localized in different impurity atoms. This energy corresponds to the translational energy of electron in the impurity band. (iii) Fluctuation of potential energy at each impurity atom induced mainly by Coulomb potential of minority impurity atoms with plus or minus charge. Amongst these effects, correlation energy is, in general, largest, and thus we can consider in fairly good approximation that only one electron is possible to occupy the state of atomic wave function localized at a particular impurity atom. In this approximation, the existence of minority impurity atoms is essentially important, because if there is no minority impurity atom the number of free electron equals just that of majority impurity atom and only one configuration that one electron is localized at each impurity atom is possible, and thus electrical conductivity does not occur. Further we can divide this range into two cases such that: (i) resonance energy is much larger than fluctuation of potential energy. (ii) fluctuation of potential energy is much larger than resonance energy. When the concentration of majority impurity atoms is not so small, the condition of first case is fulfilled. In this case, the energy width of the impurity band is determined mainly by the resonance-energy, and electron can walk about over the whole space. In §4 we calculate the mobility in this range.

(3) When the concentration of impurity atoms becomes very small, the fluctuation of potential energy becomes much larger than the resonance energy. In this case, the energy width of impurity band is mainly determined by the fluctuation of potential energy at each majority impurity atom, and the localized state belonging to a particular impurity atom becomes stable, and transport phenomenon does not occur if we consider only the freedom of electron system. In this

range, the interaction of electron with the other freedom, for example phonon system, is essentially important for transport phenomena. Electron is possible to walk about by hopping from one localized state to the other exchanging the difference of local potential energy for phonon system. Mobility in this range is calculable on this hopping model. This calculation is, however, given in the following paper, and in this paper we restrict ourselves only to the first two cases, namely (1) and (2), in which it is sufficient to consider only the freedom of electron system.

§2. General Discussion to Calculate Transport Coefficients

To treat transport phenomena of electrons, Boltzmann-Bloch equation is the most familiar technique. This equation bases on the classical gas transport theory and is obtained by straight extension to quantum particle. The logic of Boltzmann-Bloch equation is as follows: We consider that the Hamiltonian of the system is written by $H = H_0 + H_1$, where H_0 is unperturbed and H_1 is perturbing Hamiltonian. H_0 is chosen as simple form and in general the eigen-state of electron of unperturbed Hamiltonian is given by Bloch function ψ_{lk} where l represents the class of band and k wave vector. H_1 represents the remaining Hamiltonian and includes the scattering matrix of electron represented by Bloch function. When there is no external field or internal strain, the system is in thermal equilibrium subjected by total Hamiltonian H . When the external field is applied in the system, the state of above mentioned thermal equilibrium is no more equilibrium state, and the system begins to move into a new equilibrium state. When there is the internal strain initially, the state is not in thermal equilibrium and the system also moves into the state of thermal equilibrium. If the structure of the system is complicated and includes some kind of randomness, in the process of this motion, the state of the system reaches to the quasi equilibrium state with steady flows. We call this state as steady state. The time to reach to the steady state is of the order of relaxation time τ determined by the definition of conductivity, and the time to reach to the final equilibrium

state is the order of macroscopic scale and becomes infinity when the scale of the system becomes infinity, and thus the steady state is obtained if the scale of the system is fairly large. At an arbitrary time t , when the system is in steady state, we observed the system and diagonalize the state regarding to the unperturbed Hamiltonian H_0 . Thus we obtain the distribution function of unperturbed state at time t . After this observation, we pursue the change of the state dividing into two mechanisms, that is the change by drift effect (free acceleration by external force and restoring effect from internal strain when the perturbation H_1 does not exist) and the change by collision effect (the motion of state by H_1). The steady state is defined by the condition that the change of the diagonal element of the state induced by the above two mechanisms cancels out each other, namely the change of the distribution function by drift and collision effect is zero. This equation is well known Boltzmann's transport equation, and from this equation we can obtain the distribution function in steady state.

As seen from the above consideration, this process to obtain Boltzmann-Bloch equation is very complicated and the justification of this equation from the fundamental standpoint is very difficult problem although remarkable proceeding has been done recently by works of van Hove and so on²⁾. Even apart from the fundamental problem, application of this equation is limited in the case mentioned already in §1, that is the effective range of scattering potential is small and the condition

$$\kappa T > \hbar/\tau \quad (1)$$

is satisfied. In general, these conditions are not satisfied in phenomena of impurity conduction, especially in the range (2) in §1. Thus we must consider the transport phenomena on a more general standpoint.

In quantum mechanics, when the state ψ_0 of the system with Hamiltonian $\mathcal{H}$ is given at a time $t=0$, expectation value of arbitrary physical quantity A is given by $\langle \psi_0 A \psi_0 \rangle$ at time $t=0$. Wave function ψ moves by well known Schrödinger equation, and in arbitrary time $t > 0$, the initial state becomes $\exp[-i\mathcal{H}t/\hbar]\psi_0^*$ and the expectation value of A becomes as

$$\langle A(t) \rangle = \langle \psi_0 \exp[i\mathcal{H}t/\hbar] A \exp[-i\mathcal{H}t/\hbar] \psi_0 \rangle. \quad (2)$$

When the Hamiltonian of the system is given by $\mathcal{H}_0$ in time $t < 0$, and the system is in thermal equilibrium by this Hamiltonian $\mathcal{H}_0$, we should take a statistical average, and the expectation value of A at time $t > 0$ is given by

$$\langle A(t) \rangle = \text{Tr} \exp[-\beta \mathcal{H}_0] \times \exp[i\mathcal{H}t/\hbar] A \exp[-i\mathcal{H}t/\hbar], \quad (3)$$

where β represents $(\kappa T)^{-1}$. This formula is one of the most fundamental one in quantum mechanics, and also the starting formula to obtain the transport coefficient.

For example we consider the case that the Hamiltonian of the system is given by H , and in time $t < 0$, the system is in thermal equilibrium, and in time $t=0$ constant electric field F is applied suddenly. In this case, we can substitute in Eq. (3) $\mathcal{H}_0$ by $H - eF \sum_i r_i$.

When we want to know the current J in time $t > 0$, we may substitute A by $J = e \sum_i v_i$, and to know the energy flow W , substitute A by W , (general formula of W is not simple but depends on the formula of interaction Hamiltonian. If the interaction Hamiltonian is negligibly small, we obtain the usual formula of energy flow density.)

If we restrict ourselves to the linear theory concerning to the external field, we can expand the Eq. (3) into a power series of F and take the first second terms of this series. From the usual expansion formula (see Appendix I) we obtain as

$$\langle A(t) \rangle = \text{Tr} e^{-\beta H} \left\{ A - \frac{i}{\hbar} eF \int_0^t dt_1 \left[e^{-iHt_1/\hbar} \sum_i r_i e^{iHt_1/\hbar}, A \right] \right\}, \quad (4)$$

or we can rewrite into the following formula (see Appendix II)

$$\langle A(t) \rangle = \text{Tr} e^{-\beta H} \left\{ A - \frac{i}{\hbar} eF \left[\sum_i r_i, A \right] + \frac{i}{\hbar} F \int_0^t dt_1 (t-t_1) [e^{-iHt_1/\hbar} J e^{iHt_1/\hbar}, A] \right\} \quad (5)$$

* Hereafter $\hbar$ means the Planck's constant divided by 2π .

$$= \text{Tr}_r e^{-\beta H} \left\{ A + F \int_0^t dt_1 \int_0^\beta d\lambda e^{-iH(t_1+i\hbar\lambda)/\hbar} J e^{iH(t_1+i\hbar\lambda)/\hbar} A \right\}. \quad (6)$$

The same treatment is possible when the motion of the state is derived by internal strain. When the potential of internal strain is written as αV and in time $t < 0$ the system is in thermal equilibrium under the Hamiltonian $H + \alpha V$ including the potential of strain, we can replace in Eq. (3) $\mathcal{H}_0$ by $H + \alpha V$. In time $t > 0$, we consider that the potential of internal strain is removed. Then the motion of the system is subjected by the Hamiltonian H , and the system begins the motion to remove the internal strain. Thus we can replace $\mathcal{H}$ in Eq. (3) by H . Using the linear theory with respect to αV , the following formula resembling to Eq. (6) is obtained easily (see Appendix I, II)

$$\langle A(t) \rangle = \text{Tr} \left[e^{-\beta(H+\alpha V)} A + e^{-\beta H} \alpha \int_0^\beta d\lambda \int_0^t dt_1 e^{-iH(t_1+i\hbar\lambda)/\hbar} \dot{V} e^{iH(t_1+i\hbar\lambda)/\hbar} A \right], \quad (7)$$

where

$$\dot{V} = \frac{i}{\hbar} [H, V]. \quad (8)$$

In the case that internal strain means the constant gradient of electron density, we may take α as $-\kappa T \nabla(\xi/\kappa T)$ and $\dot{V}$ as $J/e = \sum_i v_i$, and when constant gradient of temperature exists, we may take α as $\kappa T \nabla(\kappa T)^{-1}$ and V' as energy flow operator W .

Even in the case that external field or internal strain is not uniform but changes in time and in space, and thus the resultant flows also change in time and in space, the same treatment is possible. For example, when the motion is derived by the external field, we can substitute in Eq. (3) $\mathcal{H}_0$ by H , and $\mathcal{H}$ by $H + eV$, where V is given by

$$V = \int \varphi(\mathbf{r}, t) n(\mathbf{r}) d\mathbf{r}, \quad (9)$$

where $\varphi(\mathbf{r}, t)$ is the potential of external field varying in time and in space, and $n(\mathbf{r})$ is the operator of density of electron. The continuous equation exists between $n(\mathbf{r})$ and the operator of current density $J(\mathbf{r})/e$ as follows

$$dn(\mathbf{r})/dt + \text{div } J(\mathbf{r})/e = 0 \quad (10)$$

where

$$n(\mathbf{r}) = \sum_i \delta(\mathbf{r} - \mathbf{r}_i) \\ J(\mathbf{r})/e = \frac{1}{2} \sum_i \{ v_i \delta(\mathbf{r} - \mathbf{r}_i) + \delta(\mathbf{r} - \mathbf{r}_i) v_i \} \quad (11)$$

The resembling equation as Eq. (6) is given by the same method as that used to induce the Eq. (6), considering the condition that the normal component of the flow $J(\mathbf{r})$ is zero at the surface of the boundary,

$$\langle A(\mathbf{r}, t) \rangle = \text{Tr}_r e^{-\beta H} \left\{ A(\mathbf{r}) + \int_0^t dt_1 \int_0^\beta d\lambda \int d\mathbf{r}' F(\mathbf{r}', t_1) e^{iH(t_1+i\hbar\lambda)/\hbar} J(\mathbf{r}') e^{-iH(t_1+i\hbar\lambda)/\hbar} A(\mathbf{r}) \right\}, \quad (12)$$

or we can write by using Fourier transformation

$$\langle A_{\mathbf{k}}(t) \rangle = \text{Tr}_r e^{-\beta H} \left\{ A_{\mathbf{k}} + \sum_{\mathbf{k}'} \int_0^t dt_1 \int_0^\beta d\lambda F_{\mathbf{k}'}(t_1) e^{iH(t_1+i\hbar\lambda)/\hbar} J_{-\mathbf{k}'} e^{-iH(t_1+i\hbar\lambda)/\hbar} A_{\mathbf{k}} \right\}, \quad (13)$$

where

$$J_{\mathbf{k}} = \int d\mathbf{r} e^{i\mathbf{k}\mathbf{r}} J(\mathbf{r}) = \frac{e}{2} \sum_i (v_i e^{i\mathbf{k}\mathbf{r}_i} + e^{i\mathbf{k}\mathbf{r}_i} v_i), \quad A_{\mathbf{k}} = \int d\mathbf{r} e^{i\mathbf{k}\mathbf{r}} A(\mathbf{r}),$$

and $A(\mathbf{r})$ is the operator of a given flow density to be required.

Also in the case that internal strain is exist, the same treatment is possible. When we write the potential of internal strain as V

$$V = \int \alpha(\mathbf{r}, t) w(\mathbf{r}) d\mathbf{r} \quad (14)$$

we obtain the following relation

$$\langle A(\mathbf{r}, t) \rangle = \text{Tr} \left[e^{-\beta(H+V)} A(\mathbf{r}) + e^{-\beta H} \int_0^t dt_1 \int_0^\beta d\lambda \int d\mathbf{r}' \right. \\ \left. \nabla' \alpha(\mathbf{r}', t_1) e^{-iH(t_1+i\hbar\lambda)/\hbar} \mathbf{W}(\mathbf{r}') e^{iH(t_1+i\hbar\lambda)/\hbar} A(\mathbf{r}) \right], \quad (15)$$

where $\mathbf{W}(\mathbf{r})$ is the operator of the flow density given by the following continuous equation

$$d\mathbf{w}(\mathbf{r})/dt + \text{div } \mathbf{W}(\mathbf{r}) = 0 \quad (16)$$

For example, when the internal strain means the density fluctuation of electron, we may substitute α by $\beta^{-1} \nabla'(\beta(\mathbf{r}) \zeta(\mathbf{r}))$, $w(\mathbf{r})$ by the operator of electron density $n(\mathbf{r})$ and $\mathbf{W}(\mathbf{r})$ by the operator of electron current density $\mathbf{J}(\mathbf{r})$, and when temperature gradient exists, α by $\beta^{-1} \nabla' \beta(\mathbf{r})$, $w(\mathbf{r})$ by the operator of energy density, and $\mathbf{W}(\mathbf{r})$ by the operator of energy flow density.

These like formulas of transport coefficients are first considered by F. Nakano¹⁾ in the case of electric conductivity and later obtained by R. Kubo, etc., in general case. Our stand point to obtain these formulas differs somewhat from that of R. Kubo etc. which bases on Onsager's fluctuation-dissipation theory and is its direct expansion to quantum mechanics. On this stand point, in both the cases that the motion of the state is derived by external field, or by internal strain, R. Kubo etc. obtained the same formulas of transport coefficients. On the other hand, we obtained the different formulas respectively in two cases as seen from Eqs. (6) and (7) or Eqs. (12) and (15) which differs each other in the first term. This difference is essential in the case to discuss the antisymmetric part of conductivity tensor. For example we consider the simple case that the system consists of only free electrons and the constant magnetic field is applied in Z -axis. When the constant electric field is applied in

X -axis, the constant electric current is induced in the direction both perpendicular to magnetic and electric field, namely Y -axis as well known. On the other hand, when the density gradient is given in X -axis and there is no electric field, electric current does not occur because in this case we can construct the eigen state with arbitrary density fluctuation in X -direction. The above situations are included in our formulation, as easily seen, and not in Kubo's formulation. This difference is owing to the fact that the electric current induced in the above case is polarization current and is reversible phenomena which is not described perfectly well in Onsager's theory. The more detailed discussion may be given in another paper⁴⁾.

To apply the above results on phenomena of impurity conduction classified by (1) and (2) in §1, we can use the one electron approximation, and the formula to obtain the electric current becomes simpler. The Hamiltonian of the system is given by

$$H = \sum_i H_i, \quad (17)$$

$$H_i = \frac{\mathbf{p}_i^2}{2m} + V_0(\mathbf{r}_i) + V_1(\mathbf{r}_i), \quad (18)$$

where V_0 is a periodic potential by atoms constructing regular lattice points, and V_1 is non periodic potential by impurity atoms locating at random. Using the second quantization method basing the eigen function ψ_s of the total Hamiltonian of one electron H_i , we can write

$$H = \sum_s E_s a_s^* a_s \quad (19)$$

$$e^{-iHt/\hbar} \sum_i v_i e^{iHt/\hbar} = \sum_s \sum_{s'} \langle s | v | s' \rangle \exp [i(E_{s'} - E_s)t/\hbar] a_s^* a_{s'}, \quad (20)$$

where a_s^* and a_s represent respectively the creation and annihilation operator of the state ψ_s . Substituting these formulas to Eq. (5), and taking A as current operator $\mathbf{J}$,

$$\mathbf{J} = e \sum_i \mathbf{v}_i = e \sum_s \sum_{s'} \langle s | \mathbf{v} | s' \rangle a_s^* a_{s'}, \quad (21)$$

and further performing the time integration and trace, we obtain the expectation value of current in time t as

$$\langle \mathbf{J}(t) \rangle = F e^2 \left\{ \frac{n}{m} t + \sum_{s' \neq s} \sum_s \langle s | \mathbf{v} | s' \rangle \langle s' | \mathbf{v} | s \rangle \frac{f_s - f_{s'}}{E_s - E_{s'}} \left(t - h \frac{\sin(E_s - E_{s'})t/h}{E_s - E_{s'}} + i h \frac{1 - \cos(E_s - E_{s'})t/h}{E_s - E_{s'}} \right) \right\}, \quad (22)$$

where n is the number density of electron, $\mathbf{A} \wedge \mathbf{B}$ means the tensor of second rank, namely $(\mathbf{A} \wedge \mathbf{B})_{ij} = A_i B_j$, and f_s is the Fermi distribution function

$$f_s = \left[\exp \left(\frac{E_s - \zeta}{kT} \right) + 1 \right]^{-1}. \quad (23)$$

In this paper we treat only the case that there is no magnetic field and further we assume that the system is isotropic. Then the induced electric current is parallel to the electric field, and Eq. (22) becomes

$$\begin{aligned} \langle \mathbf{J}(t) \rangle = F e^2 \left\{ \frac{n}{m} t - \sum_{s' \neq s} \sum_s 2 f_s \frac{|\langle s | v_x | s' \rangle|^2}{E_{s'} - E_s} t \right. \\ \left. - h \sum_{s' \neq s} (f_{s'} - f_s) \frac{|\langle s | v_x | s' \rangle|^2}{(E_s - E_{s'})^2} \sin \frac{E_{s'} - E_s}{h} t \right\}. \end{aligned} \quad (24)$$

When there is no impurity potential, eigen state ψ_s is represented by Bloch function $\psi_{l\mathbf{k}}$. Then wave vector $\mathbf{k}$ commutes with velocity operator $\mathbf{V}$, and matrix element of $\mathbf{V}$ is not zero only in the elements of interband transition except diagonal element. Therefore the third term of Eq. (24) oscillates rapidly with time and becomes zero in time average. From the relation of f -sum rule, namely

$$\sum_{l' \neq l} 2 \frac{|\langle l\mathbf{k} | v_x | l'\mathbf{k} \rangle|^2}{E_{l'\mathbf{k}} - E_{l\mathbf{k}}} = \frac{1}{m} - (\mathbf{M}_{l\mathbf{k}}^{-1})_{xx} \quad (25)$$

$$(\mathbf{M}_{l\mathbf{k}}^{-1})_{ij} = \frac{1}{\hbar^2} (\partial^2 E_{l\mathbf{k}} / \partial k_i \partial k_j), \quad (26)$$

the remaining terms of Eq. (24) becomes as

$$\langle \mathbf{J}(t) \rangle = F e^2 t \sum_{l, \mathbf{k}} f_{l\mathbf{k}} (\mathbf{M}_{l\mathbf{k}}^{-1})_{xx}, \quad (27)$$

where $\mathbf{M}_{l\mathbf{k}}$ is effective mass tensor in l -band and this equation represents a well known acceleration equation of electron in a periodic potential.

When impurity potential exists, Bloch function is no more a eigen function of total Hamiltonian and the true eigen function ψ_s is represented by complicated linear combination of Bloch function. Then we may rewrite the second term of Eq. (24) using the relation

$$\langle s | v_x | s' \rangle = \frac{i}{\hbar} \langle s | [H, X] | s' \rangle = \frac{i}{\hbar} (E_s - E_{s'}) \langle s | X | s' \rangle, \quad (28)$$

as follows,

$$\sum_{s' \neq s} 2 \frac{|\langle s | v_x | s' \rangle|^2}{E_{s'} - E_s} = \frac{i}{\hbar} \sum_{s' \neq s} \{ \langle s | v_x | s' \rangle \langle s' | X | s \rangle - \langle s | X | s' \rangle \langle s' | v_x | s \rangle \}. \quad (29)$$

In the above summation over s' , we must omit the case $s' = s$. However, if there is no singularity in the point $s' = s$, we may add the point $s' = s$ in the above summation. This is not allowed always as seen in the above case that there is no impurity potential. Even in

the system with impurity atoms, for example, Bose gas in degenerate state and perhaps the state in superconductivity, the ground state is a singular point and the above treatment may not be applicable. However, if we confine the system in a closed box, the above treatment is always possible because in this case the diagonal element of X has always finite value and the contribution from the point $s'=s$ is exactly zero. In this case, the boundary condition of wave functions becomes complicated and the singularity is removed into the third term. Therefore, we may say that the above treatment may be applicable for the system in which the state is not affected essentially by the existence of boundary condition. In this paper, we consider the case that the above treatment is applicable, and then Eq. (29) becomes as

$$\frac{i}{\hbar} \langle s | [v_x, X] | s \rangle = \frac{1}{m}, \quad (30)$$

and using the fact that $\sum_s f_s = n$, the first and the second term of Eq. (24) cancels out exactly each other.

In the third term of Eq. (24), we can expand $f_{s'} - f_s$ as

$$f_{s'} - f_s = f_1(\epsilon) \frac{E_s - E_{s'}}{\kappa T} \quad (31)$$

$$f_1(\epsilon) = [(e^2 + 1)(1 + e^{-\epsilon})]^{-1}, \quad \epsilon = \frac{E_s - E_{s'}}{\kappa T}, \quad (32)$$

when time t is sufficiently large, because in summation over $E_{s'}$ only the range that $E_{s'}$ equals nearly to E_s is important by the well known relation

$$\lim_{t \rightarrow \infty} \frac{\sin(E_{s'} - E_s)t/\hbar}{E_{s'} - E_s} = \pi \delta(E_s - E_{s'}). \quad (33)$$

Thus Eq. (17) becomes

$$\langle J(t) \rangle = Fe^2 \frac{\pi \hbar}{\kappa T} \sum_{s \neq s'} f_1(\epsilon) |\langle s | v_x | s' \rangle|^2 \delta(E_s - E_{s'}), \quad (34)$$

or replacing the summation by integration and performing the integration over s' , we obtain

$$\frac{\langle J(t) \rangle}{F} \equiv \sigma = \frac{\pi e^2 \hbar}{nT} \int_0^\infty dE S^2(E) f_1(\epsilon) \eta(E, E), \quad (35)$$

where $S(E)$ is the state density, that is, $S(E)dE$ represents number of states included in the energy range $E \sim E + dE$, and $\eta(E, E')$ is the mean value of $|\langle s | v_x | s' \rangle|^2$ over the constant energy surface E about s and E' about s' respectively, namely

$$\eta(E, E') = \sum_s \sum_{s'} |\langle s | v_x | s' \rangle|^2 \delta(E_s - E) \delta(E_{s'} - E') / S(E) S(E'). \quad (36)$$

In the above treatment, we assumed that time t is sufficiently large. The more detail condition is as follows: if we define Δ_0 as that, when the energy E' changes near by Δ_0 , one of $f_1(\epsilon')$, $\eta(E, E')$ and $S(E')$ changes apparently, time t should satisfy the condition

$$t \gg 2\pi \hbar / \Delta_0 \quad (37)$$

When time t is not so large and the above condition is not satisfied, we may expand $\sin(E_{s'} - E_s)t/\hbar$ in Eq. (24) as $(E_{s'} - E_s)t/\hbar$.

Then we obtain once more the acceleration equation (28). Thus we may say that when time t is much smaller than $2\pi \hbar / \Delta_0$, the system suffer acceleration and current $J(t)$ increases with time, and when t becomes much larger than $2\pi \hbar / \Delta_0$, the system reaches to quasi-equilibrium state and $J(t)$ becomes to steady current. We determine the conductivity σ in this steady state as in Eq. (35), and the time defined by $2\pi \hbar / \Delta_0$ means the relaxation time to reach to the steady state.

Eq. (35) is our fundamental equation to calculate the conductivity of impurity conduction. When the state density $S(E)$ is given, our main problem to obtain σ is how to calculate the value $\eta(E, E)$.

§ 3. Conductivity in the Range of Impurity Scattering

In this section we treat the conductivity of case (1) in § 1, that is, the concentration of impurity atoms is fairly large and there is only one conduction band and impurity atom plays a role of scatterer.

At first, we consider the system of a following simplified model: (i) The system is isotropic. (ii) The structure of conduction band is represented only by one band. (iii) The Hamiltonian of the system does not include the spin freedom, and thus we do not need to consider the freedom of spin to calculate the conductivity when we multiply factor two to the final result. (iv) The magnitude of interaction Hamiltonian is much smaller than both the energy width of conduction band and the energy gaps between conduction band and the other bands, and thus the effect of interband transition is negligible. Thus it is sufficient to consider only one conduction band. (v) Impurity potential V_1 can be considered as the sum of the potential of each impurity atom, that is

$$V_1 = \sum_n V_n \quad (38)$$

and V_n can be considered as δ -function type, that is, $|\langle \mathbf{k} | V_n | \mathbf{k}' \rangle|$ is constant and the scattering is isotropic.

As mentioned in § 2, our main problem is how to calculate $\eta(E, E)$ in Eq. (35). For this purpose, we expand ϕ_s by Bloch function ϕ_k as

$$\phi_s = \sum_k C_k^s \phi_k \quad (39)$$

The phase factor of the expansion parameter C_k^s may be regarded as at random in a fairly good approximation corresponding to the randomness of positions of impurity atoms and the δ -function type character of impurity potential. Absolute value of C_k^s is, however, calculable by some assumption. For example, we may write $|C_k^s|^2$ as

$$|C_k^s|^2 = \frac{\xi(E_s, E_k)}{(E_s - E_k)^2 + \Delta_s^2}, \quad (40)$$

where $\xi(E_s, E_k)$ may depend on E_k fairly

weak, and, corresponding to perturbation theory, becomes $|\langle \mathbf{k}_s | V_1 | \mathbf{k} \rangle|^2 = \text{constant} = |V_1|^2$ when E_k differs from E_s fairly larger than Δ_s . In the range that E_k does not differ so largely from E_s , mixing of states occurs in nearly equal weight, and Δ_s means the measure of the energy range where the mixing occurs. From the normalization of the wave function ϕ_s , the relation

$$\sum_k |C_k^s|^2 = \int_0^\infty S_0(E) dE \frac{\xi(E_s, E)}{(E_s - E)^2 + \Delta_s^2} = 1. \quad (41)$$

should be satisfied, where $S_0(E)$ means the state density of unperturbed system. When we assume simply as that, iv) $\xi(E_s, E)$ is given by $|V_1|^2$, we can determine Δ_s by the above relation, and thus $|C_k^s|^2$ is also determined.

When the absolute value of expansion coefficient $|C_k^s|$ is obtained, $|\langle s | v_x | s' \rangle|^2$ is given by

$$|\langle s | v_x | s' \rangle|^2 = \left| \sum_k \langle \mathbf{k} | v_x | \mathbf{k} \rangle C_k^s C_k^{s'} \right|^2. \quad (42)$$

Due to the fact that the phase factor of C_k^s is at random, cross terms such as $C_k^s C_{k'}^{s'}$, etc. cancel out each other in the average process respecting to s or s' , and only autocorrelation terms remain. Thus $\eta(E, E)$ is obtained as follows,

$$\begin{aligned} \eta(E, E) &= \sum_k (|C_k^s|^2) |\langle \mathbf{k} | v_x | \mathbf{k} \rangle|^2 \\ &= \frac{1}{3} \int \left(\frac{1}{h} \frac{\partial E_k}{\partial k} \right)_B \left(\frac{\xi(E, E')}{(E - E')^2 + \Delta_B^2} \right)^2 \\ &\quad \cdot S_0(E') dE'. \end{aligned} \quad (43)$$

From the above process, we can calculate the conductivity σ irrespective of the strength of impurity potential $|V_1|^2$. In following, we calculate σ more qualitatively in some extreme cases.

(1) Δ_B is sufficiently smaller than E_s and $S(E)$, $S_0(E)$ and $v(E)$ do not change markedly when E changes about the order of Δ_B .

In this case, we can obtain Δ_B from Eq. (41), by using the following approximation

$$\int_0^\infty S_0(E') dE' \frac{|V_1|^2}{(E - E')^2 + \Delta_B^2} = S_0(E) |V_1|^2 \frac{\pi}{\Delta_B} \quad (44)$$

such as

$$\Delta_B = \pi |V_1|^2 S_0(E), \quad (45)$$

$\eta(E, E)$ is also obtained by the same approximation,

$$\eta(E, E) = \frac{\pi}{6} v^2 S_0(E) |V_1|^2 \Delta_B^3, \quad (46)$$

or using Eq. (45)

$$= \frac{1}{6\pi^2} \frac{v^2}{S_0^2(E) |V_1|^2}. \quad (47)$$

Thus, the conductivity σ is written by

$$\sigma = \frac{e^2}{3\pi} \frac{h}{\kappa T} \int_0^\infty dE f_1(E) \frac{S^2(E)}{S_0^2(E)} \frac{v^2}{|V_1|^2}. \quad (48)$$

This result is just same as that obtained by using Boltzmann-Bloch equation, when we take $S(E) = S_0(E)$. For example, when the energy spectrum of unperturbed system is given by effective mass formular, that is $E_k = \hbar^2 k^2 / 2m$, we can get the following results in some extreme cases.

(a) $\zeta \gg \kappa T$ in Fermi degeneracy

Conductivity σ becomes

$$\sigma = \frac{e^2}{3\pi} \frac{h v \zeta^2}{|V_1|^2} \frac{S^2(\zeta)}{S_0^2(\zeta)} = \frac{2e^2}{3\pi} \frac{h \zeta_0}{m |V_1|^2} \equiv \sigma_0, \quad (49)$$

where ζ_0 is Fermi energy when the system is in perfect Fermi degeneracy, namely

$$\zeta_0 = \frac{\hbar^2}{2m} (3\pi^2 n)^{2/3}. \quad (50)$$

(b) $\zeta \ll \kappa T$

In this case, distribution function $f(E)$ is written by Maxwell's distribution function,

$$f(E) = 2^{1/2} \pi^{3/2} n \frac{\hbar^3}{(m \kappa T)^{3/2}} e^{-E/\kappa T}, \quad (51)$$

$$E = \frac{1}{2} m v^2, \quad S(E) = S_0(E) = \frac{3}{4} n \frac{E^{1/2}}{\zeta_0^{3/2}} \quad (52)$$

and thus

$$\begin{aligned} \sigma &= \frac{2^{3/2} \pi^{1/2}}{3} n e^2 \frac{\hbar^4}{m^{5/2} |V_1|^2 (\kappa T)^{1/2}} \\ &= \frac{4}{3\pi^{1/2}} \sigma_0 \left(\frac{\zeta_0}{\kappa T} \right)^{1/2}. \end{aligned} \quad (53)$$

As is well known, Boltzmann-Bloch equation is applicable when the condition

$$\kappa T > \frac{2\pi \hbar}{\tau} \quad (54)$$

is satisfied. In our theory, however, the criterion to obtain the Eq. (48) is such as given in (1), or roughly

$$\bar{E} > \bar{A}_B, \quad (55)$$

where $\bar{A}$ means the averaged value of A . When the system is non-Fermi degeneracy, $\bar{E}$ is nearly same as κT , and A_s is nearly same as $\hbar/\tau$ as easily seen from Eqs. (45) and (52), and the conditions (54) and (55) are nearly equal. When the system is in Fermi degeneracy, however, we can put E as ζ_0 and $\bar{A}_B$ as $\hbar/2\tau$, and thus the condition (55) is further applicable than that of (54). In actual, if we adopt the former condition (54), Boltzmann-Bloch equation is not applicable for nearly almost systems in Fermi degeneracy at sufficiently low temperatures. From the above treatment, we may say that when the condition (55) is satisfied, Boltzmann-Bloch equation may be applicable by adopting the real state density $S(E)$ instead of that of unperturbed system, $S_0(E)$.

(2) A_B is sufficiently larger than E .

In this case, we should determine the formula of $S(E)$ to proceed the calculation. For simplicity, we assume that $S_0(E) = S(E) = (3/4) n E^{1/2} / \zeta_0^{3/2}$ and $\xi(E, E) = |V_1|^2$ as in Eq. (52) and assumption (iv). Then using a approximation that

$$\int_0^\infty S_0(E') dE' \frac{\xi(E, E')}{(E - E')^2 + A_B^2} = \frac{3}{4} \frac{n |V_1|^2}{\zeta_0^{3/2}} \int_0^\infty dE' \frac{E'^{1/2}}{E'^2 + A_B^2} = \frac{3\pi}{4\sqrt{2}} \frac{n |V_1|^2}{\zeta_0^{3/2} A_B^{1/2}}, \quad (56)$$

we can obtain A_B from the Eq. (41) as

$$A_B \equiv A = \frac{9\pi^2}{32} \frac{n^2 |V_1|^4}{\zeta_0^3}, \quad (57)$$

and $\eta(E, E)$ becomes as follows

$$\eta(E, E) = \frac{1}{2} \frac{n |V_1|^4}{m \zeta_0^{3/2}} \int_0^\infty \frac{E'^{3/2}}{(E^2 + A^2)^2} dE' = \frac{\pi}{8\sqrt{2}} \frac{n |V_1|^4}{m \zeta_0^{3/2} A^{3/2}}, \quad (58)$$

or using Eq. (57)

$$= \frac{16}{27\pi^2} \frac{\zeta_0^3}{m n^2 |V_1|^2}. \quad (59)$$

Thus, the conductivity σ becomes

$$\sigma = \frac{e^2}{3\pi} \frac{h}{\kappa T} \frac{1}{m} \int_0^\infty dE f_1(E) \frac{E}{|V_1|^2}. \quad (60)$$

This result is just half of Eq. (48). Thus, in the case that impurity potential is approximated by δ -function type, the conductivity becomes just half of that obtained by using Boltzmann-Bloch equation when potential energy $\sqrt{n}|V_1|$ becomes much larger than Fermi energy ζ_0 .

When impurity potential is not represented by δ -function type, but is more general formula, we must consider the following effects that: (i) Born approximation is not applicable, (ii) there appears localized state, (iii) there exists some correlation amongst C_k^z in Eq. (39). By these effects, $\xi(E, E')$ and state density $S(E)$ become in general very complicated forms and it becomes fairly difficult problem to obtain $\xi(E, E')$ and $S(E)$ rigorously. Mathematically, however, we can obtain conductivity σ by assuming the energy dependence of $\xi(E, E')$, $S_0(E)$ and $S(E)$ respectively such as, $\xi(E, E') = \xi_0(E' - E)^\gamma / n \zeta_0^{\alpha-2}$, $S_0(E) = (\beta+1)nE^\beta/2\zeta_0^{\beta+1}$, and $S(E) = (\gamma+1)nE^\gamma/2\zeta_0^{\gamma+1}$. Then using the same approximation as in Eq. (56) etc. we obtain (see Appendix III)

$$A_B = A = \zeta_0 \left\{ 4 / (\beta+1) \xi_0 B \left(1 - \frac{\alpha+\beta+1}{2}, \frac{\alpha+\beta+1}{2} \right) \right\}^{1/(\alpha+\beta-1)}, \quad (61)$$

and

$$\eta(E, E) = \eta = \frac{3\xi_0^2}{4(\beta+1)} \frac{1}{n} \frac{A^{2\alpha+\beta/3-5/3}}{h^2 k_0^2 \zeta_0^{2\alpha+\beta/3-11/3}} B \left(2 - \frac{2\alpha+\beta/3+7/3}{2}, \frac{2\alpha+\beta/3+7/3}{2} \right), \quad (62)$$

or using Eq. (61)

$$= \frac{3}{4} \frac{\xi_0^2}{(\beta+1)} \left\{ 4 / (\beta+1) \xi_0 B \left(1 - \frac{\alpha+\beta+1}{2}, \frac{\alpha+\beta+1}{2} \right) \right\}^{(2\alpha+\beta/3-5/3)/(\alpha+\beta-1)} \\ \times B \left(2 - \left(\alpha + \frac{\beta}{6} + \frac{7}{6} \right), \alpha + \frac{\beta}{6} + \frac{7}{6} \right) \frac{\xi_0^2}{n h^2 k_0^2}, \quad (63)$$

where $B(a, b)$ means β -function and we assumed that $-1 < \alpha+\beta < 1$ and $-7/6 < \alpha+1/6 \cdot \beta < 5/6$ to replace the limit of integration by E' from zero to infinity.

Conductivity σ is obtained as

$$\sigma = \frac{\pi(\gamma+1)^2}{4} e^2 \frac{n^2}{\zeta_0^{2\gamma+2}} \frac{h}{\kappa T} \eta \int_0^\infty dE E^{2\gamma} f_1(E). \quad (64)$$

If we put $\alpha=0$, $\beta=\gamma=1/2$, and $\xi_0 = n|V_1|^2/\zeta_0^2$, we obtain the Eq. (60). Temperature dependence of σ is determined only by the energy dependence of the state density, namely γ . We show in following some extreme cases more quantitatively.

(i) $\zeta \gg \kappa T$

$$\sigma = \frac{\pi(\gamma+1)^2}{4} e^2 \frac{n^2 h \eta}{\zeta_0^2} = \sigma_0. \quad (65)$$

(ii) $\zeta \ll \kappa T$

$$f_1(E) = \frac{1}{(\gamma+1) \Gamma(\gamma+1)} \left(\frac{\zeta_0}{\kappa T} \right)^{\gamma+1} e^{-E/\kappa T}, \quad (66)$$

$$\sigma = \frac{\pi(\gamma+1)}{4} \frac{\Gamma(2\gamma+1)}{\Gamma(\gamma+1)} e^2 \frac{n^2}{\zeta_0^2} h \eta \left(\frac{\kappa T}{\zeta_0} \right)^{\gamma-1} \quad (67)$$

$$= \frac{1}{\gamma+1} \frac{\Gamma(2\gamma+1)}{\Gamma(\gamma+1)} \sigma_0 \left(\frac{\kappa T}{\zeta_0} \right)^{\gamma-1}, \quad (68)$$

where $\Gamma(x)$ means Γ -function.

§ 4. Impurity Band Conduction

When the concentration of impurity atoms becomes smaller, and overlapping of atomic wave functions localized at different impurity atoms becomes not so large, impurity levels split from the ordinary conduction band. Our problem in this section is how to treat the conduction phenomena in these impurity bands.

As mentioned in § 1, we adopt in this section the following model: (i) Impurity band is composed only by the 1S wave function localized at each impurity atom, and only one electron is possible to occupy a state of atomic wave function localized in a particular impurity atom. This assumption is applicable when the width of impurity band is fairly smaller than the energy gap between impurity band and conduction band. When this condition is not satisfied, we must add the wave functions of higher energy states to compose the impurity bands, and further consider the correlation energy to include the states in which more than two electrons occupy atomic wave functions localized at a particular impurity atom. In this case, the situation is fairly complicated and does not study in this paper.

Wave function ψ_s of the impurity band may be written from the above assumption such as,

$$\psi_s = \sum_n C_n^s \psi_n \quad (69)$$

where ψ_n means the atomic 1S wave function localized in the impurity atom of position R_n .

Concerning to the expansion coefficient C_n^s , we obtain the following relation from the normalization of the wave function ψ^s

$$\sum_n |C_n^s|^2 = 1 \quad (70)$$

neglecting the overlapping of atomic wave functions localizing at different impurity atoms, and further we assume that the phase factor of C_n^s is at random resulting from the randomness of the position of impurity atom. From the above consideration, we can obtain $\eta(E, E)$ easily as

$$\eta(E, E) = \sum_n \sum_m |C_n^s|^2 |C_m^s|^2 \langle \psi_n | v_X | \psi_m \rangle^2. \quad (71)$$

Further we can use the model already mentioned in § 1, that is: (ii) the resonance energy induced by the overlapping of atomic

wave functions localized at different impurity atoms is much larger than the fluctuation energy of local potential induced mainly by the Coulomb potential of minority impurity atoms, and thus the energy width of impurity band is determined mainly by the resonance energy. From the above condition, we can put $|C_n^s|^2$ roughly as constant, that is, the inverse of the number of majority impurity atoms, N_{maj}^{-1} . Then, $\eta(E, E)$ becomes simply

$$\eta(E, E) = \frac{1}{N_{\text{maj}}} \sum_m |\langle \psi_n | v_X | \psi_m \rangle|^2 \equiv \frac{1}{3} \frac{v^2}{N_{\text{maj}}}, \quad (72)$$

and the conductivity σ becomes

$$\sigma = \frac{\pi e^2 h}{3 \kappa T} \frac{v^2}{N_{\text{maj}}} \int_0^\infty dE S^2(E) f_1(E). \quad (73)$$

For the further calculation, we assume, for example, the formula of $S(E)$ such as

$$\left. \begin{aligned} S(E) &= \frac{8}{\pi} \frac{N_{\text{maj}}}{E_0^2} \sqrt{E(E_0 - E)}, \\ &\quad \text{when } 0 < E < E_0 \\ &= 0, \\ &\quad \text{when } E < 0 \text{ or } E_0 < E \end{aligned} \right\} \quad (74)$$

where E_0 means the width of impurity band and nearly equals to the resonance energy. $S(E)$ is normalized such as

$$\int_0^{E_0} S(E) dE = N_{\text{maj}}. \quad (75)$$

In some extreme cases, we can write σ more definitely as follows.

(a) ζ and $E_0 - \zeta \gg \kappa T$

$$\sigma = (\pi/3) e^2 h v^2 S^2(\zeta) / N_{\text{maj}} \quad (76)$$

$$= \frac{64}{3\pi} e^2 N_{\text{maj}} \frac{h v^2 \zeta (E_0 - \zeta)}{E_0^4}. \quad (77)$$

Using the following relation

$$\begin{aligned} v^2 &\equiv 3 \sum_n |\langle \psi_n | v_X | \psi_m \rangle|^2 \equiv \frac{3}{h^2} \sum_n |X_{nm} \langle \psi_n | H | \psi_m \rangle|^2 \equiv \frac{a_0^2}{h^2} V^2, \end{aligned} \quad (78)$$

we can write σ in a following form

$$\sigma = \frac{64}{3\pi} \frac{e^2 a_0^2}{h} N_{\text{maj}} \frac{V^2 \zeta (E_0 - \zeta)}{E_0^4}, \quad (79)$$

where V means the resonance energy

$$V^2 = \sum_n |\langle \psi_n | H | \psi_m \rangle|^2, \quad (80)$$

and a_0 means the effective distance between the nearest two impurity atoms. When N_{min}

is much smaller than N_{maj} , that is $E_0 \gg E_0 - \zeta$, we can use the following approximation

$$N_{\text{min}} = \int_{E_0 - \zeta}^{E_0} S(E) dE \doteq \frac{16}{3\pi} N_{\text{maj}} \left(1 - \frac{\zeta}{E_0}\right)^{3/2}, \quad (81)$$

and we can

$$\sigma = 8 \left(\frac{2}{3\pi}\right)^{1/3} \frac{e^2 a_0^2}{h} (N_{\text{maj}} N_{\text{min}}^2)^{1/3} \frac{V^2}{E_0^2}. \quad (82)$$

(b) $\kappa T \gg E_0$

In this case, some part of electron may occupy conduction band and conductivity may be written as a sum of two part,

$$\sigma = \sigma_c + \sigma_i, \quad (83)$$

where σ_c comes from the electron of conduction band and σ_i from the impurity band. When we write the number of electron occupying the impurity band as N , we can replace

$$f_i(E) = f(E)(1 - f(E)) \doteq \frac{N(N_{\text{maj}} - N)}{N_{\text{maj}}^2}, \quad (84)$$

and thus

$$\sigma_i = \frac{32}{9\pi} e^2 \frac{N(N_{\text{maj}} - N)}{N_{\text{maj}}} \frac{h v^2}{\kappa T E_0} \quad (85)$$

$$= \frac{32}{9\pi} \frac{e^2 a_0^2}{h} \frac{N(N_{\text{maj}} - N)}{N_{\text{maj}}} \frac{V^2}{\kappa T E_0}. \quad (86)$$

When the number of electrons occupying the conduction band is negligible small, we can replace N by $(N_{\text{maj}} - N_{\text{min}})$, in the above equations.

This like result was obtained at first by Conwell-Weiskof.³⁾ Their result is obtainable by the following consideration. We consider the case that κT is much larger than the resonance energy V_{nm} , and the probability that the atomic state localizing at each impurity atom is constant. When the external field F is applied, the transition probability to translate from state ϕ_n to ϕ_m differs from that to translate from ϕ_m to ϕ_n . This difference may be written as

$$FeX_{nm}/\kappa T \tau_{nm}, \quad (87)$$

where τ_{nm} means the resonance frequency and may be written by the resonance energy V_{nm} such as

$$\frac{h}{\tau_{nm}} = V_{nm} = |\langle \phi_n | HF | \phi_m \rangle|. \quad (88)$$

The conductivity due to this process is obtained roughly

$$\begin{aligned} \sigma &= e^2 \frac{N(N_{\text{maj}} - N)}{N_{\text{maj}}^2} \sum_n \sum_m \frac{X_{nm}^2}{\kappa T \tau_{nm}} \\ &= \frac{e^2}{h} \frac{N(N_{\text{maj}} - N)}{N_{\text{maj}}} \frac{\sum_n |X_{nm}^2 V_{nm}|^{R_n}}{\kappa T} \end{aligned} \quad (89)$$

Considering that E_0 nearly equals to V , Eq. (89) has the same form as Eq. (86) except merely a numerical factor, and thus may say that Conwell's result corresponds to the extreme case (b) of our formula.

Fig. 1.

●: minority impurity atom.
○: majority impurity atom.

When the energy fluctuation of local potential is much larger than the resonance energy, we can not regard the expansion coefficient C_n^s as nearly constant. In this case, it may be more convenient to divide impurity atoms into molecules as shown in Fig. 1, where potential energy at R_n and R_m nearly equal to E_s , and $R_{n'}$ and $R_{m'}$ differ apparently from E_s , and thus dotted closed line mean each molecule. Overlapping integral between these molecules becomes very small, and thus conductivity becomes also very small. In this situation, however, the new mechanism mentioned in (3) of §1 becomes important. We shall discuss this mechanism in the forth-coming paper, and the comparison with experimental results would be also given in that paper.

§5. Conclusion

The author wishes to express his cordial thanks to Prof. S. Nakajima, Prof. F. Nakano and the members of our laboratory for their valuable discussions.

Appendix I

We consider the system with the Hamiltonian $H + \alpha(t)V$, where $\alpha(t)$ is the expansion parameter and depends on time t . The motion of an arbitrary operator A is given by

$$\frac{dA(t)}{dt} = \frac{i}{\hbar} [H + \alpha(t)V, A(t)], \quad (\text{A1})$$

and the solution of this equation is given by

$$A(t) = e^{i(Ht + a(t)V)/\hbar} A e^{-i(Ht + a(t)V)/\hbar}, \quad (\text{A2})$$

where,

$$a(t) = \int_0^t \alpha(t) dt. \quad (\text{A3})$$

To obtain the expansion formula of (A2), we use the following relation

$$\begin{aligned} \frac{d}{dt_1} \{ e^{-iHt_1/\hbar} e^{i(Ht_1 + a(t_1)V)/\hbar} A e^{-i(Ht_1 + a(t_1)V)/\hbar} e^{iHt_1/\hbar} \} \\ = \frac{i}{\hbar} e^{-iHt_1/\hbar} [\alpha(t_1)V, e^{i(Ht_1 + a(t_1)V)/\hbar} A e^{-i(Ht_1 + a(t_1)V)/\hbar}] e^{iHt_1/\hbar}. \end{aligned} \quad (\text{A4})$$

Integrating with respect to t_1 from 0 to t , and multiplying $e^{iHt/\hbar}$ and $e^{-iHt/\hbar}$ respectively from each side, we obtain the relation

$$\begin{aligned} e^{i(Ht + a(t)V)/\hbar} A e^{-i(Ht + a(t)V)/\hbar} = e^{iHt/\hbar} \left\{ A + \frac{i}{\hbar} \int_0^t dt_1 \right. \\ \left. \times e^{-iHt_1/\hbar} [\alpha(t_1)V, e^{i(Ht_1 + a(t_1)V)/\hbar} A e^{-i(Ht_1 + a(t_1)V)/\hbar}] e^{iHt_1/\hbar} \right\} e^{-iHt/\hbar}. \end{aligned} \quad (\text{A5})$$

Using the method of iteration, we obtain the required result.

$$\begin{aligned} A(t) = e^{iHt/\hbar} \left\{ A + \sum_{n=1}^{\infty} \left(\frac{i}{\hbar} \right)^n \int_0^t dt_1 \int_0^{t_1} dt_2 \cdots \int_0^{t_{n-1}} dt_n \right. \\ \left. \times [e^{-iHt_1/\hbar} \alpha(t_1)V e^{iHt_1/\hbar} [\cdots [e^{-iHt_n/\hbar} \alpha(t_n)V e^{iHt_n/\hbar}, A] \cdots]] \right\} e^{-iHt/\hbar}. \end{aligned} \quad (\text{A6})$$

The expansion formula of $e^{-\beta(H+V)}$ with respect to V is also obtained easily by the same method as the above. We start with the relation

$$\frac{d}{d\lambda} (e^{\lambda H} e^{-\lambda(H+V)}) = -e^{\lambda H} V e^{-\lambda(H+V)}. \quad (\text{A7})$$

Integrating with respect to λ from 0 to β , and performing some transformation, we obtain the following relation

$$e^{-\beta(H+V)} = e^{-\beta H} \left\{ 1 - \int_0^\beta d\lambda e^{\lambda H} V e^{-\lambda(H+V)} \right\}. \quad (\text{A8})$$

Using the method of iteration, we obtain

$$\begin{aligned} e^{-\beta(H+V)} = e^{-\beta H} + \sum_{n=1}^{\infty} (-1)^n \int_0^\beta d\lambda_1 \int_0^{\lambda_1} d\lambda_2 \cdots \int_0^{\lambda_{n-1}} d\lambda_n \\ \times e^{(\lambda_1 - \beta)H} V e^{(\lambda_2 - \lambda_1)H} V \cdots e^{(\lambda_n - \lambda_{n-1})H} V e^{-\lambda_n H}. \end{aligned} \quad (\text{A9})$$

Appendix II

To obtain the Eqs. (5) and (6), we used the following relations.

$$(i) \quad e^{-iHt/\hbar} A e^{iHt/\hbar} = \int_0^t dt_1 \frac{d}{dt_1} (e^{-iHt_1/\hbar} A e^{iHt_1/\hbar}) + A = A - \int_0^t dt_1 e^{-iHt_1/\hbar} \frac{i}{\hbar} (HA - AH) e^{iHt_1/\hbar}. \quad (A10)$$

$$(ii) \quad \text{Tr} e^{-\beta H} [B, A] \rightarrow \text{Tr} [e^{-\beta H}, B] A = -\text{Tr} e^{-\beta H} \int_0^\beta d\lambda \frac{d}{d\lambda} (e^{\lambda H} B e^{-\lambda H} A) \\ = -\text{Tr} e^{-\beta H} \int_0^\beta d\lambda e^{\lambda H} (HB - BH) e^{-\lambda H} A. \quad (A11)$$

To obtain the second relation (A9), it is necessary to exist the first equation. The first equation does not exist in arbitrary operator B and A , because this equation exists only when we can exchange the order of the following double summation

$$\sum_s \sum_{s'} \sum_{s''} (e^{-\beta H})_{ss'} A_{s's''} B_{s''s} = \sum_{s''} \sum_s \sum_{s'} (e^{-\beta H})_{ss'} A_{s's''} B_{s''s}, \quad (A12)$$

in a suitable representation $\{s\}$. For example, in the case that $B = p_x$ and $A = x$, Eq. (A12) is not applicable.

Appendix III

We consider the case that there is no impurity atom, and the energy spectrum of the system is written as

$$E = \zeta_0 (k/k_0)^p, \quad (A13)$$

where k_0 mean the wave vector of Fermi surface at absolute zero temperature. Expectation value of velocity is written as

$$v_k = \frac{1}{\hbar} \frac{\partial E}{\partial k} = \frac{\zeta_0 p}{\hbar k_0} \left(\frac{k}{k_0} \right)^{p-1} = \frac{p \zeta_0}{\hbar k_0} \left(\frac{E}{\zeta_0} \right)^{1-1/p}, \quad (A14)$$

and the state density $S_0(E)$ is written as

$$S_0(E) = \left(\frac{1}{2\pi} \right)^3 4\pi k^2 \frac{dk}{dE} = \frac{1}{2\pi^2} \frac{k_0^3}{p \zeta_0} \left(\frac{k_0}{k} \right)^{p-3} = \frac{1}{2\pi^2} \frac{k_0^3}{p \zeta_0} \left(\frac{\zeta_0}{E} \right)^{(p-3)/p}, \quad (A15)$$

or, using the relation

$$n = \frac{k_0^3}{3\pi^2} \quad (A16)$$

$S_0(E)$ is written as

$$S_0(E) = \frac{3}{2} \frac{n}{p \zeta_0} \left(\frac{\zeta_0}{E} \right)^{1-3/p}. \quad (A17)$$

β in main paper is obtained by

$$\beta = \frac{3}{p} - 1, \quad (A18)$$

and thus v is written by using the parameter β as

$$v = \frac{3}{\beta+1} \frac{\zeta_0}{\hbar k_0} \left(\frac{E}{\zeta_0} \right)^{(2-\beta)/3}. \quad (A19)$$

Magnetic Property and Crystal Chemistry of Ilmenite (MeTiO_3) and Hematite ($\alpha\text{Fe}_2\text{O}_3$) System

I. Crystal Chemistry

By Yoshikazu ISHIKAWA*

Institute for Solid State Physics, University of Tokyo, Tokyo

and Syun-iti AKIMOTO

Geophysical Institute, University of Tokyo, Tokyo

(Received June 18, 1958)

Solid solutions of ilmenite (MgTiO_3 , MnTiO_3 , FeTiO_3 , CoTiO_3 and NiTiO_3) and hematite ($\alpha\text{Fe}_2\text{O}_3$) were prepared and their crystal structure was investigated by an X-ray analysis. It was confirmed that the solid solutions could be classified into three groups: 1) The specimens of ilmenite side and hematite side in the solid solution have the different crystal symmetries; $R\bar{3}$ and $R\bar{3}c$ respectively and there exists a miscibility gap between them (MnTiO_3 , MgTiO_3 and CoTiO_3 series). 2) Ilmenite and hematite make the solid solution in the whole range of composition and the crystal symmetry changes from $R\bar{3}$ to $R\bar{3}c$ continuously (NiTiO_3 series). 3) The ranges of the crystal symmetries $R\bar{3}$ and $R\bar{3}c$ of the solid solution are overlapped with each other and a transformation from $R\bar{3}$ to $R\bar{3}c$ is observed in one specimen of the overlapped range (FeTiO_3 series). Such differences among different ilmenite and hematite systems may be attributed to the following three factors; differences in ionic radii, in electronic conductivity and in stability of other two solid solution series with spinel and pseudobrookite structures which exist in a ternary system of $\text{MeO-Fe}_2\text{O}_3\text{-TiO}_2$.

§ 1. Introduction

Since the discovery of strong ferrimagnetic substances in the solid solution series of FeTiO_3 and $\alpha\text{Fe}_2\text{O}_3$ ¹⁾, detailed investigations of this series have been carried out by ourselves^{2), 3), 4), 5)}, and others^{6), 7), 8)}. Outstanding features of this series are the appearance of the ferrimagnetism only in a limited range of composition in the solid solution and a peculiar mode of thermomagnetic curve of all fer-

rimagnetic specimens. Such features have also been found in the solid solution of NiTiO_3 and Fe_2O_3 ⁹⁾ and it was expected that these properties are common to solid solutions having the same crystal structure. It must be mentioned, however, that there exist some differences between magnetic properties of these two solid solution series in detailed points.

Nowadays five titanates: FeTiO_3 , NiTiO_3 , CoTiO_3 , MnTiO_3 and MgTiO_3 are reported to be of the ilmenite structure¹⁰⁾. Hence it is worthwhile to prepare the solid solutions of these titanates and hematite and to examine

* Present address: Department of Applied Physics, Faculty of Engineering, University of Tokyo, Tokyo.

whether such magnetic properties as were found for FeTiO_3 and NiTiO_3 systems are also observed for other ilmenite-hematite systems or not. In this paper we shall report magnetic properties and crystal structures of the solid solutions of hematite and substance having the ilmenite structure in general and discuss in detail the differences among them. By making such comparisons we could understand better the peculiarity of the FeTiO_3 system only in which a cation stays in two different valence states.

Ilmenite (MeTiO_3) and hematite ($\alpha\text{Fe}_2\text{O}_3$); the end members of the solid solution, both being of the rhombohedral structure, have slightly different crystal symmetries $R\bar{3}$ and $R\bar{3}c$ with each other. In ilmenite and hematite, oxygen ions construct a slightly distorted hexagonal close-packed structure and cations occupy two thirds of octahedral interstices of oxygen layers, forming a honey comb structure. The cation lattice in the structure is shown in Fig. 1, where a rhombohedral unit cell is also drawn. As this figure shows, the cation lattice can be divided into four sublattices; A_1 , A_2 , B_1 , and B_2 . The $R\bar{3}$ symmetry

corresponds to a case where A and B sublattices are occupied by different cations, while in $R\bar{3}c$ all sublattices are equivalent.

In the solid solution of ilmenite and hematite, Me and Ti ions occupy only A and B sublattices respectively in $R\bar{3}$ symmetry. The ferrimagnetism is expected to appear in the solid solution with this crystal symmetry, while the antiferromagnetism is attributed to the symmetry $R\bar{3}c$ as we stated in the previous paper.³⁾ It is, therefore, necessary for understanding the magnetic properties to investigate the crystal symmetry of the solid solution first of all, which we shall treat in this paper. Magnetic properties will be discussed in the next paper with particular reference to the crystal symmetry.

In the present stage, very few magnetic oxides are of the rhombohedral structure and magnetic couplings in this structure are not so well understood compared with those in the cubic structure to which many magnetic oxides belong. Hence it may have a considerable significance to establish a new magnetic oxide system of the rhombohedral structure and to discuss its magnetic properties in general.

§ 2. Ternary System of $\text{MeO-Fe}_2\text{O}_3\text{-TiO}_2$

Hitherto an investigation of the ternary system of $\text{FeO-Fe}_2\text{O}_3\text{-TiO}_2$ has been carried out by one of the authors and it has been reported that there exist three kinds of solid solution series in this system¹¹⁾. We have found this results can be generalized to the ternary system of $\text{MeO-Fe}_2\text{O}_3\text{-TiO}_2$ with $\text{Me}=\text{Mg}^{+2}$, Mn^{+2} , Fe^{+2} , Ni^{+2} , and Co^{+2} and the solid solution of MeTiO_3 and Fe_2O_3 is better understood when

Fig. 1. Cation lattice in a rhombohedral sesquioxide. The cations deviate from the hexagonal site towards the direction of arrows. Rhombohedral unit cell is drawn by the thick line.

Fig. 2. Generalized phase diagram of $\text{MeO-Fe}_2\text{O}_3\text{-TiO}_2$ system.

we consider it as one of the solid solution series which exist in the ternary system of $\text{MeO} \cdot \text{Fe}_2\text{O}_3 \cdot \text{TiO}_2$. This generalized phase diagram is shown in Fig. 2. Through an X-ray analysis, it was confirmed that there exist three kinds of solid solution series in every ternary system of $\text{MeO} \cdot \text{Fe}_2\text{O}_3 \cdot \text{TiO}_2$ with $\text{Me} = \text{Mg}^{+2}, \text{Mn}^{+2}, \text{Fe}^{+2}, \text{Co}^{+2}$ and Ni^{+2} . They are:

- 1) $x\text{Me}_2\text{TiO}_4 \cdot (1-x)\text{MeFe}_2\text{O}_4$
with spinel structure,
- 2) $x\text{MeTiO}_3 \cdot (1-x)\text{Fe}_2\text{O}_3$
with ilmenite (hematite) structure,
- 3) $x\text{MeTi}_2\text{O}_5 \cdot (1-x)\text{Fe}_2\text{TiO}_5$
with pseudobrookite structure.

As to the end members of these solid solution series, it has been known that MeTiO_3 and MeFe_2O_4 exist for all these cations, while as to Me_2TiO_4 all but Ni_2TiO_4 have been reported to exist⁽¹²⁾. No data could have been obtained about MeTi_2O_5 except FeTi_2O_5 and MgTi_2O_5 ^{(13), (14)}. The solid solutions of the first

series (spinel) have been investigated for $\text{Me} = \text{Ni}$ and Fe and either have been reported to be ferrimagnetic⁽¹¹⁾⁽¹⁵⁾. As to the solid solution of the third series (pseudobrookite), FeTi_2O_5 and Fe_2TiO_5 have been reported to make the solid solution in the whole range of the composition and they are paramagnetic at room temperature⁽¹³⁾. It is out of our investigation whether there exist miscibility gaps in the solid solutions of the first and third series for other cations systems. In Table I, we show the ratio of the numbers of cations to oxygen ions in a molecule of the compounds of these three series. The ratio of cations to oxygen ions is the smallest for the third series, which means when the mixture of MeO , TiO_2 and Fe_2O_3 is sintered under a high oxygen pressure, the third series is the most stable, while in a reducing atmosphere, the spinel structure becomes more favourable. Hence we can understand that the second series can be prepared

Table. I. Three kinds of solid solution series.

No.	Solid solution series	Cations/Oxygens	Magnetic ions/Total ions, y
1	$x\text{Me}_2\text{TiO}_4 \cdot (1-x)\text{MeFe}_2\text{O}_4$	0.75	$0.43 \geq y \geq 0.29$
2	$x\text{MeTiO}_3 \cdot (1-x)\text{Fe}_2\text{O}_3$	0.67	$0.40 \geq y \geq 0.20$
3	$x\text{MeTi}_2\text{O}_5 \cdot (1-x)\text{Fe}_2\text{TiO}_5$	0.60	$0.25 \geq y \geq 0.125$

only in a restricted oxygen atmosphere.

When the mixture of MeTiO_3 and Fe_2O_3 is sintered in a slightly reducing atmosphere than is required for the ilmenite phase, the spinel phase begins to precipitate. At the same time, the pseudobrookite phase must precipitate in order to keep the ratio of Me , Ti and Fe constant. Then, in general, we found diffraction patterns corresponding to three phases on a "Norelco" chart when the sintering atmosphere was not controlled properly. This situation is not hold in the case of FeTiO_3 series in which Fe^{+2} can change into Fe^{+3} by the addition of oxygen ions, only two phases being sufficient to keep the ratio of cations constant in this solid solution series. In fact, we could not observe the coexistence of three phases in this solid solution series when the solid state reaction was completed. From these considerations, if we find the spinel and pseudobrookite phases only coexisted in the specimen which was prepared by sintering the mixture of MeTiO_3 and Fe_2O_3 in a desired proportion under a certain oxygen pressure,

we may suppose that there is no adequate oxygen pressure under which the ilmenite-hematite phase of this composition is stable.

In the second column of Table I, we also indicate the ratio y of the numbers of magnetic ions to the total ions which give approximately the degree of dilution of the magnetic coupling in the compound. From these values we understand the situation that the first and third series are ferrimagnetic and paramagnetic respectively. Furthermore we can expect that the magnetic coupling in the second series is not so strong particularly in the compound near the ilmenite side. We shall show in the next paper that all characteristics of the ferrimagnetic properties of the solid solution of ilmenite and hematite can be interpreted by this diluted magnetic coupling.

§ 3. Preparation of Specimens

Following the considerations above mentioned, we have tried to prepare the solid solution between MeTiO_3 and Fe_2O_3 with $\text{Me} = \text{Mg}, \text{Mn}, \text{Fe}, \text{Co}$ and Ni by usual ceramic

method. Most of the specimens were prepared by sintering the mixture of Fe_2O_3 and MeTiO_3 in the desired proportion at high temperatures, but some were prepared from the mixture of MeO , TiO_2 and Fe_2O_3 . MeTiO_3 used was also prepared in advance in our laboratory. In any case, the sintering atmosphere was controlled appropriately. Since the magnetic properties of all solid solution series except FeTiO_3 series were found not to be sensitive to the heat treatments, they were cooled naturally in the furnace. In the case of FeTiO_3 series, however, magnetic properties are greatly affected by the heat treatment, details having already been reported in the previous papers.^{3), 6)}

Chemical analysis was carried out by T. Katsura of Tokyo Institute of Technology for the prepared specimens of MnTiO_3 and FeTiO_3 series. It was confirmed that the mol. ratios of MeTiO_3 and Fe_2O_3 determined by this analysis are not so much deviated from those originally adopted in mixing, but some of the specimens in MnTiO_3 series were found to contain traces of Mn^{+3} and Fe^{+2} . It is not clear how magnetic property and crystal structure of this solid solution series are affected by these impurities. For the specimens of other series no chemical analysis has yet been practised, so that we must consider that the specimens keep their original composition unchanged during sintering. It is, therefore, expected that the real composition is deviated from the original one when other phases co-exist, which may result in a scattering of the results as are found for MgTiO_3 and CoTiO_3 series.

§ 4. Crystallographic Study of the Solid Solution

An X-ray analysis of the solid solution was conducted by a "Norelco" diffractometer with $\text{Fe } K$ radiation. Practically we determined the crystal parameters of FeTiO_3 , MnTiO_3 , CoTiO_3 and MgTiO_3 series by least square method in making use of eight diffraction peaks, i.e. (300), (214), (116), (204), (113), (110), (104) and (102) planes in hexagonal indices. On the other hand, since NiTiO_3 has the nearly same crystal parameters as those of Fe_2O_3 , five higher angle diffraction peaks, i.e. (226), (2 0 10), (1 0 10), (300) and (214) planes were taken for this series. The results of the X-ray analysis of $\text{FeTiO}_3\text{-Fe}_2\text{O}_3$ solid solution

series have already been reported in the previous paper²⁾. They are reproduced in this paper to be compared with the results of other series. A characteristic of this series is the linear change of the volume of unit cell with composition as Fig. 3 shows.

Fig. 3 (a). Volume of unit cell of $\text{FeTiO}_3\text{-Fe}_2\text{O}_3$ solid solution series.

Fig. 3 (b). Crystal parameters of $\text{FeTiO}_3\text{-Fe}_2\text{O}_3$ solid solution series.

In Figs. 4~7, we show the change of the crystal parameters a_{rh} , c_{rh} and the volume of unit cell with composition for MnTiO_3 , MgTiO_3 , CoTiO_3 and NiTiO_3 series. First of all, it must be noticed in these figures that the linear change of the volume of unit cell with composition, which was the case for FeTiO_3 series, could not be observed for any other ilmenite system. In Fig. 4 (a) the results for MnTiO_3 series are shown, where we find that the volume of unit cell does not change continuously from that of ilmenite to that of hematite but there exists a miscibility gap in the middle

Fig. 4 (a). Volume of unit cell of $\text{MnTiO}_3\text{-Fe}_2\text{O}_3$ solid solution series.

Fig. 4 (b). Crystal parameters of $\text{MnTiO}_3\text{-Fe}_2\text{O}_3$ solid solution series.

Fig. 5 (b). Volume of unit cell of $\text{MgTiO}_3\text{-Fe}_2\text{O}_3$ solid solution series.

Fig. 5 (b). Crystal parameters of $\text{MgTiO}_3\text{-Fe}_2\text{O}_3$ solid solution series.

range of composition. In this range we obtained only mixtures of two phases with spinel and pseudobrookite structures. This situation can be more clearly seen in Fig. 4 (b) where the change in the crystal parameters with composition are shown. These figures suggest that the solid solution on the ilmenite side has a different crystal symmetry from that on the hematite side, which must be a chief reason why there exists a miscibility gap between MnTiO_3 and Fe_2O_3 .

Fig. 6 (a). Volume of unit cell of $\text{CoTiO}_3\text{-Fe}_2\text{O}_3$ solid solution series.

Fig. 6 (b). Crystal parameters of $\text{CoTiO}_3\text{-Fe}_2\text{O}_3$ solid solution series.

In Figs. 5 and 6 the cases for MgTiO_3 and CoTiO_3 series are shown, where we find that the feature of the former series is very similar to that of MnTiO_3 series, but for the latter series, the volume of unit cell and crystal parameters seem to vary rather continuously. It is worthwhile to note, however, that in both cases miscibility gaps between ilmenite and hematite are found.

On the other hand, in the case of NiTiO_3 series, it was found that the ilmenite and the hematite make a complete solid solution in the

whole range of composition as is shown in Fig. 7. It must also be noticed in the figure that a slight discontinuous change of the volume and the crystal parameters can be observed between the composition range of 0.5NiTiO₃-0.5Fe₂O₃ and 0.55NiTiO₃-0.45Fe₂O₃. This discontinuous change is, however, very small and nearly within an experimental error,

Fig. 7 (a). Volume of unit cell of NiTiO₃-Fe₂O₃ solid solution series.

Fig. 7 (b). Crystal parameters of NiTiO₃-Fe₂O₃ solid solution series.

hence we can not decide whether such a change really exists in this series or not. If such a change really existed, the change of the crystal symmetry would be considered as occurring at this point, the specimen of 0.6NiTiO₃-0.4Fe₂O₃ being expected to be of the crystal symmetry $R\bar{3}$ as we have done in other ilmenite systems. On the other hand, we presumed from the magnetic study that it, being feebly ferromagnetic, belongs to the symmetry $R\bar{3}c$ and the crystal symmetry changes gradually from $R\bar{3}c$ to $R\bar{3}$ near this composition. These conflicting situations may suggest that it is very difficult to determine accurately the crystal symmetry of the middle part of NiTiO₃ series from such X-ray and magnetic analyses. The more detailed analyses are required for this series.

We have thus expected that for the solid solution series having the miscibility gap the solid solution take crystal symmetry of either

$R\bar{3}$ or $R\bar{3}c$: those of the end members. It is, therefore, necessary to determine this symmetry directly by the X-ray analysis. In the crystal structure of ilmenite and hematite, intensities of diffraction lines $I(h\bar{h}0l)$ for $l=2n+1$, are very weak and they completely disappear for the compounds with the crystal symmetry $R\bar{3}c$. In the actual cases the lines indexed by (0003) and $(1\bar{1}01)$ are the strongest of the lines for $l=2n+1$ and the presence of these lines which we call superlines is the best indication of the symmetry $R\bar{3}$. Unfortunately Me⁺² and Ti⁺⁴ ions have very closed atomic scattering factors and the superlines are very weak even for pure MeTiO₃ except MgTiO₃ and they become weaker with

Fig. 8. X-ray diffraction chart showing super lines peculiar to $R\bar{3}$ crystal symmetry.

the increase of the content of Fe₂O₃ in the solid solution. In Fig. 8 we showed the superlines which are observed in the solid solution of MgTiO₃ and Fe₂O₃. As this figure shows superlines disappear in the specimen of 0.5MgTiO₃-0.5Fe₂O₃, which is consistent with those inferred from Fig. 4. We also detected the superline (0003) in the specimens of the ilmenite side of MnTiO₃ and NiTiO₃ series though they are very weak. In the case of FeTiO₃ series it was confirmed by the X-ray analysis of a single crystal¹⁰⁾ and the neutron

Table. II. Solid solution of ilmenite and hematite: $x\text{MeTiO}_3 \cdot (1-x)\text{Fe}_2\text{O}_3$.

MeTiO ₃	Ionic radius, $r_{\text{Me}^{18}}$ (Å)	Crystal symmetry	
		$R\bar{3}$	$R\bar{3}c$
MgTiO ₃	0.65	$1 \geq x \geq 0.8$	$0.5 \geq x \geq 0$
MnTiO ₃	0.80	$1 \geq x \geq 0.7$	$0.4 \geq x \geq 0$
FeTiO ₃	0.75	$1 \geq x \geq 0.45$	$0.6 \geq x \geq 0$
CoTiO ₃	0.72	$1 \geq x \geq 0.8$	$0.4 \geq x \geq 0$
NiTiO ₃	0.70	$1 \geq x > 0.6 (?)$	$0.6 \geq x \geq 0$

- : super structure spot peculiar to $R\bar{3}$ symmetry.

is illustrated by photograph in Fig. 9, where we can clearly find many spots peculiar to the $R\bar{3}$ crystal symmetry. Accordingly we can conclude in general that the ilmenite side of the solid solution between ilmenite and hematite retains the same crystal symmetry as that of pure ilmenite. The results thus obtained are summarized in Table II. Here we used also the knowledge obtained from the magnetic study. The symmetry $R\bar{3}$ corresponds to the case where Ti and Me ions are arranged in order as we stated in introduction and we shall denote this state as the ordered one, while the symmetry $R\bar{3}c$ corresponds to the case where all ions are arranged at random. In this table, it must be noticed that, in the case of FeTiO_3 series the ranges of $R\bar{3}$ and $R\bar{3}c$ are overlapping. This means that in this overlapped range of the composition the transformation from $R\bar{3}$ to $R\bar{3}c$ or from the ordered state to the disordered state is observed in a specimen. Such a transformation phenomenon has been discussed in detail in another paper⁶⁾.

§ 5. Discussion

We have found in the preceding section that the solid solution of ilmenite and hematite can be classified into following three groups:

- (1) The solid solutions of ilmenite side and hematite side have the different crystal symmetries and there exists miscibility gap between them (MnTiO_3 , CoTiO_3 and MgTiO_3 series).
- (2) Ilmenite and hematite make a complete solid solution in the whole range of the composition and the crystal symmetry changes from $R\bar{3}$ to $R\bar{3}c$ continuously (NiTiO_3 series).
- (3) The ranges of the crystal symmetry $R\bar{3}$ and $R\bar{3}c$ are overlapped and the transformation from $R\bar{3}$ to $R\bar{3}c$ is observed in the specimen of this range (FeTiO_3 series).

analysis¹⁷⁾ that the ilmenite side of the solid solution belongs to the symmetry $R\bar{3}$. The result of the X-ray analysis of a single crystal

As this classification and Table II show, the miscibility of ilmenite and hematite varies with different ilmenite system. We may suppose that such differences in the miscibility are attributed to following three factors which will be discussed separately.

i) *Difference in the ionic radii*

Generally speaking the existence of a solid solution between two compounds can be explained thermodynamically as follows. It is well known that any reactions proceed so as to minimize the free energy $F=U-TS$ of the system, where U and S are the internal energy and entropy respectively. The internal energy, that is the electrostatic energy in our case, of the microscopic mixture of two kinds of compounds is larger than that of a macroscopic mixture of them. The entropy, is also increased considerably by making the solid solution. Hence at high temperatures the second term of the free energy predominates over the first one and it becomes to be possible that the solid solution is more stable than the mixture of two compounds.

When, therefore, we make the solid solution of two compounds having much different lattice parameters or crystal symmetries, the increase of the internal energy is too great to be compensated by the entropy term. Hence the solid solution of these compounds has often a miscibility gap. For example, there exists a miscibility gap in the solid solution between a cubic spinel and one with a slightly elongated unit cell (CuFe_2O_4)¹⁹⁾, in contrast with the situation that many cubic oxides make solid solution with each other in the whole range of the composition. The miscibility gap in the solid solution of ilmenite and hematite may be explained chiefly by this factor and the width of such a miscibility gap is expected to be proportional to the difference among the ionic radii of the cations relevant to our case.

We have found that NiTiO_3 and Fe_2O_3 make the solid solution in the whole range of the composition. This situation can be explained when we consider that Ni^{+2} and Ti^{+4} have nearly equal ionic radii (0.70Å and 0.68Å respectively) and they are not so large compared with that of Fe^{+3} (0.60Å). The range of miscibility of MnTiO_3 and MgTiO_3 series can be interpreted in the same manner: that is, as the difference between the ionic radii of Me^{+2} and Fe^{+3} is greater for Mn^{+2} (0.80Å) than for

Mg^{+2} (0.65Å), the miscible range is narrower for MnTiO_3 series than for MgTiO_3 series.

On the other hand, the fact that FeTiO_3 and Fe_2O_3 make the solid solution in the whole range of the composition or the miscibility gap of CoTiO_3 series is the widest of all series can not be explained by the difference in the ionic radii, because the ionic radius of Fe^{+2} ion is relatively large (0.75Å) and that of Co^{+2} ion (0.72Å) is not greater than that of Mn^{+2} ion (0.80Å). The miscibility gaps of these solid solution series must be controlled by other factors.

ii) *Migration of cations*

It seems rather peculiar that FeTiO_3 and Fe_2O_3 make the solid solution in the whole range of composition and the volume of unit cell changes linearly with the composition in spite of the facts that the ionic radius of Fe^{+2} ion is fairly larger than those of Ti^{+4} and Fe^{+3} and the crystal symmetry of the solid solution changes from $R\bar{3}$ to $R\bar{3}c$ at a certain value of the composition. Such a peculiarity of this series is undoubtedly correlated with the situation that only in this series a cation stays in two valence states and the electronic conductivity is very high. We can expect that the free energies of the states with crystal symmetries $R\bar{3}$ and $R\bar{3}c$ are extraordinarily close in this system compared with other systems, but it is not clear why such a situation exists in this system. It may be supposed that in this system the activation energy required for migration of Ti ions which may be very high in other ilmenite-hematite system is reduced by the situation that Fe^{+2} and Fe^{+3} ions can easily change their arrangement through the electron transfer so as to reduce the repulsive force between Ti and Fe ions when they migrate to other lattice points. The increase in the electrostatic energy due to the rearrangement of Ti ions may also be reduced by the same mechanism. We may suppose by such a mechanism that the free energies of the states with $R\bar{3}$ and $R\bar{3}c$ are close to each other and ilmenite and hematite can make the solid solution over the whole range of composition for FeTiO_3 series. The situation that the order-disorder transformation between $R\bar{3}$ and $R\bar{3}c$ takes place only in this series may also be explained by the same manner.

iii) *Stability of other phases*

There seems to exist another factor which restricts the miscibility of two compounds, and this may be a chief factor which determines the range of miscibility of CoTiO_3 series.

We have discussed in section 2 that there exist three kinds of solid solution series in the ternary system of $\text{MeO-Fe}_2\text{O}_3\text{-TiO}_2$, and showed that the series with the spinel structure is stable in the reducing atmosphere and the series with the pseudobrookite structure is stable under high oxygen pressure. Then, if the ranges of the oxygen pressure under which spinel phase is stable overlap with those for pseudobrookite phase, it comes to be possible that the free energy of these two phases are lower than that of ilmenite-hematite phase under any oxygen pressures. In this case only the first (spinel) and the third (pseudobrookite) series can be prepared when they are left in thermal equilibrium. In reality we have often observed that for the specimen in the immiscible range, when the sintering time was very short and the reaction did not proceed fully, three phases coexisted, but the ilmenite-hematite phase disappeared on more prolonged heating. This means though the ilmenite-hematite phase was stable it decomposed into other more stable two phases in thermal equilibrium.

The fact that the miscibility gap of CoTiO_3 series is the widest of all may be due to this factor. We inferred it from the following situation. It is found that FeTiO_3 and MnTiO_3 series are not stable in an open air at high temperatures, as Fe^{+2} and Mn^{+2} are unstable. This means that the range of oxygen pressure where the first series of Mn and Fe systems are stable are relatively narrow compared with that of the third series. On the other hand, in Ni system the first series is stable even in the oxygen flow at high temperature. It is, therefore, expected that in case of Co^{+2} system

both the first and third series are stable in a wide range of oxygen pressure because Co^{+2} is more stable than Mn^{+2} and Fe^{+2} ions but less than Ni^{+2} ions.

In concluding the present paper the authors express their sincere thanks to Prof. Shozo Sawada and Prof. Takesi Nagata for their encouragements and advice. Their thanks are also due to Dr. T. Katsura for his chemical analysis and to Dr. R. Sadanaga and Mr. M. Korekawa for their help in the X-ray analysis of single crystal.

Lattice Defects in Zincblende

Part I. Phenomenological Expressions of Interionic Potentials*

By Sumitada ASANO and Yasuo TOMISHIMA

Department of Physics, Faculty of Science, Okayama University

(Received July 3, 1958)

As the basis of the calculation on formation energies of lattice defects, phenomenological expressions of interionic potentials are derived. In zincblende crystal which is partly ionic and partly covalent, the effective charge on the constituent ions is reduced to a certain amount Ze ($Z=1.66$, e : magnitude of the electronic charge), whereas covalent attraction between two ions adjacent to each other is generated, which is assumed to be exponential form $-b_c \exp(-r/\rho_c)$ such as the usual expression of exchange repulsion. As a preliminary calculation to Part II, the lattice energy variation when one anion or cation is displaced from its regular position in a perfect crystal is calculated on taking account of the Madelung, Van der Waals, exchange repulsion, covalency attraction energies and the polarization energies of the displaced ion and all other surrounding ions. All the physical constants already known in references and derived in our calculation are tabulated in Table III.

§ 1. Introduction

The luminescence and photoconductivity of ionic crystals, for the most part, are inferred to originate from the crystal imperfections such as vacancies, substitutional and interstitial impurity atoms. In general, the ions surrounding the vacancy or the impurity atom deviate from their regular sites. In order to explain the behaviors of the phosphors and photoconductors known hitherto and further to devise new ones, it is desirable to clarify the aspects of the local distortions caused by the crystal imperfections and the states of the electrons trapped in the vacancies and impurity atoms. For this purpose, in the first place, it is necessary to derive the phenomenological expressions of the interionic potentials.

In this paper, we will seek these expressions for cubic ZnS (zincblende) which is one of the most useful crystal among luminescent materials. It is well known that zincblende is not purely ionic crystal but partly covalent one, and the electrons of S^{2-} ion are partly transferred to the neighbouring Zn^{2+} ion. Therefore, the effective charges of Zn and S ions are reduced to the amounts Ze and $-Ze$ respectively (e : magnitude of the electronic

charge). According to our previous calculation on the cohesive energy of zincblende, $Z=2 \times 0.83^{1)}$. As a result of this reduction in effective charges of constituent ions, Coulomb interaction energy (Madelung energy) decreases, so that we have to introduce another interaction which may be called covalent interaction.

As the interactions between constituent ions, we may point out the following five kinds:

Short range interactions which act between nearest neighbours only.

- (1) Repulsive energy E_R
- (2) Coulomb overlap energy** E_o
- (3) Covalent energy E_c

Long range interactions.

- (4) Madelung energy E_M
- (5) Van der Waals energy E_V

The necessity of the introduction of a new and fairly strong interaction such as covalency for zincblende is indicated also by the following fact. The usual Born-Mayer's method, which takes into account the Madelung, exchange and Van der Waals interactions between constituent ions, and in which the force constants are determined by using the observ-

* The results in this paper were partly reported at the Autumn Meeting of the Society of Applied Physics (Japan), held at Okayama in October 1957.

** Coulomb overlap energy means the correction to the Madelung energy for overlap of the electron clouds of ions adjacent to one another.

ed values of lattice constant and compressibility, gives a fairly low value of cohesive energy in comparison with the observed value (cf. Table V), in contrast with the typical ionic crystal such as alkali halide. On the contrary, if we determine force constants in the Born-Mayer's equation by using the observed values of lattice energy and lattice constant, the compressibility obtained becomes much smaller than the observed one.

Madelung energy has usual expression except that the effective ionic charge is reduced to $\pm Ze$. In §2, we will determine the form of Van der Waals interaction using the empirical values of polarizabilities and ionization potentials of the constituent ions, and the form of Coulomb overlap energy by using the wave functions of both ions. In §3, the forms of potentials of exchange repulsion and covalent interaction are determined from the empirical values of lattice constant, compressibility and cohesive energy. Further in §4, in order to examine the reliability of the potential forms obtained above, the lattice energy variation due to the virtual displacement of one cation or anion in (111) direction (cf. Fig. 1) are calculated, taking into account

are tabulated in Appendix.

§2. Determination of the Van der Waals Energy and Coulomb Overlap Energy

(1) Van der Waals energy

Van der Waals energy between two ions is given by²⁾

$$\varepsilon_{ij} = -C_{ij}/r_{ij}^6, \quad (2.1)$$

where r_{ij} is the interionic distance and

$$C_{ij} = \frac{3}{2} \frac{\varepsilon_i \varepsilon_j}{\varepsilon_i + \varepsilon_j} \alpha_i \alpha_j. \quad (2.2)$$

In (2.2), ε_i and ε_j may be assumed to be approximately equal to the series limits of the discrete spectra of the two ions, i.e. their ionization energies³⁾, and α_i and α_j are their polarizabilities.

The first ionization energy of free Zn^{2+} ion, ε_{Zn} , is 39.5 eV⁴⁾ and that of S^{2-} ion in zincblende, ε_{S} , is estimated to be 5 eV*.

J. R. Tessman et al⁷⁾ have given an approximate measure of the electronic polarizabilities of various ions in crystals, rather than as "free" ions. According to their estimation, in zincblende the polarizabilities of Zn ion and S ion are 0.8 Å³ and 4.9 Å³ respectively.

By inserting the numerical values of ε_{Zn} , ε_{S} , α_{Zn} and α_{S} in (2.2), we may compute C_{++} , C_{--} and C_{+-} as follows.

$$\begin{aligned} C_{++} &= 30.36 \times 10^{-60}, & C_{--} &= 144.2 \times 10^{-60}, \\ C_{+-} &= 41.81 \times 10^{-60} \text{ (erg cm}^6\text{)}. \end{aligned} \quad (2.3)$$

(2) Coulomb overlap energy

The Coulomb overlap energy ε_0 between two ions⁸⁾ is computed by numerical calculations by using the radial charge densities of S^{2-} and Zn^{2+} ions evaluated from their wave functions on the assumption of spherical charge distribution.

In zincblende, the actual state of the crystal

Fig. 1. Atomic arrangement in a unit cell of zincblende.

the polarization energy of the displaced ion and all the ions surrounding it. For this purpose, it is necessary to calculate the Madelung constant, the constants in Van der Waals energy expression, the electric field originating from the surrounding ionic charges and some constants associated with the polarization energy of surrounding medium at various positions of the displaced ion. These values

* The ionization energy for $\text{S}^{2-} \rightarrow \text{S}^-$ in free state is estimated to be about -5 eV⁶⁾. For S^{2-} ion in the crystal, however, the energy required to remove one valence electron of S^{2-} ion and to place it on a Zn^{2+} ion in the vicinity or at infinity should be used as ε_{S} , since this transition evidently corresponds to ionization. The latter energy ε is estimated to be about 10.5 eV and the former ε' is identified with that of the first excitation band 6 eV⁶⁾. On the other hand, if the absorption edge is identified with the latter energy, ε is equal to about 3.5 eV⁶⁾. Taking into consideration these numerical values, we assume $\varepsilon_{\text{S}} \approx 5$ eV.

may be assumed to be intermediate between the totally ionic state consisting of S^{3-} ($3s^2, 3p^6: ^1S_0$) and Zn^{2+} ($3d^{10}: ^1S_0$), and the totally covalent one consisting of S^{2+} ($3s, 3p^3: ^4S$) and Zn^{2-} ($4s, 4p^3: ^4S$)⁹⁾. Since the effective charge of each of the constituent ions of zincblende is estimated to be $\pm 2 \times 0.83 e^{1)}$, on the orbitals $4s, 4p^3$ of Zn ion there are 0.34 electrons on the average. These wave functions of S^{2-} and Zn^{2-} ions may be computed by interpolation¹⁾ from those of Cl^- ion¹⁰⁾ and As^+ ion¹¹⁾.

Table I. Coulomb overlap energy (eV) versus interionic distance a (AU).

a	ϵ_o
2.202	-33.4287
3.303	-13.8986
4.405	-3.1428
5.506	-0.5560
6.607	-0.0988 ₆

The computed values of ϵ_o between Zn^{2+} - S^{2-} ion pair are tabulated in Table I and plotted in Fig. 2 against interionic distance a . As shown in Fig. 2, these values fall on a straight line in semi-log plotting, except for small values of a . Therefore, in the straight part ϵ_o may be expressed in the form $\epsilon_o = -b_o \exp(-a/\rho_o)$, and the values of ρ_o and b_o are 0.336 Å and 5.259×10^{-9} erg respectively. Then

$$\begin{aligned} \epsilon_o(a) &= -b_o \exp(-a/\rho_o) \\ &= -5.259 \cdot \exp(-a/0.336 \times 10^{-8}) \times 10^{-9} \text{ erg} \\ &\hspace{10em} (a \text{ in cm}). \end{aligned} \tag{2.4}$$

Since the computed values of ϵ_o deviate from the straight line at small values of a , we obtain its actual values for that range of a by multiplying a correction factor (<1) which is determined from Fig. 2, to the values obtained by the formula (2.4).

§ 3. The Determination of Exchange Repulsion and Covalency Attraction Energies

The customary form of repulsive energy ϵ_R for two interacting ions separated by a distance a is

$$\epsilon_R(a) = b_R \exp(-a/\rho_R). \tag{3.1}$$

Furthermore, we will assume the form of the covalent binding energy in an analogous form

$$\epsilon_o(a) = -b_o \exp(-a/\rho_o). \tag{3.2}$$

Then we have to determine the four unknown parameters b_R, ρ_R, b_o and ρ_o .

At first, ρ_R may be evaluated by using Williams' method⁸⁾. According to his notation, the repulsive energy is expressed approximately by

$$\epsilon_R(a) = K' S^2/a, \tag{3.3}$$

where K' is a constant and S is the overlap integral defined by

$$S = \int \varphi_A \varphi_B dV, \tag{3.4}$$

φ_A and φ_B are $\sqrt{4\pi}$ times the square roots of the total charge densities of the unperturbed A and B ions interacting with each other respectively. In computing (3.4), Williams has used an approximate expression based on the fact that the overlap of the charge distribution only occurs near the segment connecting the nuclei of both ions in KCl.

In ZnS, however, the overlap stated above occurs appreciably even at the position apart from the segment connecting both nuclei. Therefore we will evaluate S using the following exact expression derived from (3.4) by a simple transformation

$$\frac{S}{2\pi} = S' = \frac{1}{a} \int_0^a r \varphi_A(r) dr \int_{|a-r|}^{a+r} \varphi_B(y) dy. \tag{3.5}$$

Table II. Overlap integrals versus interionic distance.

$a(\text{AU})$	S'	S'^2/a
2.202	7.371	24.260
3.303	4.260	5.494
4.405	2.246	1.145
5.506	1.153	0.241 ₅
6.607	0.592	0.053 ₁

$\rho_R = 0.391 \text{ \AA}$

The calculated values of S'^2/a as a function of a using the wave function of S^{2-} and Zn^{2+} ions stated in § 2 are tabulated in Table II and plotted in Fig. 2. Since the curve of S'^2/a in semi-log plotting may be regarded as nearly straight, we can conclude that the repulsive energy ϵ_R is expressed pretty well in an exponential form as (3.1). From Fig. 2, the value of ρ_R may be estimated to be 0.391 Å.

In order to determine the other three unknown parameters b_R , ρ_σ and b_σ , we may employ the experimental data concerning the cohesive energy, lattice distance and compressibility of zincblende.

Fig. 2. Dependences of overlap integral S' and Coulomb overlap energy $\varepsilon_\sigma(a)$ on interatomic distance a .

The cohesive energy per ion pair in the present approximation is expressed as

$$E_{pa}(a) = -A_M \frac{(Ze)^2}{a} - \frac{1}{a^6} \left[C_{+-} S_{V0} + \frac{C_{++} + C_{--}}{2} S_{V0}' \right] + 4b_R \exp(-a/\rho_R) - 4b_\sigma \exp(-a/\rho_\sigma) \quad (3.6)$$

where a is the nearest neighbour distance, A_M Madelung constant, S_{V0} and S_{V0}' well-known constants characteristic of the lattice structure²³. Ze is the magnitude of the effective charge of the constituent ions, $2 \times 0.83e$. In (3.6), the values of all constants except b_R , ρ_σ and b_σ are already known.

On the other hand, we have the well-known relations

$$(dE_{pa}/da)_{a=a_0} = 0, \quad (3.7)$$

$$\frac{1}{a_0} \left(\frac{d^2 E_{pa}}{da^2} \right)_{a=a_0} = \frac{48}{\sqrt{3} \beta}, \quad (3.8)$$

where a_0 is the observed value of a , and β is the compressibility. If we use the experimental values for a_0 ($=2.34 \text{ \AA}^{12}$), β ($=1.306 \times 10^{-12} \text{ barye}^{-1}$ ¹³) and E_{pa} ($E_L^* = N_A E_{pa} = 851$

Kcal/mol, N_A : Avogadro's number¹⁴). Three equations (3.6), (3.7) and (3.8) can determine the unknown parameters b_R , b_σ and ρ_σ as $4.092 \times 10^{-9} \text{ erg}$, $4.148 \times 10^{-11} \text{ erg}$ and $1.489 \text{ \AA}$ respectively. Then (3.1) and (3.2) become

$$\varepsilon_R(a) = 4.092 \cdot \exp(-a/0.391 \times 10^{-8}) \times 10^{-9} \text{ erg}, \quad (3.9)$$

$$\varepsilon_\sigma(a) = -4.148 \cdot \exp(-a/1.489 \times 10^{-8}) \times 10^{-11} \text{ erg} \quad (a \text{ in cm}) \quad (3.10)$$

All the constants known already in references and computed in the present paper (in *italic*) are listed in Table III for convenience.

Table III. Numerical values of parameters* in Zincblende.

A_M	1.6381
S_{V0}	4.354 ²³

* The numerical values in *italic* are computed in the present paper.

§ 4. Lattice Energy Variation due to Virtual Displacement of One Ion

As a first step of the calculation of the formation energy of lattice defects in zincblende, treated in Part II, we will here estimate the lattice energy variation due to the displacement of one anion or one cation in (111) direction indicated in Fig. 1 preserving all the other ions at their respective regular sites, by using the phenomenological expressions of interionic interactions derived in § 2 and § 3. This estimation may also give a criterion as to the accuracy of the results obtained in preceding sections by the following reason. Referring to Fig. 1, we notice that when the reference ion is displaced in positive (111) direction, the potential is steeply

increased by the repulsion originating from the unlike ion sitted in front of the displacement, whereas when the reference ion is displaced in negative (111) direction, the potential will slowly increase and then decrease through a maximum point owing to the lack of the unlike ion in front of the displacement. If the hight of the potential barrier is too low, the crystal will not be stable at high temperatures. Of course, the surrounding ions of the reference ion are also displaced, therefore the barrier height obtained fixing all the other ions is not exact, but will give a measure of the crystal stability.

In performing the calculations, other than short-range and long-range interactions, stated in § 1, between the displaced ion and all the other ions of the crystal, polarization energies of all ions due to the displacement of the reference ion from its regular site, have to be taken into account.

(1) Short-range interactions

Exchange repulsion, covalency attraction and Coulomb overlap energies, so far as they are considered to act only between nearest neighbouring ions, need be taken only between the displaced ion and its four nearest neighbours. Therefore, the energy variation due to these interactions are easily calculated by using the formulae (2.4), (3.9) and (3.10).

(2) Long-range interactions

As regards Madelung and Van der Waals energies, we have to take into considerations those from sufficiently distant ions.

Madelung energy E_M is given by

$$E_M = (Ze)^2 \sum \frac{\delta_i}{a_i} \quad (4.1)$$

where a_i is the distance from the displaced ion to the i th ion in the crystal and δ_i is 1 or -1 according as the i th ion is like or unlike the reference ion. The summation $\sum \delta_i/a_i$ is carried out for several positions of the reference ion by the Ewald's method¹⁵⁾ and the results are tabulated in Appendix.

Van der Waals energy of a reference cation or anion $E_V(+)$ or $E_V(-)$ is given by

$$E_V(\pm) = -[C_+ - S_V + C_{\pm\pm} S_V'] \frac{1}{a_0^6}, \quad (4.2)$$

where

$$S_V = a_0^6 \sum_i^{(u)} \frac{1}{a_i^6} \quad \text{and} \quad S_V' = a_0^6 \sum_i^{(l)} \frac{1}{a_i^6}.$$

$\sum_i^{(u)}$ and $\sum_i^{(l)}$ means the summations only with respect to unlike ions and like ions as the reference ion respectively. When the reference ion is at its regular site, S_V and S_V' coincide with S_{V0} and S_{V0}' respectively. The numerical results S_V and S_V' at several positions of the reference ion are also listed in Appendix.

(3) Polarization energies

If one ion in the crystal is displaced from its regular site, it is acted on by the electric field from the other ions in the crystal. This field intensity in (111) direction on the reference ion is given by

$$E = \sum e_i \bar{a}_i / a_i^3 = \pm (Ze) \sum \bar{a}_i \delta_i / a_i^3, \quad (4.3)$$

where $\bar{a}_i$ is the component in (111) direction of the vector $\mathbf{a}_i$ pointing from the i th ion with charge e_i to the displaced reference ion. $+$ and $-$ signs in (4.3) correspond to the cases of positive and negative reference ion respectively. The summation is carried out by means of Ewald's method and the numerical results are also given in Appendix. Then the polarization energy of the reference ion with polarizability α becomes

$$E_P = -\frac{1}{2} \alpha E^2. \quad (4.4)$$

On the other hand, all the other ions in the crystal are also polarized by the displacement of the reference ion stated above. These polarization energies may be estimated as follows:

If the vector drawn from the i th ion to the regular site of the reference ion with charge Ze is denoted by $\mathbf{a}_{i0}$, the electric field $\mathbf{D}_i$ exerted on the i th ion by two point free charges $-Ze$ and Ze as the results of the displacement of the reference ion in the direction (111) is given by

$$\mathbf{D}_i = \frac{Ze}{a_i^3} \mathbf{a}_i - \frac{Ze}{a_{i0}^3} \mathbf{a}_{i0}. \quad (4.5)$$

The dipole moment μ_i on the i th ion is then written as¹⁶⁾

$$\mu_i = M_{0i} a_0^3 \mathbf{D}_i, \quad (4.6)$$

where

$$M_{0i} = M_{0\pm} = \frac{2\alpha_{\pm}}{\alpha_+ + \alpha_-} \frac{1}{4\pi} \left(1 - \frac{1}{\kappa_0} \right), \quad (4.7)$$

according as the i th ion being cation or anion, and κ_0 is the optical dielectric constant of the

crystal ($=5.07^{13}$). In (4.7) the atomic polarization of the ions is not taken into account, since we have assumed all but the reference ion to be fixed at their respective regular sites.

Then the polarization energy E_{PL} of the ions except the reference ion is given by

$$E_{PL} = -\frac{1}{2} \sum_i (D_i \mu_i). \quad (4.8)$$

From (4.4), (4.6) and (4.8), we obtain

$$E_{PL} = -\frac{1}{2} (Ze)^2 a_0^3 \sum_i M_{0i} \left(\frac{1}{a_i^4} + \frac{1}{a_{i0}^4} - 2 \frac{\cos \theta_i}{a_i^2 a_{i0}^2} \right), \quad (4.9)$$

where θ_i is the angle between the vectors $\mathbf{a}_i$ and $\mathbf{a}_{i0}$. ($\cos \theta_i = (\mathbf{a}_i \mathbf{a}_{i0}) / (a_i a_{i0})$).

If we put

$$\left. \begin{aligned} C &= a_0^4 \sum_i^{(\alpha)} \frac{1}{a_i^4}, & C' &= a_0^4 \sum_i^{(l)} \frac{1}{a_i^4}, \\ G &= a_0^4 \sum_i^{(u)} \frac{\cos \theta_i}{a_{i0}^2 a_i^2}, & G' &= a_0^4 \sum_i^{(l)} \frac{\cos \theta_i}{a_{i0}^2 a_i^2}, \end{aligned} \right\} \quad (4.10)$$

E_{PL} is written as

$$E_{PL}(\pm) = -\frac{1}{2} \frac{(Ze)^2}{a_0} \{ (C_0 + C - 2G) M_{\mp} + (C'_0 + C' - 2G') M_{\pm} \}, \quad (4.11)$$

where the upper signs correspond to a positive reference ion and the lower signs to a

negative one, and C_0 and C'_0 are the values of C and C' at $\Delta a = |\mathbf{a}_i - \mathbf{a}_{i0}| = 0$. When $\Delta a = 0$, $G = C_0$ and $G' = C'_0$. Then $E_{PL}(\pm) = 0$. The values of C_0 and C'_0 is well known as¹⁷⁾

$$C_0 = 6.6697, \quad C'_0 = 3.5633.$$

The values of C , C' and G , G' for various values of Δa are computed and shown in Appendix.

Summing all the energy terms stated above, we obtain the total energy changes $\Delta E(+)$ or $\Delta E(-)$ due to one cation or anion displacement Δa .^{*} The results are plotted in Fig. 3.

Referring to Fig. 3, we may point out that the potential barrier is fairly high, so the crystal will be stable even at about 1000°C. ($\exp(-\Delta E/kT) \approx 10^{-4}$). Therefore, the potential forms derived in preceding sections may be considered as reasonable.

§ 5. Conclusions

Covalency corrections introduced in our model are summarized as follows:

- (1) The effective charges of Zn and S ions are assumed to be $2 \times 0.83e$ and $-2 \times 0.83e$ respectively.
- (2) The attractive energy originating from covalency binding is introduced in the exponential form $-b_0 \exp(-a/\rho c)$.

However, this model contains some departures from the actual aspects in the case of zincblende, since the degree of covalency will be a function of the interionic distance. Accordingly, the effective charge and the polarizability of a constituent ion may also change with the interionic distance. But it will be practically impossible to take account of these detailed behaviours thoroughly. Because it is not known nowadays in what manner the covalency degree changes with interionic distance, if we want to take account of this fact it is necessary to introduce some unknown parameters to be determined phenomenologically in addition to those occurring in (3.6). However, our model would be applicable to actual zincblende crystal approximately, so far as the displacement of a ion is not very large.

Lastly, the cohesive energy per mol, E_L^* , obtained in our model is classified in Table IV,

* The displacement in positive and negative (111) directions, Δa , are taken as positive and negative respectively.

Fig. 3. Lattice energy variation $\Delta E(+)$ and $\Delta E(-)$ due to one cation or anion displacement along (111) direction.

Table IV. Classification of lattice energy in Kcal/mol.

	Present Model	Born-Mayer
Madelung	639.2	927.9
Covalency	495.0	
Repulsion	-588.4	-167.2
Coulomb Overlap	283.6	
Van der Waals	21.6	21.6
E_L^*	851.0	782.3

where the classified values of the energy obtained by using usual Born-Mayer equation (ionic model) are also tabulated for comparison. In ionic model, Madelung, overlap repulsion and Van der Waals interactions are taken into account. For the calculation of Madelung energy, the effective charges of Zn and S ions are taken to be $\pm 2e$, and for the repulsive potential the form $b_{R'} \exp(-a/\rho_{R'})$ are

used, in which $b_{R'}$ and $\rho_{R'}$ are determined by the conditions (3.7) and (3.8);

$$b_{R'} = 1.625 \times 10^{-9} \text{ erg}, \quad \rho_{R'} = 0.370 \text{ \AA} \quad (5.1)$$

In ionic model, the repulsive energy derived in this way, includes the Coulomb overlap energy in the present model¹⁸⁾.

With regards Table IV, it may be pointed out that the covalency attractive energy nearly amends the decrease in Madelung energy, which is caused by the decrease in effective charge of the ions.

Appendix

a_i is the magnitude of a vector $\mathbf{a}_i$ pointing from the i th ion in the crystal sitting at its normal position to the reference ion, displaced in (111) direction in Fig. 1 by an amount Δa from its regular lattice site. δ_i is 1 or -1 according as the i th ion being like or unlike as the reference ion. $\bar{a}_i$ is the component of

Table V.

the vector $\mathbf{a}_i$ in (111) direction.

Madelung constant in the 1st column and the coefficient of electric field in (111) direction, in the 2nd column, originating from all the ions (regarded as point charge) except the reference ion (cf. (4.3)) are calculated anew by Ewald's method, with the precision of five decimals. It should be noticed that for $\Delta a=0$ the values 1.66216 is obtained instead of 1.6381 given first by Ewald. However, the difference in energy due to this correction is very small, so that we will use the traditional value of Madelung constant

throughout the present work.

In the 3rd, 5th and 7th columns, summations are carried out only with respect to like ions as the reference ion and in the 4th 6th and 8th columns with respect to unlike ions only. These summations are actually performed in 57 unit cells around the reference ion, where about 450 ions are contained. The small contributions from the residual outer region of the crystal are obtained by expanding the summands in terms of power series of Δa and integrating them to infinity. The lower limits of the integrations are ef-

fectually determined by comparing the sums obtained in the 57 unit cells stated above for $\Delta a=0$ with the corresponding values published in references.^{2),17)} Since the convergences of these summations are so fairly good, in particular for S_V and S_V' , that the simple method stated above may be allowed.

Lattice Defects in Zincblende Part II. Formation Energy of Lattice Defects.*

By Sumitada ASANO and Yasuo TOMISHIMA

Department of Physics, Faculty of Science, Okayama University

(Received July 3, 1958)

The formation energies of various types of lattice defects in zincblende are calculated by means of Mott-Littleton's method. A phenomenological expression of interionic potential which contains the covalency binding energy is used in the calculation. In addition, the total energy when the lattice around a defect is not in equilibrium is computed at several positions of the surrounding ions of the defect near the equilibrium point. The results of calculation show that the formation energies of Schottky defect, double hole and Frenkel defect by zinc ion are estimated to be 4~6 eV. The result that the formation energy of Schottky defect is nearly equal to that of double hole is qualitatively in agreement with the experimental results which have been obtained with pure host crystal of ZnS phosphor.

§ 1. Introduction

The formation energies of Schottky defects in alkali halides and alkali-earth oxides have been computed by using the ionic model by

several authors.^{1),2)} This model, however, is not suited for the case of zincblende, since the binding energy due to covalency has fairly large proportion in the total lattice energy. We have showed this fact actually by quantum mechanical calculation.³⁾ According to the results of this calculation, the lattice energy of zincblende is lowered by about 60 % when

* The results in this paper were partly reported at the Hiroshima Meeting of the Chugoku-Shikoku Branch of the Physical Society of Japan, in February 1958.

the covalency correction is taken into account, and the effective charges on constituent ions are estimated to be $\pm Ze = \pm 2 \times 0.83e$ (e : absolute value of electronic charge).

By using these results, we determined, in Part I⁴⁾, the phenomenological expression of the interionic potential in zincblende, which is analogous to the Born-Mayer's one in purely ionic crystals. In this paper, the formation energy of lattice defect in zincblende is computed by using the results obtained in

Part I.
First, we will calculate, in § 2 and § 3, the energy required to remove an ion in a regular site and that required to interpose an ion to an interstitial site, then in § 4 we derive the formation energies of Schottky and Frenkel defects by combining these energies. In addition, we will estimate in § 5 the dissociation energies of double hole and double interstitial ion. Table I shows the physical constants of zincblende, which are used in this calculation.

Table I. Physical constants of zincblende.

A_M	1.6381	M_+	0.0370
a_0 (Å)	2.34 ⁶⁾	M_-	0.1785
κ	8.3 ⁶⁾	C_{++} (erg cm ⁶)	30.36×10^{-80}
κ_0	5.07 ⁶⁾	C_{+-} (")	41.81×10^{-80}
α_- (Å ³)	0.87 ⁷⁾	C_{--} (")	144.22×10^{-80}
α_+ (Å ³)	4.97 ⁷⁾	E_L (eV/ion pair)	36.9212 (=851 Kcal/mol) ⁸⁾

The numerical values of C_{++} , C_{+-} and C_{--} have been calculated in § 2 of Part I.

§ 2. Energy Required to Remove an Regular Ion

In this section we will calculate $W(+)$ or $W(-)$ required to remove a cation or an anion in a regular site to an infinitely distant position respectively. First, the positions of the four ions adjacent to the vacancy are considered to be fixed at their respective

Fig. 1. Atomic arrangement around a vacancy in zincblende. An ion represented by dot is located at the center of the cube in perfect lattice. In double hole the ion $\bar{1}$ is missed also.

original sites. (cf. Fig. 1) The work necessary for the removal consists of the following terms.

(1) *Madelung and Van der Waals energies*
Since the ions removed from the crystal

must have the effective charges $\pm Z_0e$ ($Z_0=2$), the electron cloud having charge $-(Z_0-Z)e/4$ on the cation, which is transferred from the adjacent anion owing to the covalency bonding the two ions, will return to the parent anion after the bond has been cut off. Then the electronic polarizability of the anions around the cation vacancy will be slightly increased owing to the increase in magnitude of effective electronic charge. On the other hand, that of the cations around the anion vacancy will be decreased.

We assume that the electronic polarizability varies between $\alpha_{\pm}$ and $\alpha_{\pm}^0$ linearly with effective charge of the ion, where $\alpha_{\pm}$ are the electronic polarizabilities of the ordinary ions with effective charges $\pm Ze$ and $\alpha_{\pm}^0$ are those of the ions with effective charges $\pm Z_0e$. $\alpha_{\pm}$ are 0.8×10^{-24} cm³ and 4.9×10^{-24} cm³ as stated in Part I. In order to estimate $\alpha_{\pm}^0$, we will use the Kirkwood's formula,⁹⁾

$$\alpha = K \left[\sum_i \int_0^\infty r^2 P_i^2 dr \right]^2 / N, \tag{2.1}$$

where K is a constant, P_i^2 the radial density of the i th electron and N is the total number of electrons¹⁰⁾ of the ion. By using the wave functions of S and Zn ion stated in Part I, we may estimate the ratios of $\alpha_{\pm}^0$ to $\alpha_{\pm}$ to be $\alpha_+^0/\alpha_+ = 0.7314$ and $\alpha_-^0/\alpha_- = 1.059$. Therefore we have $\alpha_+^0 = 0.585 \times 10^{-24}$ cm³ and α_-^0

$5.19 \times 10^{-24} \text{ cm}^3$. Then the values of the electronic polarizabilities $\alpha^{+'}$ and $\alpha^{-'}$ of the cation and anion with effective charge

$$\pm(Z + (Z_0 - Z)/4)e = 1.75e$$

become $0.747 \times 10^{-24} \text{ cm}^3$ and $4.958 \times 10^{-24} \text{ cm}^3$ respectively.

Then the contributions from Madelung and Van der Waals energies are given by

$$E_M = A_M \frac{Z^2 e^2}{a_0} + 6 \frac{Z^2 e^2}{a_0} \left(\frac{a_0}{a_1} \right) \left[\left(\frac{Z'}{Z} \right)^2 - 1 \right] - 4 \left[A_M - 1 + \frac{3a_0}{a_1} \right] \left(\frac{Z'}{Z} - 1 \right) \frac{Z^2 e^2}{a_0} \quad (2.2)$$

and

$$E_V(\pm) = \frac{1}{a_0^6} [C_{+-} S_{V_0} + C_{\pm\pm} S'_{V_0}] - \frac{1}{a_0^6} \left\{ (S_{V_0} - 1)(C'_{\mp\pm} - C_{+-}) + \left[S'_{V_0} - 3 \left(\frac{a_0}{a_1} \right)^6 \right] (C'_{\mp\pm} - C_{\mp\mp}) \right\} \times 4 - \frac{6}{a_0^6} (C''_{\mp\mp} - C_{\mp\mp}), \quad (2.3)^*$$

where

$$Z' = Z + (Z_0 - Z)/4 = 1.75, \quad \frac{a_0}{a_1} = \frac{1}{2} \sqrt{\frac{3}{2}}, \\ S_{V_0} = 4.354,^{10)} \quad S'_{V_0} = 0.762,^{10)} \\ C'_{\mp\pm} = C_{+-} \alpha_{\mp}' / \alpha_{\mp}, \quad C'_{\mp\mp} = C_{\mp\mp} \alpha_{\mp}' / \alpha_{\mp}, \\ C''_{\mp\mp} = C_{\mp\mp} (\alpha_{\mp}' / \alpha_{\mp})^2. \quad (2.4)$$

a_0 is the nearest neighbour distance and a_1 the next-nearest neighbour distance.

(2) Polarization energy.

The polarization energy E_P of the medium is given by

$$E_P = -\frac{1}{2} \sum_i (\mu_i D_i). \quad (2.5)$$

μ_i is the dipole moment on the i th ion, including both electronic and atomic polarization, and D_i is electric field acting on it from the free charge $\mp Z_0 e$, $\mp Ze$ of which is located at the centre of the vacancy and the residual charge $\mp(Z_0 - Z)e$ is equally shared on the four nearest-neighbouring ions.

In the first order approximation, we may write the polarization energies $E_P(\pm)$ as

* The upper of the double sign in the energy expressions corresponds to the case of the removal or interposol of a cation, and the under to the case of the removal or interposol of an anion, hereafter.

$$E_P(\pm) = E_P^*(\pm) + E_{P1}(\pm). \quad (2.6)$$

The first term of the above equation is the polarization energy of all the ions in the crystal other than the four around the vacancy, calculated on the continuum model following Mott and Littleton,¹⁾ and is given by

$$E_P^*(\pm) = -\frac{1}{2} \frac{(Z_0 e)^2}{a_0} [(C_0 - 4)M_{\mp} + C_0' M_{\pm}], \quad (2.6a)^{**}$$

where C_0 and C_0' are the numerical constants 6.697¹¹⁾ and 3.563 $\left(= 6.3346 \times \left(\frac{\sqrt{3}}{2} \right)^4 \right)^{11)}$ respectively. $M_{\pm}$ are given by

$$M_{\pm} = \frac{4}{3\sqrt{3}\pi} \left(1 - \frac{1}{\kappa_0} \right) \left[\frac{\alpha_{\pm}}{\alpha_{+} + \alpha_{-}} + \frac{1}{2} \frac{\kappa - \kappa_0}{\kappa(\kappa_0 - 1)} \right], \quad (2.7)$$

where κ and κ_0 are the static and optical dielectric constants respectively. (cf. App. I) The numerical values of M_{+} and M_{-} are 0.0370 and 0.1785.

The second term in (2.6) is the contribution from four ions (ions, $\bar{1}$, $\bar{2}$, $\bar{3}$ and $\bar{4}$ in Fig. 1) adjacent to the vacancy and is given by

$$E_{P1}(\pm) = -\frac{1}{2} \left(\frac{Ze}{a_0^2} \right) \mu_1(\mp) \times 4, \quad (2.8)$$

$$\mu_1(\mp) = \frac{D + (Z_0/Z)(SM_{\pm} + S'M_{\mp})}{1 + 5\epsilon\alpha_{\mp}'/a_1^3} \left(\frac{Ze}{a_0^2} \right) \epsilon\alpha_{\mp}', \quad (2.9)$$

where $\mu_1(\mp)$ means the dipole moment on one of the four ions adjacent to the vacancy, which is derived by the same procedures as in the case of rock salt.¹²⁾ $(Ze/a_0^2)D$ is the electric field at one of these four ions due to the free charges at the vacancy and the other three ions adjacent to the vacancy and $(Z_0 e/a_0^2)(SM_{\pm} + S'M_{\mp})$ is that due to dipoles on all the ions outside these four ions. The numerical values of D , S and S' are 1.0441, 0.577 and 0.266 respectively.^{***}

The electronic polarization of an anion neighbouring to the cation vacancy is hindered to some extent by the overlap repulsive force

** In (2.6a), the calculations of electric field and dipole moment on a ion outside the four nearest neighbours around the vacancy are simplified by regarding the dispersed free charges as a point charge $Z_0 e$ at the center of the vacancy.

*** In calculating S and S' , the summations are taken over 21 rings around the vacancy. The contributions from rings outside them are estimated to be less than 0.005.

between this anion and the three cations adjacent to it.²⁾ This situation is taken into account in (2.9) by using $\varepsilon\alpha_-'$ ($0<\varepsilon\leq 1$) instead of α_-' . However, for $\mu_1(+)$ in (2.9), ε should be taken as unity, since the ionic radius and electronic polarizability of a cation are very small in comparison with those of an anion.

(3) Short-Range Force.

For the sake of simplicity, it is assumed that the three remaining covalency bonds of each ions adjacent to the vacancy is not affected by the removal of the central ion. Then the energy for removal of a central ion

due to short range forces is given by

$$E_S=4F_S(a_0)=4[b_0\exp(-a_0/\rho_0)$$

$+b_c\exp(-a_0/\rho_c)-b_R\exp(-a_0/\rho_R)]\;.$

(2.10)

The numerical values of the force constants b 's and ρ 's are given in Table III in Part I.

(4) Energy depression by atomic relaxation.

Next we will consider the reduction of lattice energy $\Delta E(\pm)$, due to atomic polarization of the four ions adjacent to the vacancy. It is evident that these four ions are symmetrically displaced in the radial directions joining the center of the vacancy to their respective regu-

Table II. Numerical values (eV) of energy terms constituting $W(\pm)$

ε	$W(+)$				$W(-)$
	1.0	0.9	0.8	0.7	1.0

W	17.5370	18.3823	19.2469	20.1249	22.9527
$E_p^{(0)}$		-16.3524			-12.0107
s_m	-0.06370	-0.05528	-0.04280	-0.02774	0.0883

s_m is the value of s corresponding to the minimum energy and $E_p^{(0)}$ is the polarization energy in zero-order approximation.

lar sites. Let us pick up only those parts of the lattice energy, which vary with the displacement of these four ions neighbouring to the vacancy.

The changes of Madelung and Van der Waals energies may be immediately computed from the results in Appendix of Part I. Here it should be noted that, for these four ions the effective charges $\mp Z'e$ and electronic polarizabilities $\alpha'_{\mp}$ have to be used unlike those of the other regular ions in the crystal.

The part of the polarization energy which changes with the displacement of the four ions consists of both $E_{p1}(\pm)$ given by (2.8 and 9), in which D, S, S' and a_1 vary with displacement sa_0^* of the four ions**, and

* Outward displacement of the ions around the vacancy is taken as positive.

** The changes of S and S' are computed with five rings around the vacancy and the small contribution from outer rings are neglected.

Fig. 2. Total energy change $\Delta E(\pm)$ with atomic relaxation around vacancy.

$E_{PL}(\pm)$, the polarization energy of all the ions other than the four, given by

$$E_{PL}(\pm) = -\frac{Z_0 Z'}{a_0} e^2 [M_{\pm} Q + M_{\mp} Q'] \times 4, \quad (2.11)$$

where Q and Q' are numericals depending on s . The derivation of (2.11) is stated in Appendix II.

The varying part of the short range energy is given by

$$E_s(s) = 3F_s(r_2) \times 4, \quad (2.12)$$

where $r_2 \left(= \frac{a_0}{\sqrt{3}} \sqrt{3s^2 - 4s + 4} \right)$ is the distance from an ion adjacent to the vacancy to one of the unlike ions neighbouring to it.

Fig. 2 shows the change of the total energy due to the displacement of the four ions for various cases. The maximum depressions $\Delta E_m(\pm)$ for the cation and anion vacancies are determined by expressing each energy contour in a quadratic form of the displacement s which are determined by the method of least mean square from several computed points near the origin $s=0$. These values are shown in Table II.

Thus $W(\pm)$ are given by

$$W(\pm) = E_M + E_V(\pm) + E_P(\pm) + E_s + \Delta E_m(\pm). \quad (2.13)$$

The results of the numerical calculation are given in Table II.

§ 3. Work Required to Interpose an Interstitial Ion.

In this section we will calculate the work $W(+)$ or $W(-)$ necessary to bring a cation or an anion to an interstitial site. In zincblende, there are two types of interstitial sites, one is adjacent to four anions and the other to four cations. (cf. Fig. 3) A cation would preferably occupy the former, whereas an anion the latter, since the electrostatic energy becomes somewhat higher in the inverse cases. In particular, when a sulphur ion is interposed to the former, the overlap repulsive energy between the interposed sulphur ion and the four sulphur ions surrounding it will be conspicuously high because of large ionic radius of sulphur ion. Therefore, we will consider only an interstitial cation adjacent to four anions and an interstitial anion adjacent to four cations.

Furthermore, we assume that the interstitial ion has no covalency bonds but only ionic

interactions with the neighbouring ions and that it does not affect the covalency bonds between these ions and their neighbours in normal sites. First, we assume that the four ions adjacent to an interstitial ion are fixed to their respective regular sites. Then the energy required for the interposition consists of the following parts.

Fig. 3. Atomic arrangement around an interstitial site in zincblende. The dot at the center of the cube represents an interstitial ion. In double interstitial ion the ion represented by circle is also interposed at the point marked by cross.

(1) *Madelung and Van der Waals energies* are expressed as follows:

$$E_M' = -A_M' \frac{Z_0 Z e^2}{a_0}, \quad (3.1)$$

where

$$A_M' = A_M - 1.7476 \times \sqrt{3}/2 = 0.1246.$$

1.7476 is the Madelung constant of rock salt type crystal.

$$E_V'(\pm) = -\frac{1}{a_0^6} [C_{\pm\mp}^0 S_{V0} + C_{\pm\pm}^0 S_{V0}''], \quad (3.2)$$

where

$$S_{V0}'' = 6.5952 \times (\sqrt{3}/2)^6 = 2.7824$$

$$C_{\pm\mp}^0 = C_{\pm} - (\alpha_{\pm}^0 / \alpha_{\pm}), \quad C_{\pm\pm}^0 = C_{\pm\pm} (\alpha_{\pm}^0 / \alpha_{\pm}).$$

6.5952 is the corresponding constant of rock salt type crystal.¹⁰⁾

(2) *Polarization energy.*

The distance between the interstitial ion and its second nearest-neighbours is $(2/\sqrt{3})a_0$ ($=1.1547a_0$). Therefore, it is necessary to treat, even in the first order approximation, six second nearest-neighbours (ions 1, 2, ... 6 in Fig. 3) together with the four first ones (ions $\bar{1}$, $\bar{2}$, $\bar{3}$ and $\bar{4}$ in Fig. 3) from the atomistic standpoint. Then

$$E_P'(\pm) = E_P^{*'}(\pm) + [E_{P1}'(\pm)]_{s=0}. \quad (3.3)$$

The first term in (3.3) is the polarization energy of all the ions except the first and the second nearest-neighbours on the continuum model, and is given by

$$E_P^{*'}(\pm) = -\frac{1}{2} \frac{(Z_0 e)^2}{a_0} [(C_0 - 4)M_{\mp} + (C_0'' - 3.3750)M_{\pm}], \quad (3.3a)$$

where $C_0'' = 5.7362 (= 10.1977 \times (\sqrt{3}/2)^{11})$

The second term E_{P1}' is the contribution from these ten ions to be added to the first term. (cf. App. III) $[E_{P1}'(\pm)]_{s=0}$ is the value of $E_{P1}'(\pm)$ at $s=0$.

(3) Short range energy.

In totally ionic state the short range forces between an interstitial ion and a nearest regular ion in the crystal will be nearly similar to those between two adjacent regular ions in the crystal. However, actually, the latter should be considered as the short range forces between S^{2-} and Zn^{2+} or Zn^{2+} and S^{2-} , binded with one another by predominantly ionic interaction. Since we cannot find any appropriate way to determine the force constants of these short-range forces, the short range interaction between S and Zn ions in zincblende in the case, where the interaction between them is considered as totally ionic, is used instead of the short range interactions between S^{2-} and Zn^{2+} or Zn^{2+} and S^{2-} .

Then the short-range interaction energy may be expressed as

$$E_S' = 4b_R' \exp(-a_0/\rho_R') = 4F_S'(a_0). \quad (3.4)$$

The numerical values of b_R' and ρ_R' are shown by (5.1) in Part I.

(4) Energy Depression by Atomic Relaxation.

Next, we will consider the energy depression $\Delta E'(+)$ or $\Delta E'(-)$ resulting from atomic polarization of four anions or actions adjacent to an interstitial cation or anion respectively. Let us pick up only the parts of lattice energy varying with the displacements of the four ions adjacent to an interstitial ion.

The change of Madelung and Van der Waals energies may be easily computed from the results shown in Appendix of Part I, considering that the interposed ion has effective charge $\pm Z_0 e = \pm 2e$ and electronic polarizability $\alpha_{\pm}^0$.

The varying parts of the polarization energy are given by the sum of $E_{P1}'(\pm)$ and

$$E_{PL}'(\pm) = \frac{Z_0 Z}{a_0} e^2 [M_{\pm} Q'' + M_{\mp} Q'] \times 4, \quad (3.5)$$

where Q'' is a numerical depending on the displacement s and may be easily obtained from the value of $\bar{Q}''$ in Appendix IV. $E_{PL}'(\pm)$ is the polarization energy of all the ions other than four nearest neighbours and six next nearest neighbours of the interstitial ion. Eq. (3.5) may be derived in a similar manner as stated in App. II.

Short range energy is given by

$$E_S'(s) = [3F_S(r_2) + F_S(a_0 + a_0 s) + F_S'(a_0 - a_0 s)] \times 4, \quad (3.6)$$

where

$$r_2 = a_0 \sqrt{3s^2 - 4s + 4} / \sqrt{3}.$$

Fig. 4. Total energy change $\Delta E'(\pm)$ with atomic relaxation around interstitial ion.

Fig. 4 shows the change $\Delta E'(\pm)$ of the total energy for various cases. The maximum energy depressions $\Delta E_m'(+)$ and $\Delta E_m'(-)$ for the interstitial cation and anion may be determined in the same manner as in § 2. These values are shown in Table III.

Then $W'(\pm)$ are given by

$$W'(\pm) = E_M' + E_V'(\pm) + E_P'(\pm) + E_S' + \Delta E_m'(\pm). \quad (3.7)$$

Table III. Numerical values (eV) of energy terms constituting $W(\pm)$.

ε	$W'(+) $				$W'(-)$
	1.0	0.9	0.8	0.7	1.0

s_m	- 0.07116	- 0.07012	- 0.06994	- 0.06427	- 0.01496

The results obtained are shown also in Table III.

§ 4. Formation Energy of Lattice Defects

As lattice defects, we will consider, in addition to Schottky and Frenkel defects, the defect such that a cation and an anion on the surface of crystal are released into crystal and located at interstitial sites distant from one another, which may be called "inverse Schottky defect."

The formation energies W_S , W_F and W_S' of Schottky, Frenkel and inverse Schottky defects are written in the following forms.

$$W_S = W(+) + W(-) - E_L, \quad (4.1)$$

$$W_F(\pm) = W(\pm) + W'(\pm), \quad (4.2)$$

and

$$W_S' = W'(+) + W'(-) + E_L, \quad (4.3)$$

where $E_L(>0)$ is the lattice energy per ion-pair. The numerical values of these formation energies obtained from the results of § 2 and § 3 are shown in Table IV.

Table IV. Numerical values (eV) of W_S , $W_F(\pm)$ and W_S' .

ε	1.0	0.9	0.8	0.7
W_S	3.5729	4.4182	5.2828	6.1608
$W_F(+)$	3.2655	4.6195	6.0945	7.4976
$W_F(-)$		10.4173		
W_S'	10.1099	10.6186	11.2290	11.7541

§ 5. Estimation of Dissociation Energies of Double Defects

As double defects, the pair of a cation vacancy and an anion vacancy adjacent to

one another and the pair of an interstitial cation and an interstitial anion adjacent to one another are considered here. We call the former a double hole and the latter a double interstitial ion. (cf. Figs. 1 and 3)

First the polarization energy of medium which appears in forming a double defect is put aside. Then the formation energy $\bar{W}(+-)$ of a double hole is simply given by

$$\begin{aligned} \bar{W}(+-) &= \bar{W}_1(+) + \bar{W}_2(-) + E_L \\ &= \bar{W}_1(-) + \bar{W}_2(+) + E_L, \end{aligned} \quad (5.1)$$

where

$$\bar{W}_1(\pm) = E_M + E_V(\pm) + E_S \quad (5.1a)$$

$$\bar{W}_2(\pm) = E_{M2} + E_{V2}(\pm) + E_{S2} \quad (5.1b)$$

$\bar{W}_1(\pm)$ is the energy to remove an ion in the crystal to an infinitely distant point (cf. (2.13)), and $\bar{W}_2(\pm)$ is the similar energy for an ion adjacent to the vacancy formed by the removal of the first ion. The right-hand side of (5.1a) is already known in § 2. E_{M2} , $E_{V2}(\pm)$ and E_{S2} are given in the forms:

$$\left. \begin{aligned} E_{M2} &= (A_M - 1) \frac{Z' Ze^2}{a_0} + \delta E_{M2} \\ E_{V2}(\pm) &= \frac{1}{a_0} [C'_{\pm\mp}(S_{V0} - 1) + C'_{\pm\pm}S'_{V0}] + \delta E_{V2}(\pm) \\ E_{S2} &= 3F_S(a_0) = \frac{3}{2}E_S. \end{aligned} \right\} \quad (5.2)$$

δE_{M2} and $\delta E_{V2}(\pm)$ are the changes of Madelung and Van der Waals energies associated with the charge transfer stated in § 2.

In the similar manner, the formation energy $\bar{W}'(+-)$ of a double interstitial ion is given by

$$\begin{aligned}\bar{W}'(+ -) &= \bar{W}_1'(+) + \bar{W}_2'(-) - E_L \\ &= \bar{W}_1'(-) + \bar{W}_2'(+) - E_L\end{aligned}\quad (5.3)$$

where

$$\bar{W}_1'(\pm) = E_M' + E_V(\pm) + E_S' \quad (5.3a)$$

(cf. 3.7))

$$\bar{W}_2'(\pm) = E_M' + E_{V2}(\pm) + E_{S2} \quad (5.3b)$$

and

$$\left. \begin{aligned}E_{M2}' &= -A_M' \frac{Z_0 Z'}{a_0} c^2 - \frac{Z_0^2 e^2}{a_0} \\ E_{V2}'(\pm) &= -\frac{1}{a_0^6} [C_{\pm\mp} S_{V0} + C_{\pm\pm}^0 S_{V0}'] - \frac{C_{+-}^{00}}{a_0^6} \\ E_{S2}' &= 5F_{S'}'(a_0) = \frac{5}{4} E_{S'}' \\ C_{+-}^{00} &= C_{+-}(\alpha_+^0 \alpha_-^0 / \alpha_+ \alpha_-) .\end{aligned} \right\} \quad (5.4)^*$$

Next we consider the polarization energy of the medium except the atomic polarization of the six nearest-neighbours of a double hole (ions $\bar{2}$, $\bar{3}$, $\bar{4}$ and 1, 2, 3 in Fig. 1) and that except the eight nearest-neighbours (ions $\bar{1}$, $\bar{2}$, $\bar{3}$, $\bar{4}$ and 1, 2, 3, $1'$ in Fig. 3) and the two interstitial ions of a double interstitial ion. Then the polarization energy $E_P(+ -)$ for a double hole is given by

$$\begin{aligned}E_P(+ -) &= E_P^*(+ -) + E_{P1}(+ -) , \quad (5.5) \\ E_P^*(+ -) &= -\frac{1}{2} \frac{(Z_0 e)^2}{a_0} \left\{ [(C_0 - 4) \right. \\ &\quad \left. + (C_0' - 0.4219)](M_+ + M_-) \right\} \\ &\quad + \frac{(Z_0 e)^2}{a_0} [(Q_0 - 0.9192)(M_+ + M_-)] ,\end{aligned}\quad (5.5a)$$

where $\bar{Q}_0$ is a numerical constant. (cf. App. IV.) In the similar manner the polarization energy $E_P'(+ -)$ for a double interstitial ion is given by

$$\begin{aligned}E_P'(+ -) &= E_P^{*'}(+ -) + E_{P1}'(+ -) , \quad (5.6) \\ E_P^{*'}(+ -) &= -\frac{1}{2} \frac{(Z_0 e)^2}{a_0} \left\{ [(C_0 - 4) \right. \\ &\quad \left. + (C_0'' - 1.7500)](M_+ + M_-) \right\} \\ &\quad + \frac{(Z_0 e)^2}{a_0} [(\bar{Q}_0'' - 1.5485)(M_+ + M_-)] ,\end{aligned}\quad (5.6a)$$

* The short range forces between two interstitial ions of double interstitial ion is assumed to be the same as those between an interstitial ion and the four regular ions adjacent to it. (cf. § 3. (3))

where $\bar{Q}_0''$ is a numerical constant. (cf. App. IV.)

$E_{P1}(+ -)$ and $E_{P1}'(+ -)$ in (5.5) and (5.6) are the electronic polarization energy of the six neighbours of a double hole and that of the eight neighbours and the two interstitial ions of a double interstitial ion respectively. $E_{P1}(+ -)$ and $E_{P1}'(+ -)$ may be computed in the similar manner as in the calculation of $E_{P1}(\pm)$ in (3.3). (cf. App. II.) $E_P^*(+ -)$ and $E_P^{*'}(+ -)$ in (5.5) and (5.6) are the polarization energies of all the ions other than these ions on the continuum model. The numerical subtrahends 4, 0.4219 and 0.9192 in (5.5a) and 4, 1.7500 and 1.5485 in (5.6a) originate from the lack of ion at the vacancy and from the exception of the neighbours.

It would be very difficult to calculate the atomic polarization energy of these ions, since the electric field around the double defect has lower symmetry than that around a single defect. Therefore, we roughly assess the atomic polarization energy of these ions by using the values of their electronic polarization energy as follows:

$$\left. \begin{aligned}\Delta E_m(+ -) &= (\Delta E_m(+) + \Delta E_m(-)) \\ &\quad \times \frac{E_{P1}(+ -)}{E_{P1}(+) + E_{P1}(-)} , \\ \Delta E_m'(+ -) &= (\Delta E_m'(+) + \Delta E_m'(-)) \\ &\quad \times \frac{E_{P1}'(+ -)}{E_{P1}'(+) + E_{P1}'(-)} ,\end{aligned} \right\} \quad (5.7)$$

where $\Delta E_m(+ -)$ and $\Delta E_m'(+ -)$ are the total energy changes due to atomic polarization, at equilibrium configuration, of the six neighbours of a double hole and that of the eight neighbours and the two interstitial ions of a double interstitial ion respectively. Then the total formation energies $W(+ -)$ and $W'(+ -)$ of a double hole and a double interstitial ion are given by

$$\left. \begin{aligned}W(+ -) &= \bar{W}(+ -) + E_P(+ -) + \Delta E_m(+ -) , \\ W'(+ -) &= \bar{W}'(+ -) + E_P'(+ -) + \Delta E_m'(+ -) .\end{aligned} \right\} \quad (5.8)$$

Then dissociation energies V_D and V_D' of a double hole and a double interstitial ion into two single holes and two single interstitial ions are written respectively as

$$\left. \begin{aligned}V_D &= W_S - W(+ -) \\ V_D' &= W_S' - W'(+ -) .\end{aligned} \right\} \quad (5.9)$$

The results of numerical calculation are shown

Table V. Numerical values (eV) of energy terms constituting $W(+ -)$.

$E_p^{(0)'}(+ -)$		-12.7790		

in Tables V and VI. In the calculation of V_D and $V_{D'}$, the difference is taken between the values of W_s and $W(+ -)$, and those of $W_{s'}$ and $W'(+ -)$ with the same ε value, by assuming that the effective reduction in polarizability of anions is nearly equal for single defect and double defect.

§ 6. Conclusion

Referring to Table IV, we may point out that Frenkel defect caused by sulphur ion and inverse Schottky defect will be hardly formed at ordinary high temperatures ($<1020^\circ\text{C}$)*, which are realized in synthesis of luminescent materials. In particular, $W_F(-)$ will be somewhat more larger than the value in Table IV, since the overlap between the interposed sulphur ion and the six sulphur ions located at next-nearest sites, will be fairly large, although this overlap is not taken into account in the calculation. If inverse Schottky defects and double interstitial ions were formed in zincblende at a high temperature, there might be a dissociative equilibrium between these

two kinds of defects. However, the relation $(1/2)W_{s'} > V_{D'}$ holds except for the case $\varepsilon=1$. Then most of the interstitial ions will be dissociated.¹³⁾ (cf. Tables IV and VI)

As easily understood from Table IV and V, most probable defects in zincblende are Shottky defects, double holes and Frenkel defects by zinc ion. Since the dissociation energy of double hole into two isolated holes in negative for the case $\varepsilon=1$, ε would be somewhat smaller than unity. Recalling the fact that zincblende shows no ionic conductivity even at high temperatures, we may estimate ε to be $0.9\sim 0.8$, namely $W_s=4\sim 5$ eV, and V_D to be less than 1 eV. The fact that V_D is considerably small compared with W_s suggests that nearly random distribution of vacancies will be realized in zincblende. If this is the case, the number of double holes in zincblende is proportional to the square of the number of single holes¹⁴⁾ and this fact has been to some extent experimentally evidenced by R. H. Bube.¹⁵⁾ The activation energy for Shottky defects and double holes are assessed to be $(1/2)W_s=2\sim 3$ eV and $W(+ -)=4\sim 6$ eV respectively. These values may be compared with the activation energies of shallow and

* 1020°C is the transition temperature between zincblende and wurzite structures.

deep traps in zincblende 4.5 eV and 7.4 eV obtained experimentally by Bube.

Referring to Table IV, the formation energy of Frenkel defect by zinc ion, $W_F(+)$, is estimated to be 4.5~6 eV. Smallness of $W_F(+)$ in comparison with $W_F(-)$ is attributed to the large electronic polarizability of sulphur ions surrounding the zinc ion to be removed and interposed. This tendency will be much more exaggerated, when the overlap repulsion between the interposed sulphur ion and six sulphur ions located at next-nearest sites is taken into account. According to current views, neutral atoms of some foreign metals may be located at interstitial sites in zincblende, and form efficient luminescence centers. If we assume that these foreign atoms are located at interstitial sites surrounded by four sulphur ions and that repulsive force between these foreign atoms and sulphur ions is nearly equal to that between interstitial zinc ion and sulphur ion, we may estimate the energy required to interpose the foreign atoms into the crystal from the exterior. Then the polarization energy of the medium, $E_{F'}$ in Table III, will be negligibly small, and the energy for the interposal may be assessed to be 2~3 eV. Thus atoms of some foreign metals with atomic radii of appropriate magnitude will be located easily at interstitial sites during the heating procedure of phosphor preparation.

The calculation in this paper is also applicable to the other sphalerite-type crystals such as ZnSe, provided that Hartree solutions of constituent ions and effective charges on them are known.

Appendix I

When an additional free charge Ze is put into the crystal, the polarization $P(R)$ at the distance R from the free charge is given by

$$P(R) = \left(1 - \frac{1}{\kappa}\right) \frac{Ze}{R^2} \quad (\text{AI-1})$$

in continuum model, where κ is the static dielectric constant. Further, the macroscopic polarization caused by electronic polarization of individual ions is given by

$$P_e(R) = \left(1 - \frac{1}{\kappa_0}\right) \frac{Ze}{R_2}, \quad (\text{AI-2})$$

where κ_0 is the optical dielectric constant.

If we denote electronic dipole moments on

a cation and an anion in the crystal by μ_+ and μ_- respectively, and the atomic dipole moment by μ_a , we may write, for sphalerite-type crystals,

$$\left. \begin{aligned} P(R) &= (\mu_+ + \mu_- + 2\mu_a) / 2 \left(\frac{2}{\sqrt{3}} \right)^3 a_0^3, \\ P_e(R) &= (\mu_+ + \mu_-) / 2 \left(\frac{2}{\sqrt{3}} \right)^3 a_0^3, \\ \mu_+ / \mu_- &= \alpha_+ / \alpha_-, \end{aligned} \right\} \quad (\text{AI-3})$$

where a_0 is the nearest-neighbour distance, and α_+ and α_- are the electronic polarizabilities of the cation and anion. By using (AI-1, 2 and 3), ratio of electronic polarization to atomic one is given by

$$(\mu_+ + \mu_-) / 2\mu_a = \frac{\kappa(\kappa_0 - 1)}{\kappa - \kappa_0}. \quad (\text{AI-4})$$

Furthermore, if we introduce the dimensionless quantities M_+ and M_- which are defined by

$$M_{\pm} \frac{a_0^3 Ze}{R^3} = \mu_{\pm} + \mu_a, \quad (\text{AI-5})$$

we may obtain

$$M_{\pm} = \frac{4}{3\sqrt{3}\pi} \left(1 - \frac{1}{\kappa_0}\right) \left\{ \frac{\alpha_{\pm}}{\alpha_+ + \alpha_-} + \frac{1}{2} \frac{\kappa - \kappa_0}{\kappa(\kappa_0 - 1)} \right\}. \quad (\text{AI-6})$$

The numerical values of M_+ and M_- for zincblende are shown in Table I.

Appendix II

Polarization energy of the medium except four ions adjacent to the vacancy is given by (2.5), where $\sum_i$ should be taken over all ions except these four ions. When the four ions adjacent to the vacancy are displaced on the tetrahedral directions, the field D_i from the free charges acting on the i th ion in the crystal and the dipole μ_i on it are given by (cf. Fig. 5)

$$D_i = \mp \frac{Z_0 e}{R_i^3} R_i \pm \sum_{j=1}^4 \left[\frac{Z'_j e}{r_{ij}^3} \mathbf{r}_{ij} - \frac{Z'_j e}{r_{ij}^3} \mathbf{r}_{ij}' \right], \quad (\text{AII-1})*$$

$$\mu_i = M_i a_0^3 D_i \quad (M_i = M_+ \text{ or } M_-). \quad (\text{AII-2})$$

$\sum_j$ should be taken over the four ions surrounding the vacancy. When the displacements sa_0 of the four ions are not so large, the second term in the brackets of (AII-1) is very small, comparing with the first term. If

* cf. foot-note concerning (2.6a) in § 2.

we neglect the square of this small term, then we obtain the following form by inserting (AII-1 and 2) into (2.5)

$$E_P = -\frac{1}{2} \frac{(Z_0 e)^2}{a_0} \sum_i M_i \frac{a_0^4}{R_i^4} + \frac{Z_0 Z' e^2}{a_0} \sum_i \sum_j M_i \frac{a_0^4 \cos \theta_{ij}}{R_i^2 r_{ij}^2} - \frac{Z_0 Z' e^2}{a_0} \sum_i \sum_j M_i \frac{a_0^4 \cos \theta_{ij}'}{R_i^2 r_{ij'}^2}. \quad (\text{AII-3})$$

When $s=0$, $r_{ij}=r_{ij'}$ and $\theta_{ij}=\theta_{ij'}$. Then E_P coincide with the first term in (3.5). Only the last term in (AII-3) varies with displacements sa_0 . It may be written as

$$E_{PL} = -\frac{Z_0 Z' e^2}{a_0} [M_{\pm} Q + M_{\mp} Q'] \times 4, \quad (\text{AII-4})$$

where

$$Q = a_0^4 \sum_i^{(w)} \frac{\cos \theta_{ij'}}{R_i^2 r_{ij'}^2}, \quad Q' = a_0^4 \sum_i^{(l)} \frac{\cos \theta_{ij'}}{R_i^2 r_{ij'}^2}.$$

$\sum_i^{(l)}$ and $\sum_i^{(w)}$ mean the summations over the like

and unlike ions respectively referring to the j th ion, to which one of the nearest neighbour unlike ions is absent. The numerical values of Q and Q' for various values of s are easily computed from those of $\bar{Q}$ and $\bar{Q}'$ in Appendix IV, where the summations are taken over all the cations or anions in perfect crystal except the reference ion (j th ion).

Appendix III

If the local electrostatic field exerted on an ion in the crystal is denoted by $\mathbf{E}$ and the dipole moment induced on it by μ ,

$$\mu = \alpha \mathbf{E} = \alpha (\mathbf{D} + \mathbf{E}'), \quad (\text{AIII-1})$$

where α is the polarizability of the ion, $\mathbf{D}$ the electric field from free charges, $\mathbf{E}'$ that due to dipoles induced on all the other ions. If we write down this equation with respect to the ions 1 and $\bar{1}$ in Fig. 3,

$$\mu_s = \epsilon \alpha_{\mp} \left[D_s(s) - \frac{15}{16} \sqrt{\frac{3}{2}} \frac{1}{(1+s)^3} \frac{\mu_s}{a_0^3} - \left(\Gamma_1(s) \frac{9}{f_1(s)^3} + \Gamma_2(s) \frac{9}{f_2(s)^3} \right) \frac{\mu_x}{a_0^3} + (S' M_{\pm} - S' M_{\mp}) \frac{Z_0 e}{a_0^2} \right] \quad (\text{AIII-2})$$

$$\mu_x = \alpha_{\pm}^* \left[D_x(s) - \left(\Gamma_1(s) \frac{6}{f_1(s)^3} + \Gamma_2(s) \frac{6}{f_2(s)^3} \right) \frac{\mu_s}{a_0^3} - \left(\frac{3\sqrt{3}}{32} + \frac{9}{8} \sqrt{\frac{3}{2}} \right) \frac{\mu_x}{a_0^3} - (0.016 M_{\mp} + 0.170 M_{\pm}) \frac{Z_0 e}{a_0^2} \right], \quad (\text{AIII-3})$$

where

$$f_1(s) = \sqrt{(1-s)^2 + 2(1+s)^2}, \quad f_2(s) = \sqrt{(3+s)^2 + 2(1+s)^2} \\ \Gamma_1(s) = 1 + 3 \frac{(1+3s)(1-s)}{f_1(s)^2}, \quad \Gamma_2(s) = -1 + 3 \frac{(5+3s)(3+s)}{f_2(s)^2} \\ D_x(s) = \frac{3}{4} \frac{Z_0 e}{a_0^2} + \frac{Z e}{a_0^2} \left[\frac{2}{\sqrt{3}} + \frac{18}{11\sqrt{11}} - \frac{6(1-s)}{f_1(s)^3} - \frac{6(3+s)}{f_2(s)^3} \right].$$

sa_0 is the radial displacement of the four ions adjacent to the interstitial ion, μ_s and μ_x the dipole moments pointed to (111) and (100) on the ions $\bar{1}$ and 1 in Fig. 3 respectively. $\alpha_{\pm}^*$ are the total polarizabilities of cation and anion, containing atomic and electronic polarizabilities, and are given by

$$\alpha_{\pm}^* = \alpha_{\pm} \frac{\mu_{\pm} + \mu_a}{\mu_{\pm}} = \alpha_{\pm} + \frac{(\alpha_{+} + \alpha_{-})(\kappa - \kappa_0)}{2\kappa(\kappa_0 - 1)}.$$

$D_s(s)$ and $D_x(s)$ is the electric fields acting on the ions $\bar{1}$ and 1, from the free charges. When $s=0$, $D_s(s) = Z_0 e / a_0^2$ and $D_x(s) = (3/4) Z_0 e / a_0^2$.

The last terms in (AIII-2) and (AIII-3) are the electric field due to the dipoles on the ions $\bar{1}$ and 1 from all the ions outside the ion 1. (cf. Fig. 3) The change of $D_s(s)$ with s is easily obtained from the results in Appendix of Part I. S' is the same quantity as in (2.9). The value of S' at $s=0$ is 0.372. This value and the numericals 0.016 and 0.170 occurring in (AIII-3) are obtained in the same manner as in calculation of S and S' in (2.9). The change of S' with s is computed with five rings around the interstitial ion, as in the case of S and S' in (2.9).

By solving (AIII-2) and (AIII-3) simultaneously we may obtain μ_s and μ_x at a given s value. Then electronic polarization energy $E'_{PI}(\pm)$ of the four nearest-neighbours ($\bar{1}$, $\bar{2}$, $\bar{3}$ and $\bar{4}$ in Fig. 3) and the six next nearest neighbours (1, 2, ...6 in Fig. 3) given by

$$E'_{PI}(\pm) = \frac{1}{2} [4D_s(s)\mu_s + 6D_x(s)\mu_x] \quad (\text{AIII-4})$$

$\varepsilon(\leq 1)$ has the same meaning as stated in § 2. Accordingly, in the case of an interstitial anion ε in (AIII-2) should be taken as 1.

Appendix IV

$\bar{Q}''$ is defined by

$$\bar{Q}'' = a_0^4 \sum_i^{(w)} \frac{\cos \theta_{ij'}}{R_i^2 r_{ij'}^2}, \quad (\text{AIV-1})$$

Fig. 5. Diagram illustrating the relation among vectors R_i , r_{ij} and $r_{ij'}$.
O: Center of vacancy.
 A_j : Regular site of the j th ion adjacent to vacancy ($j=1, 2, 3, 4$).
 sa_0 : Displacement of the j th ion.

Table VII.

s	$\bar{Q}$	$\bar{Q}'$	$\bar{Q}''$
-0.3	3.5618	3.8488	5.1684
-0.2	3.5534	3.7192	4.8915
-0.15	3.5440	3.6584	4.7472
-0.1	3.5305	3.5995	4.5946
-0.05	3.5141	3.5403	4.4504
0	3.4876	3.4876	4.3054
0.05	3.4588	3.4235	4.1657
0.1	3.4174	3.3828	4.0392
0.15	3.3670	3.3307	3.9233
0.2	3.3161	3.2858	3.8334
0.3	3.1910	3.1934	3.6944

$\bar{Q}_0$ and $\bar{Q}_0''$ in (5.5) and (5.6) are the values of $\bar{Q}$ and $\bar{Q}''$ at $s=0$, respectively.

where the summation should be taken over all ions but the reference ion (j th ion). The meaning of the notations in (AIV-1) is to be referred in Fig. 5, where the point O is regarded as an interstitial site for this case. The summation for like ions, $a_0^4 \sum_i^{(l)} \frac{\cos \theta_{ij'}}{R_i^2 r_{ij'}^2}$ equals to $\bar{Q}''$ stated in App. II and given in Table VII. $\bar{Q}''$ in (3.5) may be obtained by excluding from $\bar{Q}''$ the summation with respect to the other three ions equivalent to the j th ion and the six next-nearest ions of the interstitial site.

In calculating $\bar{Q}$, $\bar{Q}'$ and $\bar{Q}''$ the summations are taken over the ions within 57 cells around vacancy or the interstitial site, and the residual parts are computed by integrating the summands which are expanded in terms of power series of the displacement s . As the lower limits of integrations, those for the calculations of $a_0^4 \sum_i^{(w)} \frac{1}{R_i^4}$ and $a_0^4 \sum_i^{(l)} \frac{1}{R_i^4}$ are used. (cf. Part I Appendix)

Internal Friction of Lead. I

By Yosio HIKI

The Government Mechanical Laboratory, Suginami-ku, Tokyo, Japan

(Received July 5, 1958)

Internal friction of single crystal of lead (99.99% pure) was measured with longitudinal vibration in kilocycle range using the composite piezo-electric quartz oscillator. The dependences of the internal friction on the strain amplitude ($0.5-12 \times 10^{-6}$), on the frequency (64, 192 kc/sec) of vibration, and on temperature (140–340°K) were mainly studied. The internal friction is of the order of 10^{-3} at low temperatures, and increases slightly as the temperature is raised, and increases also with increasing strain amplitude. Near the room temperature, the value of the internal friction rises steeply. A peculiar temperature (about 300°K) has been found above which the internal friction decreases with increasing amplitude. The amplitude-dependent internal friction does not depend on the frequency of vibration and the amplitude-independent one seems to be proportional to the frequency.

§ 1. Introduction

Internal friction, which is the ratio of the mechanical energy dissipated per cycle to twice the total vibrational energy, is one of the most structure-sensitive quantities of the crystalline solids¹. There are several kinds of origins of internal friction according as the frequency of the vibration is different. In general, the internal friction also depends on other parameters such as strain amplitude of the vibration, temperature, purity, crystallographic orientation and mechanical or heat treatment of the specimens.

There have been some investigations about the internal friction of lead. In the audio-frequency range, the internal friction was measured as a function of frequency, and several resonance-type peaks were found². Some of these peaks seem to have relations with the crystal dislocation. A peak was also found which might be due to the thermal current in the specimen vibrating transversely³. In the kilocycle range, the pronounced dependence on the strain amplitude of the internal friction was observed⁴. This phenomenon may be explained by assuming the dislocation damping. Measurements at very large vibrational strain, which was in the range of plastic fatigue, were also carried out⁵. The effect of impurity on the internal friction of lead was investigated, and it was found that impurity atoms decrease the value of the internal friction and alter the feature of the amplitude dependence⁶. At low temper-

ature, the Bordoni's peak was observed in lead as in other metals⁷. The behavior of the internal friction at high temperatures was also studied⁸. In the megacycle range, the difference of the ultrasonic attenuation in normal and superconducting states was firstly detected in lead metal⁹. This phenomenon is considered to be originated from conduction electrons.

In the present investigation, the internal friction of lead single crystals in the kilocycle range has been measured as a function of strain amplitude, temperature and frequency.

§ 2. Experimental Procedures

The composite piezo-electric oscillator was used to measure the internal friction¹⁰. Two identical 18.5° X-cut quartz bars, 40 mm × 2 mm × 2 mm, were cemented together in their end faces with Araldite 101. Gold electrodes were plated through vacuum deposition on the faces perpendicular to their electrical axes. Their fundamental frequencies of longitudinal vibration were about 64 kc/sec, being matched within 0.01 per cent. The composite quartz oscillator was supported upright with four fine phosphor-bronze wires welded to the vibrational nodes on each electrodes and these wires also served as electrical leads. Such supporting device made the oscillation stable and the reproducibility of the measured values of the internal friction was improved markedly. The energy loss of this oscillator system was about 10^{-6} in *vacuo* and could be neg-

lected in comparison with the internal friction of lead which was larger than 10^{-3} .

A cylindrical specimen was cemented to the quartz oscillator. The diameter of the specimen was 2 mm, and its length was adjusted so as to make its frequency of vibration coincide with that of quartz. This matching need not be very strict when the internal friction of the specimen is not small. Phenyl salicylate was used as the adhesive between the specimen and the quartz for room temperature measurements. Silicone compound DC-40C was used for the case of low or high temperature. These joints are always located at the stress nodes of vibration and generally have little effects on the measurement.

When the frequency of the input alternating voltage on the electrodes of one quartz oscillator coincides with its fundamental or one of the odd overtone frequencies, the composite system oscillates longitudinally, and the output voltage occurs on the electrodes of the other quartz. The input and output voltages were measured by vacuum tube voltmeters. The ratio of the input voltage to the output voltage is proportional to the internal friction of this system, while the maximum strain amplitude of the specimen is proportional to the output voltage. After the resonance curve of the quartz system is measured without specimen, these proportionality constants can be determined using the known elastic and electrical constants of quartz. The accuracy of the internal friction measurement was estimated to be better than 5 per cent. Young's modulus of the specimen is also obtained by measuring the resonant frequency of the oscillator system.

The total assembly was enclosed in a evacuated brass tube in order to eliminate the air damping. Temperatures were measured by means of a copper-constantan thermocouple mounted very close by but not in contact with the specimen.

Specimens were made from 99.99% lead. The impurities were determined by chemical analysis and the results were as shown in Table I. Single crystals were prepared in the following way. The lead was melted and sucked up into a glass tube. It was re-melted by a horizontally moving furnace and then solidified as a single crystal. The glass tube was dissolved away with hydrofluoric acid.

The crystal was deeply etched electrolytically by sulfamic acid. For cutting the crystals, the electrolytical method was also applied to avoid the cold-working by mechanical cutting. When the specimens were to be annealed, they were heated in ethylene glycol to protect themselves from oxidation.

§ 3. Experimental Results

3.1. Time dependence

When the measurements were started as soon as the specimen was mounted to the quartz oscillator at room temperature, the internal friction, δ , varied with time, t , as shown in Fig. 1. These curves were composed of three portions: (i) $t=0-10^2$ min. In slowly cooled specimen, δ decreased with time. In quenched specimen, there appeared a small peak. (ii) $t\sim 3\times 10^2$ min. There existed irregular peaks which were so large that their maximum values could not be measured. (iii) $t>3\times 10^2$ min. δ decreased monotonously and approached to a constant value although the change could be detected

after several ten days after mounting.

For the measurement of the internal friction of lead, attention should be given to the time lapse after mounting the specimen.

3.2. Amplitude dependence

Internal friction of lead, δ , depends on the strain amplitude of vibration, ϵ , markedly. Following measurements were always carried out 18 hours after the mounting and at constant temperature, 8°C.

δ vs ϵ curves of a specimen as grown, and annealed at 150°C for 1, 3, 5 and 8 hours are shown in Fig. 2. The same specimen was also annealed at 135°C for 1, 3 and 5 hours; 120°C for 1, 3 and 5 hours; 105°C for 2, 4 and 7 hours, successively, and similar sets of curves were obtained. As a general feature, δ increased monotonously with increasing amplitude. When the amplitude was very small, however, δ decreased as the amplitude was increased. This extraordinary part in small amplitude region disappeared as temperature was lowered.

To analyze the data, the amplitude-dependent part of the internal friction $\delta_a = \delta - \delta_i$ was considered, where δ_i was obtained by extrapolating the value of δ to $\epsilon = 0$, disregarding the extraordinary part at small amplitude. In well annealed specimens, δ_a did not depend on frequency of vibration, f , as illustrated in Fig. 3.

Young's modulus E varied with ϵ and its fractional change, $\Delta E/E$, was proportional to δ except the small amplitude part [Fig. 4].

When ϵ is increased to a large value and then decreased, δ vs ϵ curve always shows an apparent hysteresis loop as can be seen in Fig. 5(a). The value of δ corresponding to the decreasing amplitude part diminishes gradually when the vibration is stopped, as the following manner. After the specimen was vibrated with $\epsilon = 12 \times 10^{-6}$

for 5 min, internal friction was measured with small amplitude of about 2.9×10^{-6} . As soon as δ was measured, the vibration was stopped and the specimen was rested. The changes of the ratio δ/δ_0 with the resting time, at different temperatures, are shown in Fig. 5 (b), where δ_0 is the initial value of δ .

3.3. Temperature dependence

The variation of δ and $\Delta E/E$ with temperature, T , were measured from 140°K to 340°K. Fig. 6 shows the results for a specimen as grown, and annealed at 150°C for 2, 15 and 40 hours. These measurements were always carried out exactly at the constant vibrational strain amplitude $\epsilon = 2.86 \times 10^{-6}$. This fixed condition is important because of the strain

Fig. 7. Internal friction vs temperature curves for the specimen B1-5-B, annealed at 150°C for 60 hours, at various strain amplitudes.

amplitude hysteresis mentioned above, particularly at low temperatures. If ϵ is once increased and then decreased, δ does not return to its initial value so rapidly. This may be one origin of "false peak" which is sometimes observed in δ vs T curve.

It seems that δ vs T curves can be divided into three regions. (i) In the low temperature region ($T < 270^\circ\text{K}$), δ increases slightly with increasing T . There also exist small peaks which disappear when the specimen is well annealed. These peaks are sometimes not reproducible, but it cannot be considered that they come from experimental failure because $\Delta E/E$ also shows anomalies at the same temperatures. (ii) In the intermediate region near room temperature, δ increases steeply. An anomalous point T_0 (290 – 330°K) exists which sometimes appears to be an inflection point rather than a maximum of a peak. (iii) In the high temperature region ($T > T_0$), δ increases with increasing T , but the increasing rate is lowered in comparison with that of the second region.

In another well annealed specimen, δ was measured as a function of temperature, taking ϵ as a parameter. The results are summarized

Fig. 8. Internal friction vs strain amplitude curves at various temperatures.

in Fig. 7. When δ is replotted against ϵ under the condition that T is constant, Fig. 8 is obtained. The amplitude dependence of the internal friction in high temperature region is entirely different from that in low temperature region. Namely, δ increases or decreases with increasing amplitude according as T is lower or higher than T_0 . At temperatures lower than but not far from T_0 , the high-temperature type curve is partly superposed upon the usual low-temperature type curve in the region of small amplitude (e.g., curve e in Fig. 8), which has been already noticed in section 3.2.

Fig. 9. Internal friction vs temperature curves for two specimens measured at two frequencies.

3.4. Frequency dependence

In Fig. 9, δ vs T curves for two specimens are shown. Two frequencies were used by exciting the fundamental and third harmonic oscillation of the quartz. Higher harmonics of sufficient intensity applicable for measurement could not be obtained. These measurements were carried out about two or three hundred hours after mounting the specimen and no appreciable change of δ with time was observed.

The strain amplitude used was so small that the measured value of δ might be regarded as the amplitude-independent internal

friction δ_i . At low temperatures, δ_i seems to be proportional to the vibrational frequency, f . The same specimen vibrating in its second overtone was measured by other quartz oscillator. Low temperature δ was more than twice as large as the value of fundamental vibration. Probably, the specimen was cold-worked through handling.⁴¹⁾

§ 4. Discussion

Various mechanisms were proposed to account for the internal friction of crystalline solids. When the internal friction is measured with a high frequency vibration at low temperatures, it may not be attributed to the "relaxation by diffusion"¹¹⁾. The only possible diffusion-like mechanism which may contribute to the internal friction of single crystals under longitudinal vibration of high frequency is the thermoelastic heat flow in the crystal¹²⁾. It can be estimated, however, that the magnitude of the internal friction of lead from this origin is less than 10^{-4} at 64 kc/sec. Moreover, the remarkable amplitude dependence of the internal friction cannot be explained only by assuming the damping with the nature of dynamic hysteresis including the "anelasticity." Some notions of static hysteresis are required.

Since Read¹³⁾ suggested the possibility of dislocation damping as a source of internal friction, this idea was applied to interpret some of the experimental facts. There are now two types of models to treat the dislocation damping theoretically: "pinned-down" dislocation model by Koehler¹⁴⁾ and Granato-Lücke¹⁵⁾, and "unpinned" model as that of Weertman¹⁶⁾. The former assumes pinned-down or fixed state of dislocations by point imperfections such as impurity atoms. This model may be valid to the case of rather pure crystals at low temperatures. On the contrary, the latter, using the solution hardening theory of Mott-Nabarro, may be suitable to treat the internal friction of impure metals.

It seems that the amplitude and frequency dependences of the internal friction of lead single crystals at low temperatures can be understood satisfactorily by adopting the treatment of Granato and Lücke. This can be summarized as follows.

A thoroughly annealed single crystal contains a stable three-dimensional network of disloca-

tions and their intersections are usually immovable. If there exist enough impurity atoms which exert forces on the dislocation lines, the network loops of dislocations may be further pinned down here and there by impurities. When the external alternating stress is applied to the crystal, the dislocation lines between pinning points bow out in their slip planes like stretched strings. With increasing stress, at the instance when some part of the dislocation line is torn away from an impurity atom, the other impurity-pinning points in that network loop are also broken down as a catastrophe, while the network-pinning points are fixed. During the decreasing part of the stress cycle, the loop collapses elastically until it is again pinned down by impurities. Using this picture, it can be shown that the internal friction of single crystal is expressed as a sum of two losses. The first is the dynamic one originated from the damping force to the dislocation motion. This force is assumed to be proportional to the velocity of the dislocation. The second loss is the one of the static hysteresis type which originates necessarily from the break-away process mentioned above. The former loss is proportional to the frequency and independent on the strain amplitude, while the latter increases with increasing amplitude and does not depend on the frequency.

The temperature dependence of the internal friction of lead, however, cannot be fully explained by this theory only. The steep increase of the internal friction near room temperature may be due to the break-away of pinning points through thermal agitation. The reverse of the amplitude dependence at high temperatures is particularly noticeable and some expositions are wanted for it.

It is supposed that there also exist some unstable dislocations or other imperfections in crystals. These may be the origins of the transient phenomena such as the variation of the internal friction with time after mounting the specimen.

Detailed analysis of the present experimental results will be published later.

Acknowledgements

The author wishes to express his sincere gratitudes to Dr. T. Kawada for the continual encouragement during the course of this work.

He is also greatly indebted to Professor Y. Tomono and Professor R. Hasiguti for kind advices. Thanks are also due to Mr. A. Hikata for his valuable discussions.

Scattering of Electrons by Carbon Films

By Yoshihiro KAMIYA

Physical Institute, Nagoya University, Nagoya, Japan

(Received April 2, 1958)

Intensity distribution of electrons scattered by carbon films was measured by the photographic method using a sector camera. The absolute intensity was obtained by the use of an intensity scale. The angular range of the measurement was $1.0 \times 10^{-2} \sim 1.2 \times 10^{-1}$ rad., the thickness of films $350 \sim 4,400 \text{ \AA}$ and the accelerating voltage 47 kv. Results of the measurement were in fair agreement with the theory of Lenz (*Z. Naturforsch.* **9a** (1954), 185). For the detailed agreement, however, we must take a smaller atomic radius than that of Lenz and we must take into account the inter-atomic interference effect.

§ 1. Introduction

The contrast of electron microscope images is determined mainly by scattering of electrons in the specimen. Intensity distributions of scattered electrons were extensively studied in the field of the electron diffraction. This field, however, is mainly concerned with the single scattering for large angles. For an interpretation of electron microscope images, a knowledge of multiple scattering as well as of single scattering is required, particularly for small angles.

v. Borries¹⁾ and Lenz²⁾ treated this problem theoretically. Lenz²⁾ calculated the intensity

distribution for carbon, chromium and gold films of various thickness. Their theory assumes amorphous substances, *viz.*, perfectly random arrangement of atom. The assumption is not satisfied for thin films of chromium and gold prepared by vacuum evaporation because they produce Debye-Scherrer rings.

Biberman *et al.*³⁾ measured the intensity distribution for a very thin chromium film. A more extensive experimental investigation of gold and collodion films was carried out by Leisegang⁴⁾. To prove Lenz's theory by experiment, the use of carbon films are more appropriate than metal films because they are

amorphous. Carbon films also are convenient because they do not show charging-up like collodion films. Kempf and Lenz⁵⁾ measured the *relative* value of intensity distribution for thin carbon films, while the measurements of contrast for carbon films were carried out by Lippert⁶⁾ and Komoda⁷⁾. In the present paper we describe our measurement of *absolute* value of scattering distribution for carbon films. The thickness was 350~4,400 Å and scattering angle $1.0 \times 10^{-2} \sim 1.2 \times 10^{-1}$ rad.

§ 2. Experimentals

Carbon films were prepared by the method of vacuum evaporation developed by Bradley. A film was evaporated on glass, floated on water and scooped up on a copper plate having a hole 0.5~1.0 mm ϕ . The thickness of films was estimated using the proportional

Table I. Thickness of specimens; p mass-thickness in unit "Aufhellungsdicke": 1.4×10^{-5} g/cm².

No. of specimen	Thickness	p
1	350 Å	0.55
2	700	1.1
3	1400	2.1
4	2200	3.5
5	4400	7.0

relation between thickness and darkness⁹⁾: darkness 1.0 corresponds to thickness 1,000 Å. The mass-thickness was derived from the thickness using the density of graphite. Specimens used in the experiment are listed in Table I. The thickness measurement becomes inaccurate for films thicker than 1,500 Å. Therefore for specimen No. 4, the evaporation was carried out in two successive stages. By measuring the thickness for each stage, we determined the thickness of specimen No. 4. Specimen No. 5 was made by overlapping two films, each having the same thickness as that of specimen No. 4.

The apparatus used for the intensity measurement was the electron diffraction camera provided with a rotating sector¹⁰⁾, designed specially for the intensity measurement¹¹⁾ (Fig. 1). In our arrangement, the opening of the sector ϕ is $2\pi r/3.6$ rad., where r is the radius on the plane of the sector, the unit of r being cm. Scattering angle θ is given by $\theta = r/L = r'/L'$ where L is the specimen-to-sector distance, r' the radius on the photographic plate and L' the specimen-to-plate distance. By rotating the sector in front of the photographic plate during an exposure, the effective exposure time is made proportional to the scattering angle, resulting in a flat blackening of the photograph allowing an accurate intensity measurement.

Fig. 1. Schematic drawing of sector camera.

Fig. 2. Sector $\phi = 2\pi r/3.6$ rad, radius in cm

The incident beam has a cross section of about 0.1 mm ϕ at the specimen and an aperture angle of less than 2.0×10^{-4} rad. The whole beam passes through a specimen which is larger than 0.5 mm ϕ . Under this condition, no charging-up effect was detectable for carbon films, while for Formvar films it was detected. Before and after exposure, the incident beam was received by a Faraday cage 10 mm in length and 1.8 mm in diameter and the beam current was measured by a small current amplifier with sensitivity of 5×10^{-12} A.

The loss of the received charge by the secondary emission¹²⁾ was less than the experimental error. The exposure time was measured by counting the number of 50 cycle pulses which were produced by oscillating an electromagnetic tuning-fork. We discarded photographs when the current varied more than 10% during the exposure.

One of the most important factor in photographic intensity measurement is the characteristic of the used plate. The characteristic can be determined by two methods, *i.e.* by the successive method^{11),13)} and by the intensity scale method¹⁴⁾. The former gives only the relative characteristic while the latter

ness defined by

$$D = \log(Y_0/Y_t) \quad (2)$$

where Y_0 is the intensity of incident light and Y_t the intensity of transmitted light. Fig. 4 is a typical example of the characteristic. Circles in the figure were obtained by the successive method. The circle at $D = 0.43$ was normalized to the absolute measurement. Absolute characteristics agree with each other within the experimental error of 10% provided the emulsion number and the developing conditions are the same. Relative characteristics agree within 5% error when they are properly normalized. Scattered intensity scale were taken on the same plate. The plate used was "Fuji, Process Hard" and it was developed with D 76 d for 10 min. at 18°C and fixed with F-5 for 10 min. During the microphotometry, the plate was rotated around the incident spot so that the grain effect of the plate was eliminated.

Fig. 3. (a) Intensity scale. (b) Microphotometry curve of (a).

gives the absolute characteristic which is indispensable for our purpose. Two pairs of electro-static deflectors were set in the camera perpendicular to each other (Fig. 1). On one of the pair, 15 kc saw-toothed voltage was applied and on the other the voltage damping exponentially with time constant 0.023 sec. was applied. Thus by the deflected beam, the intensity scale is made on the photographic plate (Fig. 3). The exposure on the intensity scale was estimated from the geometrical relation

$$Exp. = I_0 \tau / bx \quad (1)$$

where I_0 is the incident current, τ the time constant of damping voltage, b the width of intensity scale and x is indicated in Fig. 3. By means of micrometer, we measured dark-

Fig. 4. Characteristic curve.

§ 3. Experimental Result and Comparison with Lenz's Theory

For each specimen given in Table I, photographs of scattering were taken. Darkness $D(r')$ obtained by the microphotometry was converted into exposure $E(r')$, making use of the characteristic of the plate. Intensity distribution $f(\theta)$, which is the probability of electrons scattered between θ and $\theta + d\theta$, was derived from $E(r')$ by

$$\theta f(\theta) = 2\pi c E(r') L' / I_0 t \quad (3)$$

where I_0 is the incident current, t the exposure time and c a numerical factor which depends on the opening of the sector: $c = 4.0$ for the sector used. The experiment was

carried out at 47 kv. Each result, however, was rewritten for 50 kv by $\theta_{50\text{kv}} = \theta_{47\text{kv}} \times (47/50)^{1/2}$ so that it can be compared with Lenz's theory. Rewritten results are given in Figs. 5a~e.

For the differential cross section of an atom Lenz assumed an analytical function

$$\frac{d\sigma}{d\Omega} = \frac{4Z}{q_H^2} \left[\frac{ZR^4}{(1+q^2R^2)^2} + \frac{1}{q^4} \left(1 - \frac{1}{(1+q^2R^2)^2} \right) \right]$$

(4)

where Z is the atomic number, a_H Bohr radius, $q=4\pi \sin (\theta/2)/\lambda$ and R the atomic radius derived from the diamagnetic suscepti-

bility. This formula includes inelastic scattering as well as elastic scattering. By applying the theory of multiple scattering¹⁵⁾ to Eq. (4), Lenz derived the formula for the intensity of scattering by a film:

$$f(\theta) = \int_0^\infty e^{2\pi N_L \gamma l \bar{\phi}(\chi)} J_0(\chi \theta) \chi d\chi$$

(5)

$$\bar{\phi}(\chi) = \int_0^\infty \frac{d\sigma}{d\Omega} [J_0(\chi \theta) - 1] \theta d\theta$$

(5a)

where J_0 is Bessel function of zero order, N_L Loschmidt number and γl the mass-thickness of the film. He carried out numerical calculation at 50 kv for various thickness,

Fig. 5. Scattering intensity curves
—○— Experimental result.

c) specimen No. 3	p=2.0
d) specimen No. 4	p=4.0
e) specimen No. 5	p=8.0

assuming the radius of carbon atom to be $R=0.35\text{\AA}$. He gave his result in "Abb. 14" of his paper, taking the thickness as a parameter p which is given in the unit of "Aufhellungsdicke $\gamma l'$ "

$$P=\frac{\gamma l}{\gamma l'}$$
$$\gamma l'=\frac{M}{N_L\sigma_{el}t}$$

(6)

where M is the atomic weight and $\sigma_{el}t$ is the

total cross section for the elastic scattering. Fig. 6 illustrates the effect of multiple scattering to be considerable even for film with thickness of only $320\text{\AA}$. Lenz's results are given by solid line curves in Figs. 5a~e. It must be emphasized that a fair agreement has been obtained for absolute values. At small angles, however, experimental curves are lower than theoretical ones. This trend is observed for all specimens. Small peaks which are observed at 2.5×10^{-2} and 4.5×10^{-2} rad. in Fig. 5 are attributed to diffraction halos. (Sec. 4 c).

§ 4. Discussions

a) Comparison with the result of Kempf and Lenz

To compare our result with that of Kempf and Lenz⁶⁾, Figs. 5a~e were replotted taking $\log(f(\theta))$ as the ordinate and $\log\theta$ as the abscissa (Figs. 7a~e). We found that for small scattering angles, tangent $\eta=d(\log(f(\theta)))/d(\log\theta)$ is a constant independent of θ , which agrees with their findings for angles smaller than 1.0×10^{-3} rad. They plotted η against p and confirmed that the following relation holds:

$$\eta=\frac{4Z}{p}-2$$

(7)

Since their experiment was carried out at 70 Kv, our value of p obtained at 47 Kv was rewritten for 70 Kv through the relation

$$p_{70kv}=0.8\,p_{47kv}$$

(8)

where the coefficient 0.8 was derived from "Abb. 2" of Lenz's paper²⁾. Their result

Fig. 6. Calculated intensity of scattering from carbon film Thickness: $320\text{\AA}$ i.e. 7×10^{-6} g/cm² or $p=0.5$

Fig. 7. Scattering intensity curves.

and ours are plotted in Fig. 8. Our result is also in agreement with relation (7) (Fig. 8).

In our experiment the absolute value of $f(\theta)$ was measured in the angular range which did not cover such small angles as those in the experiment of Kempf and Lenz. Since the values of η obtained in both experiments are in agreement, the relative value of $f(\theta)$ in their experiment can be normalized to our absolute value.

24.0	0.74	1.0	0.9
49.0	0.36	0.36	0.36

b) Comparison with the result of Komoda

At various objective apertures, Komoda⁷⁾ measured the contrast of carbon films having a thickness 180 ~ 1,800 Å. Contrast is given by the empirical formula¹⁶⁾

$$\text{Contrast} = 1 - e^{-\mu l} \tag{9}$$

where l is the thickness of film and μ is the scattering absorption coefficient which depends on the objective aperture. In Table II, values of μ calculated from both Komoda's data and ours are given as well as those derived from Lenz's theory. Our experimental value is normalized to Komoda's value at objective aperture 4.9×10^{-2} rad.* A discrepancy is

* The numerical agreement between Komoda and Lenz's values at objective aperture 4.9×10^{-2} rad. is accidental.

observed between Komoda's result and Lenz's theory at small objective apertures. This fact indicates that experimental intensity curves are lower than theoretical ones at small angles. This trend is also found in our experimental result. Although the discrepancy is not conspicuous in plots such as Fig. 7, it appears markedly in Fig. 5.

c) Value of atomic radius

Lenz adopted 0.35 Å as the atomic radius of carbon. Since, however, there is variety in data of diamagnetic susceptibility, the corresponding atomic radius turns out to be between 0.29 and 0.40 Å. For the diamond structure, the atomic radius turns out to be only 0.11 Å. According to Kakinoki et al.,¹⁷⁾ the structure of evaporated carbon film is a combination of diamond-like structure and graphite-like structure. Thus we expect an atomic radius much smaller than Lenz's value. If we adopt a smaller atomic radius, agreement between theory and experiment is improved. In Figs. 5a~e broken line curves represent the calculated intensity assuming $R=0.3$ Å. Agreement might be improved by assuming R smaller than 0.3 Å. We did not carry out the calculation under such an assumption because the interference effect described in the next subsection may be larger than the effect of atomic radius.

d) Interference effect

Although evaporated carbon film is amorphous, atomic arrangement in the film is not perfectly at random. Thus the diffraction halos appear (Fig. 5). The effect of halos on image contrast is not considerable and may be neglected in the present discussion. We cannot, however, neglect the interference effect which is caused by non-overlapping of atoms; two atoms cannot overlap even though the atomic arrangement is otherwise at random. In Lenz's theory the effect of non-overlapping is neglected. By this effect the intensity of the elastic scattering at small angles is much reduced and vanishes at zero of the scattering angle¹⁸⁾. Fig. 9 illustrates the effect. Since inelastic and multiple scatterings are neglected, Fig. 9 cannot be directly compared with experimental results. At any rate, the trend of the effect is in accordance with the experimental results in Figs. 5a~e, i.e. at small angles, experimental

curves are lower than Lenz's theory. Since this effect takes place for any sample, it must always be taken into account in calculating image contrast.

Fig. 9. Relative intensity distribution of elastic scattering by a thin film. (theory)

— Interference effect, neglected.

- - - Interference effect, taken into account.

e) Inelastic scattering

In the theory of scattering, atoms in solid films are usually assumed to be free. The theory, therefore, is a good approximation for inner shells which are effective for large angles. The bonding effect changes the state of outer shells. In Lenz's theory this effect is taken into account by using the atomic radius derived from diamagnetic susceptibility. However, for scattering at such small angles as 10^{-4} rad., the assumption of free atoms is not adequate. Broadly speaking, the scattering at the scattering angle θ is caused mainly by electrons which are spread in dimension $d = \lambda/\theta$. For $\theta = 10^{-4}$ rad., d has the order of magnitude $400\text{\AA}$. Thus it is more reasonable to consider that the inelastic scattering at such small angles is caused by a free electron.

Recent investigations on energy losses from electrons revealed that in solids the important part of the inelastic scattering is caused by the excitation of plasma oscillations¹⁹⁾⁻²⁰⁾.

For this type of inelastic scattering we must have a mental picture of the scattering taking place within the whole electron system existing in the film. The inelastic scattering due to band-band transition is also caused by electrons extended in solid material. It should be noted that at small angles, the scattering distribution depends not alone on the substance but also on the shape which is well known in X-ray optics as "small angle scattering". In order to know the intensity distribution of scattered electron more exactly, it is necessary to measure the intensity of elastic and inelastic scatterings separately at small scattering angles.

Acknowledgement

The author expresses his deep appreciation to Prof. Ryozi Uyeda of Nagoya University for his advice and encouragement throughout this work and thanks to Mr. H. Morimoto for his kind guidance and indispensable help. Thanks are also due to Prof. K. Kinoshita and Dr. Y. Doi for measuring the thickness of films and to Mr. T. Komoda for pre-publication information on his results.

The Crystal Structure of Germanium Selenide GeSe

By Atsushi OKAZAKI

*Department of Physics, Faculty of Science,
Kyusyu University, Fukuoka, Japan*

(Received May 12, 1958)

The crystal structure of germanium selenide has been analysed by X-ray method. The structure is orthorhombic with the space group D_{2h}^{16} - $Pcmn$. The dimensions of the unit cell containing four chemical units, GeSe, are $a=4.38$, $b=3.82$ and $c=10.79$ Å. It follows from the positions of all atoms determined by means of the electron-density projection that the structure is of a distorted NaCl type isomorphous with SnS and SnSe. The distances Ge-Se are 2.54, 2.58, 3.30 and 3.39 Å.

§ 1. Introduction

The semiconducting properties and the crystal structures of some intermetallic compounds composed of elements of IV b and VI b groups in the periodic table have been studied in our laboratory. In connection with the investigation of the semiconducting properties of germanium selenide GeSe¹⁾, the structure analysis of this compound was performed by X-ray method to determine the accurate atomic coordinates.

The result was compared with the structural data for the crystals of germanium sulphide GeS²⁾, stannous sulphide SnS³⁾ and stannous selenide SnSe⁴⁾. The structure of GeS reported by Zachariasen, giving atomic coordinates inconsistent with those in the other isomorphous compounds, was criticized.

§ 2. Crystallographic and X-ray Data

Single crystals of GeSe were prepared by the following method: germanium (resistivity = a few Ω cm) and selenium (99.997%) in stoichiometric proportions were sealed in an evacuated silica tube. The mixture was heated up to about 1000°C and kept at the temperature for 50 hours (M.P. of GeSe is about

780°C). Then it was cooled gradually down to room temperature taking 50 hours, containing 12 hours for annealing at 600°C. Throughout these procedures temperature was controlled automatically.

The crystals have metallic lustre and are gray and fairly soft. They cleave along the (001) planes very remarkably.

X-ray diffraction data were obtained mainly from rotation and oscillation photographs taken with nickel-filtered Cu *K* radiation. Laue photographs and oscillation photographs taken with zirconium-filtered Mo *K* radiation were used auxiliarily. The preliminary results are shown in Table I.

Table I. Elementary X-ray data.

Laue symmetry	orthorhombic
Lattice constants	$a=4.38$, $b=3.82$, $c=10.79$ Å
Compositions	4 units of GeSe

The $hk0$ reflexions with $h+k$ odd and the $0kl$ with l odd are systematically absent. This extinction rule is satisfied in the orthorhombic system only in the cases of the space groups D_{2h}^{16} - $Pcmn$ and C_{2v}^9 - $Pc2_1n$, in which there are possible fourfold positions as follows:

for $D_{2h}^{16}\text{-Pcmn}$: $x, \frac{1}{4}, z; \bar{x}, \frac{3}{4}, \bar{z};$

$$\frac{1}{2}+x, \frac{3}{4}, \frac{1}{2}-z; \frac{1}{2}-x, \frac{1}{4}, \frac{1}{2}+z,$$

for $C_{2v}^9\text{-Pc}2_1n$: $x, y, z; \bar{x}, \frac{1}{2}+y, \bar{z};$

$$\frac{1}{2}+x, \frac{1}{2}+y, \frac{1}{2}-z; \frac{1}{2}-x, y, \frac{1}{2}+z.$$

It is evident that these are centro- and noncentro-symmetrical, respectively, and that if all the y parameters of the two kinds of atoms in $C_{2v}^9\text{-Pc}2_1n$ are equal to $\pm\frac{1}{4}$, these two space groups give the same results.

§ 3. Intensities

The integrated intensities of the $0kl$ and $h0l$ reflexions were recorded on oscillation multiple-film photographs. The integration was carried out only in the rotational direction by means of manual control. All the intensities were determined visually. The intensity ratio of the strongest reflexion to the weakest one was about 2000.

A few pieces of crystals cut from a large block of single crystal were used to get X-ray data. It was necessary to take care of the shape of the specimen since the linear absorption coefficient μ is 4.1×10^3 and $3.7 \times 10^3 \text{ cm}^{-1}$ for Cu $K\alpha$ and Mo $K\alpha$ radiations, respectively. Due to the softness of the crystals, attempts to obtain specimens of thin cylindrical shape by grinding were unsuccessful. Therefore use had to be made of specimens having rectangular cross-section (about $0.01 \times 0.1 \text{ mm}$) and length of about 1 mm parallel to the rotation axis prepared as follows. A slice with thickness of about 0.01 mm were carefully cleaved off along the (001) planes at liquid air temperature. After the determination of the crystallographic axes by Laue photographs, the slice was carefully cut along the a or b axis again at liquid air temperature.

Because the absorption effect is not significant except for several reflexions for which the paths of the X-ray beam are nearly parallel to the rectangular edge with length of about 0.1 mm, no corrections were made at the first stage of analysis.

The corrections for polarization and Lorentz factors were made in the usual way. The secondary extinction was not taken into account.

§ 4. Structure Determination

(i) x and z parameters

There is no difference between the atomic

positions $4c$ of D_{2h}^{16} and $4a$ of C_{2v}^9 in the (010) projection and both have centres of symmetry.

The Patterson synthesis on the (010), evaluated making use of Beevers and Lipson strips at 6° intervals, is shown in Fig. 1. The cross-section of the broad maximum at $x=a/2$ is shown in Fig. 2 and is resolved into two peaks A and B by the following way. The left half of the peak B indicated by a broken line is drawn symmetrically to the right half.

Fig. 1. Patterson projection on (010). Position of maxima obtained from the final atomic coordinates are indicated by the three kinds of marks

Fig. 2. Cross-section of the broad peak in Fig. 1 at $x=a/2$, which is resolved into two peaks A and B.

Table II. Preliminary atomic coordinates.

	x	z
Ge	0.092	0.151
Se	0.492	0.879

The peak A is obtained by subtracting the peak B from the broad peak. The maxima A and B were considered to be due to the Ge-Ge and Se-Se vectors, respectively. From these figures preliminary atomic coordinates are determined as shown in Table II.

With the help of the above coordinates the signs of the observed structure factors $F(h0l)$ were determined and the two-dimensional electron-density map on (010) was computed. From this map it was found that the z parameters of Ge and Se atoms had to be inter-

changed. This did not influence the signs of $F(h0l)$. After computing the second electron-density map the absorption correction was applied in a simple way. That is, the ratio of the observed unitary structure factors to

the calculated ones was first evaluated as the function of the path length of X-ray beam in the specimen. Then the correction was made by dividing the observed $F(h0l)$ by the above ratios. Thereafter the computation of the electron-density map was repeated. In Fig. 3 the fourth electron-density map is shown, from which the final atomic coordinates were determined as shown in Table III.

In Table IV the observed structure factor F_o is compared with the calculated one F_c . F_o was calculated using atomic scattering factors of Ge and Se atoms given by Thomas and Umeda⁵⁾ with an isotropic temperature

1012	0	1.4	305	5.8	5.3	504	0	- 0.6
1013	11.8	-12.3	306	8.6	-11.7	505	3.4	6.2

factor $\exp[-B(\sin \theta/\lambda)^2]$ for $B=1.6 \text{ \AA}^2$. The observed structure factors were placed on an absolute scale by being multiplied by a scale factor. The temperature and scale factors were determined by plotting $\log (F_o/F_c)$ against $(\sin \theta/\lambda)^2$.

The reliability index $R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$ is 20%. If the nonobservable reflexions are omitted, R becomes 18%. The total electron numbers at Ge and Se peaks in Fig. 3 were

about 30 and 36, respectively, and the ratio of the heights of these peaks were also equal to the ratio 30:36. This suggests that about 2 electrons might be transferred from a neutral Ge atom to a neutral Se atom. The accuracy of this analysis, however, was not sufficient to discuss the electron transfer in detail, because the value of R was not sensitive to the slight change of atomic scattering factor due to the slight change of the total

electron numbers*.

(ii) *y* parameters

The intensity data of the $(0kl)$ reflexions were obtained using a specimen of shape similar to that of the $(h0l)$ specimen. Measurements and transformation to $F(0kl)$ of the $(0kl)$ intensities were carried out in the manners similar to those in the case of the $(h0l)$ reflexions. The observed values of $F(0kl)$ up to $(07l)$ reflexions are in good agreement with the calculated one, with *y* parameters of $\pm \frac{1}{4}$.

Fig. 4. Intensity distributions for the $(0kl)$ and the $(h0l)$ reflexions. The broken lines give the theoretical distributions.

Three statistical tests were applied to distinguish whether a symmetry centre was present or not. The results of the $N(z)$ test⁶⁾ are illustrated in Fig. 4. The observed distribution is raised due to a few extremely strong reflexions. Furthermore there are only 28 independent $(0kl)$ reflexions so that the results of the Wilson ratio test⁷⁾ and the variance test⁸⁾ deviated from the theoretical values.

But the comparison with the results of these tests for 57 independent $(h0l)$ reflexions shows that the space group $D_{2h}^{16}\text{-Pcmn}$ is more probable.

Thus the space group for GeSe was concluded to be $D_{2h}^{16}\text{-Pcmn}$.

* These values obtained by Zachariasen seem to be not correct as described in § 5.

the Ge-Se bonds. These six bonds correspond to those between the nearest neighbours in NaCl.

In Table V the results of the structure analyses of GeS²⁾, GeSe, SnS³⁾ and SnSe⁴⁾ are compared. In the table some of the crystallographic axes in the original papers are inter-

* The change of the value of *R* was estimated to be less than 2% for a particular case where Ge and Se atoms were substituted by Zn and Kr atoms, respectively, in the calculation of F_o .

changed and the origins are displaced from those in the original papers. The atomic coordinates in the crystals of GeSe, SnS and SnSe correspond to each other. The coordinates in the crystal of GeS, however, are not consistent with them. Wyckoff⁹⁾ remarked the fact that very different parameters had been assigned to the atoms in GeS and SnS crystals in spite of the similarity of their cell size. The strangeness becomes more conspicuous by the above comparison of the four

compounds. Thus the analysis of GeS²⁾ performed by Zachariasen was reexamined and a mistake was found in the determination of the x parameters. The calculated structure factors for GeS assuming the same parameters as GeSe are in better agreement with the intensity data. Consequently it seems that the atomic coordinates in GeS are similar to those in the other three compounds and all the four compounds belong to the *B29* type.

The author wishes to express his hearty thanks to Prof. T. Okada for his kind guidance and also to Mr. S. Asanabe for preparation of GeSe single crystals. This investigation was partly supported by the Scientific Research Expenditure of the Ministry of Edu-

cation.

Anisotropy of Nuclear Magnetic Resonance due to Crystal Dislocations

By Eizo OTSUKA

Institute of Polytechnics, Osaka City University, Osaka

(Received June 9, 1958)

Using plastically deformed crystals of KI, the nuclear magnetic resonance of I^{127} has been observed. The broadened signals of I^{127} show distinct anisotropy as regards the direction of the external magnetic field. This anisotropy is interpreted to arise from the definite orientation of a crystal dislocation. The experimental results are analyzed in terms of the gradient-elastic tensor which has been introduced by Shulman-Wyluda-Anderson. It is concluded that densities of edge and screw dislocations are fairly well balanced and increase for a certain range almost linearly with degree of cold-working, in agreement with the previously reported result for KBr. Assuming the total dislocation density to be 10^9 cm^{-2} for ten percent deformation, we get $|C_{44}| \sim 8 \times 10^4$ statvolts/dyne and its one-third for $|C_{11}|$. Comparison with the result for KBr shows that the amplification factor of eQq is greater than 50 for I^{127} in KI.

§ 1. Introduction

Nuclear magnetic resonance technique has proved to be an immensely convenient means to lay open the characteristics of the internal defects of solids. Of all these internal defects, a most interesting one is the crystal dislocation, which has a close relation with the plasticity of a solid. So far many both theoretical and experimental approaches have been

made on this subject¹⁾ and now nobody doubts the dislocation concept. There remain, however, still many unsolved problems and the need of more experimental works is strongly emphasized. This paper aims to offer a new material from the side of nuclear resonance studies.

In a previous investigation of KBr²⁾, we made a plain assumption that the electric field

gradients caused by the dislocations are simply proportional to the strains around them, and using the amplification factor of eQq , obtained from a different source of experiment, we estimated the order of magnitude densities of dislocations, and along with this described the unsuccessful attempt of getting directional effects of dislocation lines, in other words, the anisotropy of nuclear magnetic resonance due to dislocations. If such anisotropy is caught on the resonance line, it will provide a direct way to study the crystalline field around the dislocation. With this point in view, a further investigation has been made with single crystals of KI, taking the resonance lines of I^{127} , which has a larger eQq than Br^{79} or Br^{81} and hence a greater effect is expected.

Although the dislocation concept was first developed in the theory of plasticity, which deals with an ideal continuum, the direction of a dislocation line in an actual solid is restricted by the crystallographic configuration. In the case of alkali halides, the slip plane is always (110) with the slip direction being along [110]. Hence an edge dislocation line lies parallel to [100], while a screw dislocation has its axis along [110]. This definiteness of the crystallographic orientations of dislocations should reflect itself upon the curve shape of a nuclear resonance line, if the field gradients due to the dislocation have an appreciable interaction with the nuclear quadrupole moment of the nucleus in question.

A pioneer work was done by Watkins³⁾ about the effect of dislocations on the nuclear magnetic resonance. He considered merely the stress field of an edge dislocation and further simplified that the field gradients arise only from the shear strain σ_{xy}/G , which we also followed in the previous paper²⁾ in dealing with an edge dislocation, in view of the small shear modulus of $KBr^{4)}$. Watkins then calculates the angular distribution of dislocation lines and deduces the net frequency shift toward the lower frequency side in the case of the second order broadening, which conforms well with the experiment. This calculation, however, is based upon the assumption that the crystal is an ideal continuum and a dislocation line may have its axis in an arbitrary direction, which fundamentally differs from the actual situation. On account of this

randomness of directions of dislocation lines, such a continuum model can predict no anisotropy of nuclear magnetic resonance line, and the net frequency shift is not affected by the direction of the applied magnetic field. If the crystallographic orientation of the dislocation line is taken into account, the net frequency shift goes in the opposite direction for $H_0//[100]$, so far as the shear strain of the edge dislocation is concerned. In order to explain the experimental result, we had therefore to introduce the effect of the screw dislocations, which, if invested with nearly equal density to that of edge dislocations, could well account for the observed frequency shift²⁾.

Further, the definite orientation of a dislocation line will evidently give rise to some kind of anisotropy of the resonance line, if the quadrupolar interaction is sufficiently strong. In the previous attempt with $KBr^{3)}$, we wanted to get many unidirectional edge dislocations through the bending technique. The reason why this attempt ended in failure was ascribed to the insufficiency of the density of the produced edge dislocations. It is indeed a rather difficult task to produce so many pure edge dislocations free from the screw dislocation group. Moreover, the electric field around an edge dislocation is not so simple in reality, if a proper account is paid also on the stress components other than shear. The calculation would not go beyond a qualitative stage. And as long as we are satisfied with a qualitative result, the presence of screw dislocations would not fatally spoil our treatment, since the stress field and hence electric field around a screw dislocation is much simpler than that of an edge dislocation.

Recently Shulman, Wyluda and Anderson⁵⁾ performed an interesting NMR experiment on single crystals of $InSb$ which were subject to axial elastic deformation and measured the eQq with In^{115} caused by this artificial distortion of the originally cubic lattice. In the course of analysis, they introduced the so-called gradient-elastic tensor which, under the assumption of linear response as usual, converts stress or strain to field gradient. With this new tensor concept, formal treatment of field gradients has got much easier and hence a more extensive study of crystal dislocations has become possible. Accordingly, much of this successful gradient-elastic tensor

concept has been utilized in the present work.

§ 2. Field Gradients of Dislocations

In a cubic crystal as alkali halide, there is originally no electric field gradient at the site of a given nucleus. If some imperfection is created within the crystal, however, there arises a deviation from the cubic symmetry and we have a finite field gradient. If the quadrupole moment of the nucleus is sufficiently large, the quadrupolar interaction cannot be treated by a simple first order perturbation and higher order perturbation should be taken into account. Plastically deformed KBr or KI belongs to the category which needs this higher order approximation, since the eQq at Br or I is so great. So far the electric field due to a dislocation line has been approximated to be an axially symmetric one and simply replaced by the elastic shear

strain. In order to make an order of magnitude argument, such as dislocation density, it would be still useful to employ such a simplified model. Yet in dealing with a little more delicate problem like anisotropy of the resonance line, it is quite doubtful how such a rough treatment is lucky enough. Hence we shall follow a more orthodox way of approach. Thus the hypothesis of an axially symmetric field will no longer be retained and the stress field around a dislocation will be converted to the electric field according to the Shulman-Wyluda-Anderson's gradient-elastic tensor⁶⁾.

The energy eigenvalues of the nuclear Hamiltonian

$$\mathcal{H} = -\gamma \hbar \mathbf{I} \cdot \mathbf{H} + \mathbf{Q} \cdot \nabla \mathbf{E} \quad (1)$$

have been calculated by the method of perturbation to the third order and the result is as follows⁶⁾:

$$\begin{aligned} E_m = & -m\gamma \hbar H + A[3m^2 - I(I+1)](\nabla E)_0 \\ & - 3A^2 \frac{(\nabla E)_1(\nabla E)_{-1}}{\gamma \hbar H} m[4I(I+1) - 1 - 8m^2] \\ & - 3A^2 \frac{(\nabla E)_2(\nabla E)_{-2}}{\gamma \hbar H} m[2I(I+1) - 1 - 2m^2] \\ & - 9A^3 \frac{(\nabla E)_0(\nabla E)_1(\nabla E)_{-1}}{\gamma^2 \hbar^2 H^2} [I(I+1) + m^2\{12I(I+1) - 7\} - 20m^4] \\ & - 9A^3 \frac{(\nabla E)_0(\nabla E)_2(\nabla E)_{-2}}{\gamma^2 \hbar^2 H^2} [I^2(I+1)^2 - 2I(I+1) + m^2\{-6I(I+1) + 7\} + 5m^4] \\ & + \frac{3\sqrt{6}}{2} A^3 \frac{(\nabla E)_1^2(\nabla E)_{-2} + (\nabla E)_{-1}^2(\nabla E)_2}{\gamma^2 \hbar^2 H^2} [2I^2(I+1)^2 - 3I(I+1) + m^2\{-24I(I+1) + 15\} + 30m^4] \end{aligned} \quad (2)$$

where

$$\begin{aligned} (\nabla E)_0 &= \frac{1}{4}eq(3\cos^2\theta - 1) + \frac{1}{4}\eta eq \sin^2\theta \cos 2\psi \\ (\nabla E)_{\pm 1} &= \mp \frac{\sqrt{6}}{4}eq \sin\theta \cos\theta e^{\pm i\varphi} + \frac{1}{4\sqrt{6}}\eta eq \sin\theta \{(1 \pm \cos\theta)e^{\pm i\varphi + 2i\psi} - (1 \mp \cos\theta)e^{\pm i\varphi + 2i\psi}\} \\ (\nabla E)_{\pm 2} &= \frac{\sqrt{6}}{8}eq \sin^2\theta e^{\pm 2i\varphi} + \frac{1}{8\sqrt{6}}\eta eq \{(1 \pm \cos\theta)^2 e^{\pm 2i\varphi + 2i\psi} + (1 \mp \cos\theta)^2 e^{\pm 2i\varphi - 2i\psi}\} \end{aligned} \quad (3)$$

and

$$A = eQ/2I(2I-1).$$

These are the results of the general treatment by Bersohn⁷⁾, and the asymmetry parameter η , which is defined by

$$\eta = \left(\frac{\partial E_x^*}{\partial x^*} - \frac{\partial E_y^*}{\partial y^*} \right) / \frac{\partial E_z^*}{\partial z^*} \quad (4)$$

has been included. In (4) x^* , y^* and z^* are the principal axes of the field gradient tensor,

the largest component being along $0z^*$. θ , φ and ψ are the Eulerian angles of the principal axis system with respect to the coordinate system, the z -axis of which is the direction of the magnetic field.

Although the full expression (2) is rather lengthy, the first and third order terms contain only even powers of the magnetic quantum number m ; hence these have no contribution to the broadening of the resonance line which arises from the transition $m=1/2$ to $m=-1/2$. Thus the energy difference between these two states becomes

$$E_{1/2 \rightarrow -1/2} = h\nu_0 + \frac{3}{r\hbar H} \frac{2I+3}{4I^2(2I-1)} \left[(\nabla E)_1 (\nabla E)_{-1} + \frac{1}{2} (\nabla E)_2 (\nabla E)_{-2} \right], \quad (5)$$

where ν_0 is the Zeeman frequency. Taking the full expressions (3) for ∇E components into (5), we obtain

$$\begin{aligned} E_{1/2 \rightarrow -1/2} = h\nu_0 + \frac{3}{r\hbar H} \frac{2I+3}{4I^2(2I-1)} e^2 q^2 Q^2 \\ \times \frac{1}{16} \left[\sin^2 \theta \left\{ -6 \cos^2 \theta + 4\eta \cos 2\psi \cos^2 \theta + \frac{\eta^2}{6} (2 \sin^2 \theta \cos 4\psi - 2 \cos^2 \theta - 2) \right. \right. \\ \left. \left. + \frac{1}{8} (6 \sin^2 \theta + 4\eta \cos 2\psi (1 + \cos^2 \theta)) \right\} + \frac{\eta^2}{24} (\sin^4 \theta \cos 4\psi + 1 + 6 \cos^2 \theta + \cos^4 \theta) \right]. \quad (6) \end{aligned}$$

Since we have taken the z -axis to be the direction of the applied magnetic field, the Eulerian angles are defined as follows: $\theta = \angle z0z^*$, φ the angle between the y -axis and the intersecting line of the xy -plane with the x^*y^* -plane and ψ between the y^* -axis and the same intersecting line. φ has disappeared in (6) merely because the choice of the x and y -axes are quite arbitrary within the plane normal to the magnetic field. For simplicity, we shall denote (6) in the following simplified form:

$$h(\nu - \nu_0) \propto q^2 f(\theta, \psi). \quad (7)$$

Our next step is to determine q , η , θ and ψ around a dislocation line. At present, a dislocation line is thought to be a closed loop and consists of edge and screw types being mixed-up. Then, there should be a certain amount of iodine nuclei, which undergo the composite stress field due to both type dislocations. Those iodines, if treated properly, would yield a complicated cross term in the expression of the net frequency shift. This dislocation loop, however, is expected to be nearly rectilinear rather than curvilinear and the two types of the dislocation are considered to be well separated. Hence the stress field around a given iodine nucleus may be approximated to be either screw or edge type one and the small portion of iodines which see the composite stress field will be neglected.

Shulman-Wyluda-Anderson's gradient-elastic

tensor is composed of 36 components C_{ij} 's with properties very similar to the ordinary elastic constants in the stress-strain relation. The C_{ij} 's are not necessarily symmetric, but the requirement that the trace of the field gradient tensor should vanish on account of the Laplace equation reduces the number of independent components. In particular, the case of a cubic crystal becomes exceedingly simple and we have only two independent components C_{11} and C_{44} , which appear in the stress-field gradient conversion formulae in the following manner:

$$\left. \begin{aligned} q_{XX} &= C_{11} [\sigma_{XX} - \frac{1}{2} (\sigma_{YY} + \sigma_{ZZ})], \\ q_{XY} &= C_{44} \sigma_{XY}. \end{aligned} \right\} \quad (8)$$

Here the q 's are the field gradient tensor components and σ 's are the stress tensor ones. The suffixes X , Y , Z refer to the cubic axes and the relations (8) are cyclic. Starting from (8), we shall investigate the field gradients resulting from the dislocations.

1) Screw Dislocation

On account of the simplicity of the stress field, this one is taken first. The only non-vanishing stress components of the screw dislocation are

$$\left. \begin{aligned} \sigma_{xz} &= -\frac{Gb}{2\pi} \frac{y}{x^2 + y^2} \\ \sigma_{yz} &= \frac{Gb}{2\pi} \frac{x}{x^2 + y^2} \end{aligned} \right\} \quad (9)$$

where b is the magnitude of the Burgers

vector and G is the shear modulus. The z -axis is taken along the dislocation line and we shall take the x -axis to be $[100]$ direction, which is perpendicular to the dislocation line. Then, the xyz system is obtained by rotating the XYZ system by 45° around the X -axis. With this relation, the transformation of the tensor is carried out in quite an elementary manner and the field gradient tensor is represented in the xyz system as follows:

$$q_{xyz} = \begin{pmatrix} 0 & 0 & q_{zx} \\ 0 & 0 & q_{yz} \\ q_{zx} & q_{yz} & 0 \end{pmatrix} \quad (10)$$

where

$$\left. \begin{aligned} q_{zx} &= C_{44}\sigma_{zx}, \\ q_{yz} &= \frac{3}{2}C_{11}\sigma_{yz}. \end{aligned} \right\} \quad (11)$$

Next solving the usual eigenvalue equation given in the Appendix, we obtain the q tensor with respect to the $x^*y^*z^*$ system:

$$q_{x^*y^*z^*} = \begin{pmatrix} -\sqrt{q_{yz}^2 + q_{zx}^2} & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & \sqrt{q_{yz}^2 + q_{zx}^2} \end{pmatrix}. \quad (12)$$

It is seen from (12) that the asymmetry parameter defined by (4) is constant and has the value -1 . The directions of the principal axes $x^*y^*z^*$ are derived in the Appendix and it is found that one of them always lies in the xy -plane, while the other two have the slope of 45° to this plane. We have chosen the first one to be the y^* -axis and the latter two to be the z^* and x^* -axes, respectively. It is immaterial whether we choose the first one to be x^* or y^* ; the former choice will give $\eta=1$ instead of $\eta=-1$, but the coefficient of η in (6) also changes its sign and the result is quite identical.

a) $H_0//[100]$

$$\left. \begin{aligned} \sin^2 \theta &= \frac{1}{2} + \frac{1}{2} \frac{q_{yz}^2}{q_{yz}^2 + q_{zx}^2}, \\ \sin^2 \theta \cos 2\phi &= \frac{1}{2} - \frac{3}{2} \frac{q_{yz}^2}{q_{yz}^2 + q_{zx}^2}, \end{aligned} \right\} \quad (16)$$

b) $H_0//[010]$

$$\left. \begin{aligned} \sin^2 \theta &= \frac{3}{4} - \frac{1}{2} \frac{q_{yz}}{\sqrt{q_{yz}^2 + q_{zx}^2}} - \frac{1}{4} \frac{q_{yz}^2}{q_{yz}^2 + q_{zx}^2}, \\ \sin^2 \theta \cos 2\phi &= -\frac{1}{4} - \frac{1}{2} \frac{q_{yz}}{\sqrt{q_{yz}^2 + q_{zx}^2}} + \frac{3}{4} \frac{q_{yz}^2}{q_{yz}^2 + q_{zx}^2}, \end{aligned} \right\} \quad (17)$$

From (12) it is evident that q is given by the relation

$$q^2 = q_{yz}^2 + q_{zx}^2 \quad (13)$$

$$= C_{44}^2 \sigma_{zx}^2 + \frac{9}{4} C_{44}^2 \sigma_{yz}^2 \quad (13a)$$

$$= \left(\frac{Gb}{2\pi} \right)^2 \frac{1}{r^2} \left[C_{44}^2 \sin^2 \alpha + \frac{9}{4} C_{11}^2 \cos^2 \alpha \right] \quad (13b)$$

$$= \left(\frac{Gb}{2\pi} \right)^2 \frac{C_{44}^2}{r^2} [1 + \delta \cos^2 \alpha] \quad (13c)$$

where

$$\delta = \frac{9C_{11}^2 - C_{44}^2}{C_{44}^2} \quad (14)$$

and

$$\alpha = \tan^{-1} \frac{y}{x}. \quad (15)$$

δ defined by (14) is a measure of elastic anisotropy, the isotropic condition being $\delta=0$, or $9C_{11}^2 - 4C_{44}^2 = 0$, in which case q has no angular dependence. One of our task is to determine the value of δ .

$f(\theta, \phi)$ defined by (7) depends on the direction of the magnetic field. In the course of experiment, we have chosen three different directions of the magnetic field: With $[001]$ being the direction of linear compression, a) $H_0//[100]$, b) $H_0//[010]$ and c) $H_0//[110]$. The difference between a) and b) is that in the former the field direction is parallel to the slip plane, while in the latter it makes an angle of 45° with it. Such discrimination requires that only a single pair of slip systems which are perpendicular to each other go into action upon the linear compression. As will be described in the next section, it was indeed possible to produce a slip of such fashion. Anyway, the Eulerian angles in each case are given as follows:

c) $H_0/[110]$

$$\left. \begin{aligned} \sin^2 \theta &= \frac{5}{8} + \frac{1}{\sqrt{q_{yz}^2 + q_{zx}^2}} \left(\frac{1}{2\sqrt{2}} q_{zx} - \frac{1}{2} q_{yz} \right) + \frac{1}{q_{yz}^2 + q_{zx}^2} \left(\frac{1}{8} q_{yz}^2 + \frac{1}{2\sqrt{2}} q_{yz} q_{zx} \right), \\ \sin^2 \theta \cos 2\psi &= -\frac{3}{8} + \frac{1}{\sqrt{q_{yz}^2 + q_{zx}^2}} \left(\frac{1}{4} q_{yz} - \frac{1}{2\sqrt{2}} q_{zx} \right) \\ &\quad + \frac{1}{q_{yz}^2 + q_{zx}^2} \left(\frac{1}{8} q_{yz}^2 - \frac{3}{2\sqrt{2}} q_{yz} q_{zx} + \frac{1}{2} q_{zx}^2 \right) \\ &\quad + \frac{1}{(q_{yz}^2 + q_{zx}^2)^{3/2}} \left(-\frac{1}{2} q_{yz}^3 + \frac{1}{\sqrt{2}} q_{yz}^2 q_{zx} - \frac{1}{2} q_{yz} q_{zx}^2 + \frac{1}{\sqrt{2}} q_{zx}^3 \right). \end{aligned} \right\} \quad (18)$$

2) *Edge Dislocation*

The treatment is quite similar to the case of a screw dislocation. The stress field of an edge dislocation, however, is much more complicated than that of a screw dislocation; hence some approximation becomes unavoidable. The q tensor in the representation with respect to the dislocation axes is found to be

$$q_{xyz} = \begin{pmatrix} q_{zx} & q_{xy} & 0 \\ q_{xy} & q_{yy} & 0 \\ 0 & 0 & q_{zz} \end{pmatrix} \quad (19)$$

with

$$\left. \begin{aligned} q_{zx} &= \frac{C_{11}}{2} \left(\frac{1}{2} - \nu \right) (\sigma_{xx} + \sigma_{yy}) - \frac{C_{44}}{2} (\sigma_{yy} - \sigma_{xx}), \\ q_{yy} &= \frac{C_{11}}{2} \left(\frac{1}{2} - \nu \right) (\sigma_{xx} + \sigma_{yy}) + \frac{C_{44}}{2} (\sigma_{yy} - \sigma_{xx}), \\ q_{xy} &= \frac{3}{2} C_{11} \sigma_{xy}, \quad q_{zz} = C_{11} \left(\nu - \frac{1}{2} \right) (\sigma_{xx} + \sigma_{yy}), \end{aligned} \right\} \quad (20)$$

and

$$\left. \begin{aligned} \sigma_{xx} &= -D \frac{y(3x^2 + y^2)}{(x^2 + y^2)^2}, & \sigma_{yy} &= D \frac{y(x^2 - y^2)}{(x^2 + y^2)^2}, \\ \sigma_{xy} &= D \frac{x(x^2 - y^2)}{(x^2 + y^2)^2}; & D &= Gb/2\pi(1 - \nu) \end{aligned} \right\} \quad (21)$$

ν being the Poisson ratio.

After the transformation to the $x^*y^*z^*$ system we have

$$q_{x^*y^*z^*} = \begin{pmatrix} -\frac{q_{zz}}{2} - \frac{1}{2} \sqrt{(q_{xx} - q_{yy})^2 + 4q_{xy}^2} & 0 & 0 \\ 0 & q_{zz} & 0 \\ 0 & 0 & -\frac{q_{zz}}{2} + \frac{1}{2} \sqrt{(q_{xx} - q_{yy})^2 + 4q_{xy}^2} \end{pmatrix}. \quad (22)$$

It is seen that on account of the presence of q_{zz} , the tensor is rather involved compared with that of a screw dislocation. One is relieved, however, if he observes that the mean square of q_{zz} is only $\frac{9}{4}C_{11}^2/(9C_{11}^2 + 4C_{44}^2)$ times that of $\sqrt{(q_{xx} - q_{yy})^2 + 4q_{xy}^2}$, that is, the former is less than a tenth of the latter. Hence we shall neglect q_{zz} in the subsequent treatment. If this is allowed, the tensor reduces to

$$q_{x^*y^*z^*} \sim \begin{pmatrix} -\frac{1}{2}\sqrt{(q_{xx}-q_{yy})^2+4q_{xy}^2} & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & \frac{1}{2}\sqrt{(q_{xx}-q_{yy})^2+4q_{xy}^2} \end{pmatrix}. \quad (23)$$

As shown in the Appendix, the two nonvanishing axes of the field gradient tensor in this approximation always lie in the xy -plane of the dislocation line and rotate as the angle $\alpha = \tan^{-1} y/x$ changes. The q value and the necessary Eulerian angles are found to be

$$q^2 = \frac{1}{4} [(q_{xx}-q_{yy})^2 + 4q_{xy}^2] \quad (24)$$

$$= \frac{D^2}{r^2} \left[C_{44}^2 \sin^2 2\alpha + \frac{9}{4} C_{11}^2 \cos^2 2\alpha \right] \cos^2 \alpha \quad (24a)$$

$$= \frac{D^2}{r^2} C_{44}^2 (1 + \delta \cos^2 2\alpha) \cos^2 \alpha \quad (24b)$$

and

a) $H_0/[100]$

$$\left. \begin{aligned} \sin^2 \theta &= 1, \\ \sin^2 \theta \cos 2\psi &= -1; \end{aligned} \right\} \quad (25)$$

b) $H_0/[010]$

$$\left. \begin{aligned} \sin^2 \theta &= \frac{1}{2} - \frac{q_{xy}(q_{yy}-\lambda)}{q_{xy}^2 + (q_{yy}-\lambda)^2}, \\ \sin^2 \theta \cos 2\psi &= \frac{1}{2} - \frac{q_{xy}(q_{yy}-\lambda)}{q_{xy}^2 + (q_{yy}-\lambda)^2}; \end{aligned} \right\} \quad (26)$$

c) $H_0/[110]$

$$\left. \begin{aligned} \sin^2 \theta &= \frac{3}{4} - \frac{1}{2} \frac{q_{xy}(q_{yy}-\lambda)}{q_{xy}^2 + (q_{yy}-\lambda)^2}, \\ \sin^2 \theta \cos 2\psi &= -\frac{1}{2} - \frac{q_{xy}(q_{yy}-\lambda)}{q_{xy}^2 + (q_{yy}-\lambda)^2}. \end{aligned} \right\} \quad (27)$$

where λ is the root of the eigenvalue equation given in the Appendix. The final step to get the net frequency shift is to take the average and add together the effects due to both type dislocations. This procedure, of course, assumes the insignificance of the composite stress field as mentioned before. The result in each case is

a) $H_0/[100]$

$$\langle \nu - \nu_0 \rangle = B \left[\left(-\frac{2}{3} + \frac{2}{3} \delta \right) \pi a^2 c_s \ln \frac{1}{9\pi a^2 c_s} + \left(\frac{2}{3} + \frac{1}{3} \delta \right) \pi a^2 c_e \ln \frac{1}{9\pi a^2 c_e} \right], \quad (28)$$

b) $H_0/[010]$

$$\langle \nu - \nu_0 \rangle = B \left[\left(-\frac{1}{6} + \frac{1}{6} \delta \right) \pi a^2 c_s \ln \frac{1}{9\pi a^2 c_s} + \left(-\frac{7}{12} + \frac{1}{12} \right) \pi a^2 c_e \ln \frac{1}{9\pi a^2 c_e} \right], \quad (29)$$

c) $H_0/[110]$

$$\langle \nu - \nu_0 \rangle = B \left[\left(-\frac{1}{24} + \frac{1}{24} \delta \right) \pi a^2 c_s \ln \frac{1}{9\pi a^2 c_s} + \left(\frac{179}{768} + \frac{101}{384} \delta \right) \pi a^2 c_e \ln \frac{1}{9\pi a^2 c_e} \right]; \quad (30)$$

where

$$B = \frac{3}{400} \frac{1}{\pi^2} \frac{e^2 Q^2}{h^2 \nu_0} C_{44}^2 G^2. \quad (31)$$

As in the last paper²⁾, the radial integration has been carried out from $3a$ to $(\pi c)^{-1/2}$, where a is the lattice spacing. c_s and c_e are the densities of screw and edge dislocations, respectively. In view of the approximation made in dealing with edge dislocations, the Poisson ratio which has the value of $\sim 1/7$ has been neglected compared with unity. These expressions for three different angles of the applied magnetic field clearly indicate the possibility of the anisotropy of the nuclear magnetic resonance, which is to be demonstrated in the fourth section.

§ 3. Experimental Procedures

The measuring equipments for the resonance experiment are almost the same as reported in the previous papers,^{2),7)} except for the use of a Sumitomo-made permanent magnet. This magnet has poles of 13 cm in diameter and 4 cm in gap. The produced magnetic field is 4150 gauss at the center of the gap. The sweep of the magnetic field was made by changing the current through the auxilliary coils with a motor-driven slide rheostat.

The specimens of KI were produced by the Kyropoulos method from the melt of commercial reagent branded as "of special degree." Using the platinum crucible, crystallization was twice repeated in order to raise purity of the produced crystals. These grown crystals were then annealed at 30°C below the melting point for 24 to 48 hours by means of a potentiometric temperature-adjusting programmer and then cooled down to room temperature by the rate of 5°C per hour.

The method of plastic deformation was limited to a linear compression along one of the cubic axes. The oil-compressing weight-tester of the Civil Engineering Department was used in order to produce the deformed crystals of any desired degree of deformation, ranging from ten to twenty percent, which are most suitable for the present purpose.

Some of the crystals were so deformed that only a single pair of slip systems which are perpendicular to each other went into motion upon the compression. This queer way of slip was recognized by examining the resultant shape of the deformed crystal. In general the rectangular cleaved crystal is swollen to its all four side directions upon deformation.

By a method with some knack, however, only a pair of opposite side planes get swollen, indicating that the slip has occurred only two-fold. This situation is schematically shown in Fig. 1, in which it is assumed that the direction of linear compression is along $[001]$. Such a slip is easily achieved when the cross-sectional edge lengths of the cleaved crystal are different by a factor of more than two. Yet in the case of a crystal having a square cross section, the achievement of such slipping is rather fortuitous and critically depends on the initial conditions of the stress application.

Fig. 1. The ways of slip after linear compression along one of the cubic axes. Two- and four-fold slips are indicated in the figures of the resultant deformed crystals.

In order to study the anisotropy of the resonance line, we prepared two such specimens with two-fold slip, one having a square cross section and the other consisting of six small pieces with rectangular cross sections. The degree of deformation for these crystals were around fourteen percent.

Except for some test experiment in the liquid air temperature, every measurement was carried out in the room temperature at the sacrifice of signal-to-noise ratio, since the specimens, especially heavily cold-worked ones,

got easily cracked upon soaking into the liquid air, however carefully we did it.

§ 4. Experimental Results and Analyses

Owing to the large eQq , the resonance line promptly broadens upon plastic deformation. Under the usage of a relatively low magnetic field, this effect is more pronounced, since the frequency shift and hence the broadening is

inversely proportional to the applied field strength in the case of the second order perturbation. Even the resonance line of an undeformed crystal has a slight asymmetry, indicating that the defects have not completely been removed. This slight asymmetry, however, is next to independent of the direction of the magnetic field and hence is expected to arise partly from point defects such as impurities or vacancies or their clusters. If the magnetic field were somewhat raised, say to 6,000 gauss, this asymmetry would almost completely escape one's notice.

The intensity reduction of the resonance line against the degree of deformation is shown in Fig. 2, and in Fig. 3 are plotted the observed first moments (asymmetry) of the resonance lines for $H_0//[100]$ with the crystals which underwent the ordinary four-fold slip. Since the latter is a linear function of the dislocation density,* the straight line

Fig. 2. Reduction of peak intensity of the resonance absorption curves upon the linear compression. A similar result with KBr under a lower magnetic field of 3,600 gauss is indicated by the dotted line.

Fig. 3. The first moments of the resonance absorption curves in the case of $H_0//[100]$. Those crystals used were with four-fold slips as indicated in Fig. 1.

Fig. 4. Anisotropy of the resonance lines for a deformed crystal which underwent a two-fold slip. The directions of the magnetic field are as specified in Fig. 1.

* The logarithmic factors are considered to be constant.

drawn in the figure indicates that the dislocation density increases linearly with the degree of plastic deformation in the range of 10 to 15 percent. This is in essential agreement with the conclusion of the previous paper²⁾. The datum on the heaviest deformed specimen may not be looked upon with much weight, since the smaller sample size and poor signal-to-noise ratio owing to a large broadening considerably obscured the evaluation of the first moment.

By the specimens with two-fold slip, we see a conspicuous anisotropy characteristic of the resonance line shape as shown in Fig. 4. If we specify the directions of the magnetic field as defined in §2, the degree of asymmetry is greatest for $H_0//[010]$ and smallest for $H_0//[110]$. The results of the first moment evaluations for the two specimens are listed in the Table I. The sample I is that with square cross section and the other is a glued pack of six small rectangular slices.

Table I. The first moments of the resonance lines for the deformed crystals with two-fold slip (in units of gauss).

Sample	$H_0//[100]$	$H_0//[010]$	$H_0//[110]$
I	0.30 ± 0.02	0.38 ± 0.04	0.11 ± 0.04
II	0.31 ± 0.02	0.41 ± 0.03	0.13 ± 0.03

If we handle these figures with the formulae (28), (29) and (30), we shall get the values of δ and the ratio of the dislocation densities of two types. We should, however, not take the figures in Table I at their face values, since the specimens already had a slight initial asymmetry before plastic deformation. This initial asymmetry was sensibly constant for each undeformed crystal and within experimental error equal for $H_0//[100]$ and $H_0//[110]$, having the value of (0.12 ± 0.03) gauss. If we subtract this from the figures in Table I, we get the pure effect caused by the plastic deformation. Owing to the relatively large errors, which are inherent in the measurement of the first moment, such subtraction is rather arbitrary and might be regarded with some doubt. Especially, with $H_0//[110]$ the result of such subtraction will be quite meaningless. We should be more sensible by stating that for $H_0//[110]$ the resonance line has no asymmetry so long as the effect of the plastic

deformation is concerned. This situation was scanned also for other deformed crystals which rather underwent the four-fold slip and the result is given in Fig. 5. In contrast with $H_0//[100]$, in which asymmetry increases with increasing degree of deformation, any heavy amount of cold-working seems not to affect the asymmetry characteristic of the resonance line more than its initial stage for $H_0//[110]$.

Fig. 5. The first moments of the resonance absorption curves in the case of $H_0//[110]$. The crystals are the same as in Fig. 3.

Hence we may in a rough sense equate (30) to zero. For the other two directions, the above-mentioned subtraction should be allowed with some ease. When it is done, the ratios of the first moments of the resonance lines for $H_0//[100]$ to $H_0//[010]$ become 0.69 and 0.65 for samples I and II, respectively. For brevity, we substitute 0.67, their mean, to both. Then, by connecting (28) with (29), we have

$$\left(-\frac{2}{3} + \frac{2}{3}\delta\right)p + \frac{2}{3} + \frac{1}{3}\delta = 0.67 \left[\left(-\frac{1}{6} + \frac{1}{6}\delta\right)p + \left(-\frac{7}{12} + \frac{1}{12}\delta\right) \right], \quad (32)$$

while equating (30) to zero, we have another equation

$$\left(-\frac{1}{24} + \frac{1}{24}\delta\right)p + \frac{179}{768} + \frac{101}{364}\delta = 0. \quad (33)$$

Here $p = c_s/c_e$, and the logarithmic factors have been removed out being regarded as constants. Solving these simultaneous equations, we obtain $p = 0.88 \sim 0.9$ and $\delta = -0.76$. It is seen that the densities of the two dislocation types are essentially of the same order of magnitude

and the above value of δ yields $|C_{44}/C_{11}| \sim 3$.

§ 5. Discussion

It is reasonable that the dislocation density is divided nearly equally to screw and edge types. If the edge dislocations were predominant, (28) predicts that the sign of the first moment would be contrary to the experimental result for $H_0/[100]$. Inversely, one observes that neither screw dislocations can be overwhelming, since (29) should give one-fourth the first moment of (28) for screw dislocations, which again is contradictory to the experimental result. Thus, the dislocation densities are found to be quite well balanced.

The absolute values of C_{11} and C_{44} cannot be determined directly from the present experiment. They are, however, obtained if we give the densities of dislocations. In the previous paper we determined the dislocation densities of plastically deformed KBr²⁾. The way of analysis used there is less precise and hence no such delicate analysis as obtaining anisotropy of the resonance line should be extracted from it; nevertheless we expect that a rather rough talk like an order of magnitude density estimation of dislocations would not be so far from the real one. If all the four slip systems have acted, the total asymmetry is given by

$$\begin{aligned} & \langle \nu - \nu_0 \rangle_{\text{total}} \\ &= \frac{-9 + 15\delta}{6400} \frac{1}{\pi^2} \frac{e^2 Q^2}{h^2 \nu_0} C_{44}^2 G^2 \pi a^2 c \ln \frac{1}{9\pi a^2 c} \quad (36) \end{aligned}$$

where it is assumed $c_s = c_e = c/2$. Take a value from Fig. 2 for $\langle \nu - \nu_0 \rangle_{\text{total}}$ and give a proper corresponding value of c ; then we shall get C_{44} . For ten percent deformation $\langle \nu - \nu_0 \rangle_{\text{total}}$ is -130 cps, while the corresponding dislocation density for KBr was $\sim 10^9 \text{ cm}^{-2}$ as reported in the last paper, which would be nearly the same for KI. We thus obtain $C_{44} = \pm(8.3 \times 10^4)$ statvolts/dyne with $C_{11} = \pm(2.7 \times 10^4)$ statvolts/dyne. If we put $c = 10^8 \text{ cm}^{-2}$, they are multiplied by a factor of ~ 3 , and for $c = 10^{10} \text{ cm}^{-2}$ reduced by the same factor. Those values given above are somewhat larger than those for In¹¹⁶ in InSb, which have been found to be $C_{11} = \pm(2.4 \times 10^4)$ statvolts/dyne and $C_{44} = \mp(2.4 \times 10^4)$ statvolts/dyne.

Shulman et al. conclude from their analysis that C_{11} and C_{44} should have opposite signs

for InSb. Since our case is concerned only with the second order effect, these tensor components always appear as square and hence their signs cannot be determined. The derivation of C tensor does not predict that C_{11} and C_{44} should have opposite signs. Hence in our analyses both C values have been given a simple double sign.

Finally some comments should be made on the intensity reduction of the deformed crystals. Since we formerly performed a similar experiment on KBr, it is of interest to compare the effects on Br⁷⁹ and I¹²⁷. In Fig. 2 is plotted also the result for Br⁷⁹ with a dotted line. It seems that the effect is nearly 1.3 times greater with KI. The nuclear spin values for them, however, are different; i.e., $I=3/2$ for Br⁷⁹ and $I=5/2$ for I¹²⁷. Furthermore, the experiment on KBr was performed under a lower magnetic field of 3,600 gauss. If these differences are taken into account, we see that the amplification factor of eQq of I¹²⁷ is nearly twenty percent larger than that of Br⁷⁹. Therefore, if we take $\lambda \sim 40$ for the latter, as derived in the last paper, the amplification factor of I¹²⁷ in KI should become $\lambda \sim 50$. It should further be noted, however, that in the case of KI, the intensity standard itself is not actually 1.0 as given in Fig. 2, but is already reduced a bit, and hence we should consider the actual effect must be somewhat larger with KI. Then, $\lambda \sim 50$ should be regarded only as the lower limit of the real value of λ . In the previous paper, determination of λ for KBr was achieved by the mixed crystal technique; namely, the studies of eQq due to the minority component NaBr, which was introduced into the mother crystal KBr, enabled us to estimate λ . Such a procedure might be followed also for KI, by growing another kind of mixed crystal, say KI-NaI, and studying a similar effect. For the intensity standard, we should, of course, require a more perfect crystal than that used in the present work. Or, at least we require a higher magnetic field. Using the value of λ thus determined, we might as well go along the line as described in the former paper in order to do a simplified dislocation analysis. The present treatment requires two parameters C_{11} and C_{44} and hence is rather complicated compared with the former one.

§ 6. Conclusion

The anisotropy of nuclear magnetic resonance due to crystal dislocations can be well accounted for, if we assume nearly equal densities for edge and screw dislocations and $\delta = -0.76$. Since $\delta = 0$ is the isotropic condition, this values indicates that KI is highly anisotropic in elastic properties. This is supported by the fact that the anisotropy factor defined by $2c_{44}/(c_{11} - c_{12})$ is 0.37 and much smaller than unity which is the condition for elastic isotropy. Assuming the total dislocation density to be $\sim 10^9 \text{ cm}^{-2}$ for a ten percent deformed crystal, we get $|C_{44}| \sim 8 \times 10^4$ stat-volts/dyne and its one-third for $|C_{11}|$.

§ 7. Acknowledgement

The author wishes to express his sincere thanks to Prof. H. Kawamura, under whose guidance this work has been completed. Comments and discussions on this subject made by Prof. T. Nagamiya and his laboratory members are highly appreciated. Particular thanks go to Mr. H. Okura in our laboratory for his kind cooperation in preparing single crystals of KI, which were most essential in the present work. The author also thanks Mr. Y. Fukui for his technical assistance in some parts of experiment. This work has partially been supported by the Scientific Research Grant of the Ministry of Education.

Appendix

The principal axes of the field gradient tensor around a screw dislocation are found by solving the determinantal equation

$$\begin{vmatrix} -\lambda & 0 & q_{zx} \\ 0 & -\lambda & q_{yz} \\ q_{zx} & q_{yz} & -\lambda \end{vmatrix} = 0 \quad (\text{A1})$$

for λ , and we get

$$\left. \begin{aligned} \lambda_1 &= 0, \\ \lambda_2 &= +\sqrt{q_{yz}^2 + q_{zx}^2}, \\ \lambda_3 &= -\sqrt{q_{yz}^2 + q_{zx}^2}. \end{aligned} \right\} \quad (\text{A2})$$

Their direction cosines with respect to the axes of the dislocation, l_p , m_p , n_p , where p is the suffix of λ , are obtained through the linear relations:

$$\left. \begin{aligned} q_{zx}n_p &= \lambda_p l_p, \\ q_{yz}n_p &= \lambda_p m_p, \\ q_{zx}l_p + q_{yz}m_p &= \lambda_p n_p. \end{aligned} \right\} \quad (\text{A3})$$

For $p=2$ and 3, we get

$$\left. \begin{aligned} l_p^2 &= \frac{1}{2} \frac{q_{zx}^2}{q_{yz}^2 + q_{zx}^2}, \\ m_p^2 &= \frac{1}{2} \frac{q_{yz}^2}{q_{yz}^2 + q_{zx}^2}, \\ n_p^2 &= \frac{1}{2}. \end{aligned} \right\} \quad (\text{A4})$$

and for $p=1$

$$\left. \begin{aligned} l_1^2 &= \frac{q_{yz}^2}{q_{yz}^2 + q_{zx}^2}, \\ m_1^2 &= \frac{q_{zx}^2}{q_{yz}^2 + q_{zx}^2}, \\ n_1^2 &= 0. \end{aligned} \right\} \quad (\text{A5})$$

In the text we have allotted λ_2 to the z^* -axis, λ_3 to the x^* -axis and λ_1 to the y^* -axis.

A similar treatment is applied to the field gradient tensor around an edge dislocation. In this case we must solve the determinantal equation

$$\begin{vmatrix} q_{xx} - \lambda & q_{xy} & 0 \\ q_{xy} & q_{yy} - \lambda & 0 \\ 0 & 0 & q_{zz} - \lambda \end{vmatrix} = 0. \quad (\text{A6})$$

The homogeneous equations determining the direction cosines of the principal axes become

$$\left. \begin{aligned} q_{zx}l_p + q_{xy}m_p &= \lambda_p l_p, \\ q_{xy}l_p + q_{yy}m_p &= \lambda_p m_p, \\ q_{zx}n_p &= \lambda_p n_p; \end{aligned} \right\} \quad (\text{A7})$$

where $p=1, 2, 3$ and

$$\left. \begin{aligned} \lambda_1 &= q_{zz}, \\ \lambda_2 &= -\frac{q_{zz}}{2} + \frac{1}{2} \sqrt{(q_{xx} - q_{yy})^2 + 4q_{xy}^2}, \\ \lambda_3 &= -\frac{q_{zz}}{2} - \frac{1}{2} \sqrt{(q_{xx} - q_{yy})^2 + 4q_{xy}^2}. \end{aligned} \right\} \quad (\text{A8})$$

The allocation of λ_p 's to the $x^*y^*z^*$ axes is likewise to a screw dislocation.

From the third equation of (A7), we get

$$n_{2,3} = 0; \quad (\text{A9})$$

then we have for $p=2$ and 3:

$$\left. \begin{aligned} l_p^2 &= \frac{q_{xy}^2}{(q_{xx} - \lambda_p)^2 + q_{xy}^2} = \frac{(q_{yy} - \lambda_p)^2}{q_{xy}^2 + (q_{yy} - \lambda_p)^2}, \\ m_p^2 &= \frac{(q_{xx} - \lambda_p)^2}{(q_{xx} - \lambda_p)^2 + q_{xy}^2} = \frac{q_{xy}^2}{q_{xy}^2 + (q_{yy} - \lambda_p)^2}. \end{aligned} \right\} \quad (\text{A10})$$

It should be emphasized that although we have neglected q_{zz} compared with $\sqrt{(q_{xx} - q_{yy})^2 + 4q_{xy}^2}$ in the course of analysis described in the text,

we must use exact λ_p values in (A10) in order to evaluate the direction cosines. Only with this care being taken, we may calculate the average of $q^2 f(\theta, \psi)$.

Effect of Velocity Gradient on the Radial Distribution of Polymer Molecules in Dilute Solution

By Ryuzo KOYAMA

Electrical Communication Laboratory, Musashino-shi, Tokyo.

(Received June 11, 1958)

A differential equation which determines the time dependence of the radial distribution function of polymer molecules in dilute solution is derived. The equation is represented in a form of a diffusion equation.

For a case in which the solution is flowing with the constant velocity gradient, and the system is at a steady state, a calculation is carried out, adopting a Gaussian intermolecular potential between free draining chain polymer molecules. The result shows that the velocity gradient in solution causes the radial distribution function to be deformed into a non-spherical symmetry, and this deformation is increased with the increase of the velocity gradient and the molecular weight of polymer.

§ 1. Introduction

In the recent articles¹⁻³⁾ we considered the interaction properties of polymer molecules in solution, and derived theoretical expressions for the mean intermolecular potential and the radial distribution function between two centers of gravity of two polymer molecules in dilute solutions. In these treatment the solutions were considered to be in thermodynamical equilibrium, and the mean intermolecular potential function and the radial distribution function obtained are spherically symmetric and of course do not depend on time. In the present article, such problems are considered from a more detailed situation, and the methods are extended to a more general case where the solutions are not always in thermodynamical equilibrium.

§ 2. Distribution of Molecular Pairs in Solution

In the following treatment we shall assume that the every point in our polymer solution is in the same external condition at the same moment. However, it is considered that if this assumption is not satisfied in a solution, the same discussion can be applied separately for each individual domain of different external condition of the solution.

For the simplicity of discussion, we shall neglect the internal configurations of the polymer molecules, and shall notice only the coordinates and the velocity of the center of gravity of each polymer molecule in the solution.

We denote the coordinates of the center of gravity of the i -th polymer molecule existing

in our polymer solution by $\mathbf{r}_i$, and define the pair vector $\mathbf{r}_{ij}$ which represents the relative coordinates of two polymer molecules i and j , as follows:

$$\mathbf{r}_{ij} = \mathbf{r}_j - \mathbf{r}_i, \quad i \neq j \quad (2.1)$$

If n polymer molecules exist in a unit volume of the solution, the total number z of the possible pair vectors which can be taken from this unit volume is given by $z = n(n-1)$.

We also define a density distribution function of these pair vectors $g(\mathbf{r}, t)$ and represent the number of the pair vectors which fall in a small volume element $d\mathbf{r}$ situated at the position $\mathbf{r}$ at the time t by $zg(\mathbf{r}, t)d\mathbf{r}$. If all the possible pair vectors in this unit volume of solution are represented in a common space ($\mathbf{r}$) of three dimensions, we can consider an assembly of the representative points of the pair vectors in this space, and the number density of these points at the position $\mathbf{r}$ at the time t is given by $zg(\mathbf{r}, t)$.

As in our case every point in the solution is at the same external condition, the distribution function $g(\mathbf{r}, t)$ defined here is equivalent to the radial distribution function of polymer molecules in the solution at the same external condition. Therefore, as we stated in the previous section, when the polymer solution is in the thermodynamical equilibrium, and any external field does not exist, the distribution function $g(\mathbf{r}, t)$ is spherically symmetric about the origin and does not depend on the time. But, in more general case where the solution is not in equilibrium, the function $g(\mathbf{r}, t)$ would be supposed to have a more complicated feature and generally to depend on the time. We shall consider such a problem in this work.

A solute polymer molecule in solution is moving under complex exertion of the various intermolecular forces of the solvent and the other solute molecules surrounding it, and its instantaneous acceleration or velocity is generally determined by all the coordinates of these molecules. However, in our treatment, following an ordinary theoretical method for dilute polymer solution, we shall suppose that our polymer solution is composed of a continuous medium of solvent and of the solute polymer molecules dispersed in this solvent medium.

Assuming such a theoretical model, we can

decompose generally the molecular velocity of a solute polymer molecule into the following several components:

i) The component for the random thermal motion, which is considered to represent the random Brownian motion of an isolated solute molecule in the pure solvent of the same external conditions.

ii) The component caused by the intermolecular effects exerted by the other solute molecules and by other external forces. (In the present work, for the simplicity of discussion, we shall not consider any effects of external forces).

iii) The component due to the velocity of solvent medium.

When a single solute molecule is isolated in a pure solvent, the motion of this molecule is considered to be a certain isotropic random Brownian motions. But it is supposed that if another solute molecule is introduced into the system, the random motion of the former molecule is affected by the presence of the latter molecule, and certain components of velocity which depends on the relative coordinates of two molecules are added. Such components can be described as the effects of intermolecular interaction.

Generally the solute molecules interact according to the intermolecular force acting between them. As shown in the general statistical mechanics of solution, the possible microscopic configurations of the solution yield the average intermolecular force between the solute molecules in the solution, which is dependent on the relative coordinates of the two molecules. Besides this, we can consider another kind of intermolecular effect of solute molecules, which we may call the hydrodynamic interaction. Since the solvent medium is regarded as a viscous liquid, the relative motion of the solute molecule to the solvent causes the viscous motion in the surrounding solvent, and affects the motion of the other solute molecules. This intermolecular effect is dependent on the relative coordinates of two molecules and also on their velocities in the solvent. Therefore we may consider that even if the intermolecular force does not exist between the solute molecules, their thermal motions are usually affected by this effect.

However, according to ordinary discussions, these intermolecular effects are usually not

conspicuous excepting the case where the molecular separating is so small that the distance between the centers of gravity of two polymer molecules is comparable with the dimension of the molecules, and that the segments of the other molecule can contact with each other. As the solution becomes dilute, the mean intermolecular distance between neighbouring solute molecules becomes large, and so the average number of molecules which exert the conspicuous interaction effects on one solute molecule is decreased.

We shall here assume that our polymer solution is sufficiently diluted and that the whole intermolecular effects exerted on one polymer molecule from the surrounding molecules can be neglected except that exerted from its nearest neighbouring molecule, and also that if a solute molecule has not any neighbouring molecules in a certain distance, such a molecule can be described to be isolated.

Thus, more quantitatively, it is assumed that we can choose a certain distance, l , in our solution, which satisfies the following conditions:

i) The total intermolecular effects exerted on one solute molecule from the whole part of the solution which is at a distance of more than l from this molecule can be neglected or at least can be left out of account in our discussion.

ii) If a spherical surface having radius of l is supposed in our solution, the probability of finding more than three solute molecules in the interior of this spherical surface is negligibly small compared with that of finding two solute molecules in it.

On this assumption, we suppose a spherical surface, S , whose center is at the origin of the space $(\mathbf{r})$, and radius is l , then we can conclude that every point of the molecular pair involved in the interior of this surface is moving independently with each other. For the two molecules i and j corresponding to a vector $\mathbf{r}_{ij}$ in this domain are interacting with each other, but there is considered not to exist any other molecules exerting the conspicuous interactions on them, and so the motion of the vector $\mathbf{r}_{ij}$ is determined by itself and does not depend on the other vectors in the interiors of S , except on the inverse $\mathbf{r}_{ji}$. Thus, from this conclusions we can obtain

the change of the distribution function $g(\mathbf{r}, t)$ in space $(\mathbf{r})$.

We shall consider the motion of a point of pair vector $\mathbf{r}_{ij}$ in the interior of the spherical surface S . We denote the friction constants of two molecules i and j by ζ_i and ζ_j respectively, and define the diffusion constants D_i and D_j of the respective molecules by the well known relations:

$$D_i \zeta_i = kT, \quad D_j \zeta_j = kT, \quad (2.2)$$

where T is the absolute temperature, and k is Boltzmann's constant. Since the two molecules i and j are interacting hydrodynamically, the constants ζ_i , ζ_j ; D_i and D_j depend on the coordinates $\mathbf{r}_{ij}$ and are generally to be represented in the tensor forms, whose elements are functions of $\mathbf{r}_{ij} = \mathbf{r}$.

Fig. 1. Pair vector and spherical surface S in the space $(\mathbf{r})$.

The velocity of the point $\mathbf{r}_{ij}$ in space $(\mathbf{r})$ is given by the difference of those of two molecules i and j in the solution. So we can decompose the velocity of the point into several components in a similar manner as that in case of the solute molecule in the solution.

i) The components for the random thermal motion of two solute molecules i and j in solution induce a similar component of motion for the point $\mathbf{r}_{ij}$ in space $(\mathbf{r})$, which is given by the resultant of those of two molecules in the solution. Therefore the diffusion constant D_{ij} associated with the induced thermal motion of point $\mathbf{r}_{ij}$ in space $(\mathbf{r})$ is clearly given by the sum of those of two molecules,

$$D_{ij} = D_i + D_j. \quad (2.3)$$

From the conception of the diffusion constant and from the symmetry property of the configuration of two molecules, we can conclude that

$$\left. \begin{aligned} D_i &= D_j = D_0(\mathbf{r}_{ij}) = D_0(\mathbf{r}), \\ D_{ij} &= 2D_0(\mathbf{r}) \end{aligned} \right\} \quad (2.4)$$

where $\mathbf{r}$ denotes the coordinates of the point of pair vector in space ($\mathbf{r}$).

As has been often indicated⁴⁾, the Brownian motion of a solute particle in the solution can be replaced by a stochastic random flight motions, in which the element of the diffusion tensor is represented as proportional to the number of flights in unit time. This consideration leads us to the relations of Eq. (2.3) and (2.4), with the aid of a hydrodynamic consideration.

The points of pair vectors in space ($\mathbf{r}$) are distributed according to the distribution function $g(\mathbf{r}, t)$, and hence the flow of the density of points due to the thermal motion in space ($\mathbf{r}$) is given by

$$-2D_0(\mathbf{r}) \text{grad } g(\mathbf{r}, t). \quad (2.5)$$

ii) The components of velocities of two molecules i and j caused by their intermolecular force $f(\mathbf{r}_{ij})$ also induce a component of velocity for the motion of the point $\mathbf{r}_{ij}$, which is equal to the difference of those of two molecules. Similarly as in case of the diffusion constants, we can get the following relations for the friction constants,

$$\zeta_i = \zeta_j = \zeta_0(\mathbf{r}_{ij}) = \zeta_0(\mathbf{r}) \quad (2.6)$$

So employing the friction tensor $\zeta_0(\mathbf{r})$, the flow of the density of points in space ($\mathbf{r}$) caused by the intermolecular force $f(\mathbf{r})$ is written as

$$2\zeta_0(\mathbf{r})^{-1}f(\mathbf{r})g(\mathbf{r}, t). \quad (2.7)$$

iii) Also, the velocity gradient in the solvent medium causes a hydrodynamic relative velocity $v(\mathbf{r}, t)$ between two solute molecules which are separated by the distance $\mathbf{r}$. As in our case every point in the solution is at the same external condition at the same time, the velocity $v(\mathbf{r}, t)$ is a function of only the relative coordinates of two molecules and of the time. The corresponding flow of the density of points in space ($\mathbf{r}$) due to the velocity gradient of solution can be written as

$$v(\mathbf{r}, t)g(\mathbf{r}, t). \quad (2.8)$$

Thus the total flow of the density of the points, $u(\mathbf{r}, t)$ is represented by

$$\begin{aligned} v(\mathbf{r}, t) &= -2D_0(\mathbf{r}) \text{grad } g(\mathbf{r}, t) \\ &+ 2\zeta_0(\mathbf{r})^{-1}f(\mathbf{r})g(\mathbf{r}, t) + v(\mathbf{r}, t)g(\mathbf{r}, t) \end{aligned} \quad (2.9)$$

and we obtain a differential equation for the distribution function $g(\mathbf{r}, t)$, in the form of the equation of continuity, as follows:

$$\begin{aligned} \text{div} [D_0(\mathbf{r}) \text{grad } g(\mathbf{r}, t) - \zeta_0(\mathbf{r})^{-1}f(\mathbf{r})g(\mathbf{r}, t) \\ - 2^{-1}v(\mathbf{r}, t)g(\mathbf{r}, t)] = 2^{-1}\partial g(\mathbf{r}, t)/\partial t. \end{aligned} \quad (2.10)$$

In case that the intermolecular force $f(\mathbf{r})$ is derived from a potential function $W(\mathbf{r})$, that is

$$f(\mathbf{r}) = -\text{grad } W(\mathbf{r}), \quad (2.11)$$

Eq. (2.10) can be written in the form,

$$\begin{aligned} \text{div} [D_0(\mathbf{r}) \text{grad } g(\mathbf{r}, t) + \zeta_0(\mathbf{r})^{-1} \text{grad } W(\mathbf{r})g(\mathbf{r}, t) \\ - 2^{-1}v(\mathbf{r}, t)g(\mathbf{r}, t)] = 2^{-1}\partial g(\mathbf{r}, t)/\partial t. \end{aligned} \quad (2.12)$$

When the velocity gradient does not exist through the solution, and the system is at the equilibrium, we have

$$v(\mathbf{r}, t) = 0; \quad \partial g(\mathbf{r}, t)/\partial t = 0, \quad (2.13)$$

and also the total flow $u(\mathbf{r}, t)$ should vanish, i.e.

$$u(\mathbf{r}, t) = 0 \quad (2.14)$$

so from Eq. (2.9) or Eq. (2.12) we obtain the relation:

$$D_0(\mathbf{r}) \text{grad } g(\mathbf{r}) + \zeta_0(\mathbf{r})^{-1} \text{grad } W(\mathbf{r})g(\mathbf{r}) = 0 \quad (2.15)$$

Employing the relation, $D_0(\mathbf{r})\zeta_0(\mathbf{r}) = kT$, of Eq. (2.2), we have a natural solution for this case,

$$g_0(\mathbf{r}) = \exp \{-W(\mathbf{r})/kT\}. \quad (2.16)$$

§ 3. A Simple Calculation for Free Draining Macromolecules

There can be considered various examples or applications of Eq. (2.10)⁸⁾. We shall here treat a simple example, in which the solution is flowing with the constant velocity gradient, and the system is at the steady state. In this case the distribution function $g(\mathbf{r}, t)$ and the velocity function $v(\mathbf{r}, t)$ do not depend on the time, and Eq. (2.12) can be written as follows:

$$\begin{aligned} \text{div} [D_0(\mathbf{r}) \text{grad } g(\mathbf{r}) + \zeta_0(\mathbf{r})^{-1} \text{grad } W(\mathbf{r})g(\mathbf{r}) \\ - 2^{-1}v(\mathbf{r})g(\mathbf{r})] = 0. \end{aligned} \quad (3.1)$$

As previously stated, there exist generally two kinds of interaction effects between solute polymer molecules in solution, and it is considered that the properties of such molecular interaction effects are different for the individual solute-solvent system, and also they de-

pend on the physical states of the solution. Therefore it is convenient to discuss the various examples according to their individual characterized properties of the system.

In our present problem we shall assume that the effects of the hydrodynamic interaction of the solute molecules is very small compared with that of the static intermolecular potential, and shall examine the effect of the velocity gradient on the radial distribution of the polymer molecules in solution.

According to this assumption we shall put the molecular diffusion tensor $D_0(\mathbf{r})$ and the friction tensor $\zeta_0(\mathbf{r})$ to be constants which are independent of the coordinates $\mathbf{r}$.

The velocity function $v(\mathbf{r})$ is generally to be determined by the pure hydrodynamical calculation for the system of two molecules. But, as in our calculation we are not considering the hydrodynamic molecular interaction, here we also assume a so-called free draining molecule, which has been often adopted in the various theoretical treatment⁽⁵⁾, that is, in which the streaming line of the solvent is assumed not to be disturbed by the presence of the solute molecules. Thus, denoting the velocity gradient by q , we put

$$\left. \begin{aligned} v(\mathbf{r}) &= (qy, 0, 0); \\ v_x &= qy, \quad v_y = v_z = 0, \end{aligned} \right\} \quad (3.2)$$

where the coordinate axes are so chosen that the streaming line is parallel to the x -axis and the velocity gradient is in y -direction as shown in Fig. 2. This assumption directly gives us the relation:

$$\text{div } v(\mathbf{r}) = 0 \quad (3.3)$$

We have also necessity of the knowledge of the intermolecular potential function $W(\mathbf{r})$ in our calculation. In the recent paper⁽²⁾, we derived an expression of the mean intermolecular potential between chain polymer molecules, which is written in the form:

$$W(\mathbf{r}) = kT X e^{-\alpha - 2r^2} \quad (3.4)$$

where X and α are constants depending upon the molecular weight of polymer and on the temperature. We shall adopt this form of the potential function $W(\mathbf{r})$ in the following calculation.

Next, we shall consider the equipotential surface in space $(\mathbf{r})$, which is defined by the equation:

$$g(\mathbf{r}) = \text{constant} \quad (3.5)$$

This equation means that the distribution function $g(\mathbf{r})$ or the apparent intermolecular potential $-kT \log g(\mathbf{r})$ should assume a constant value on the equipotential surface.⁽¹⁾ As is often repeated, when the solution has not the velocity gradient, and the system is at the thermodynamical equilibrium, the distribution function $g(\mathbf{r})$ depends only on the magnitude of the coordinates $\mathbf{r}$ as shown in Eq. (2.16), and hence the equipotential surface is clearly given as the spherical surface. Therefore, it is generally considered that when the velocity gradient exist in the solution, the equipotential surface would be deformed into the non-spherical symmetry, corresponding to the magnitude of the velocity gradient. If the differential equation (3.1) is integrated, the equipotential surface can be determined from the definition in Eq. (3.5). But, in the following discussions we shall not integrate the equation directly, but employing a suitable assumption for the equipotential surface, an approximate calculation shall be shown.

Fig. 2. Deformation of the equipotential surface by the velocity gradient.

From the symmetric property of our physical state of solution and a simple geometrical consideration, we shall here assume that the equipotential surface can be approximately represented by the ellipsoidal surface, and we write the equation of the equipotential surface as the following form:

$$(1-\lambda)\xi^2 + (1-\mu)\eta^2 + (1-\nu)\zeta^2 = \text{constant} \quad (3.6)$$

where the coordinate axes ξ , η and ζ are so chosen as to coincide with the principal axes of the ellipsoid. The parameters λ , μ and ν

are considered to be functions of the velocity gradient, and when the velocity gradient vanishes they should assume an equal value. Then, according to this assumption, and Eqs. (2.41) and (3.4), the distribution function $g(\mathbf{r})$ should be put as follows:

$$\left. \begin{aligned} g(\mathbf{r}) &= \exp \{ -X e^{-\alpha^{-2}(r^2 - \psi(r, q))} \} , \\ \psi(r, q) &= \lambda \xi^2 + \mu \eta^2 + \nu \zeta^2 . \end{aligned} \right\} \quad (3.7)$$

From the symmetricity of the physical condition of our solution we can conclude that one of the principal axis, ζ is coincident with the z axis of the original coordinate system. Thus, substituting Eq. (3.7) into Eq. (3.1), and comparing the terms of the constants and those of each second power of ξ , η and ζ respectively, the following relations are obtained.

$$\left. \begin{aligned} 4\lambda(7-2\lambda) - 8X\lambda(1-\lambda) \\ -(1-\lambda)\alpha^2 D_0^{-1} q \sin 2\chi &= 0 , \\ \mu &= -\lambda , \\ \nu &= 0 , \\ \tan^2 \chi &= \frac{1-\lambda}{1+\lambda} , \end{aligned} \right\} \quad (3.8)$$

where χ denotes the angle between the flow direction x and the principal axis of the ellipsoid ξ , or between the direction of the velocity gradient y and another principal axis η as shown in Fig. 2. Thus, knowing the value of the quantity $\alpha^2 D_0^{-1} q$, the parameters λ , μ and ν and the angle χ can be calculated from these equations. As is shown in Eq. (3.8), in case that the velocity gradient q is very small, and the deviation of the equipotential surface from the spherical surface is also very small, the angle χ is nearly equal to $\pi/4 = 45^\circ$, and λ and μ are approximately represented by the formula:

$$\lambda = -\mu = \frac{\alpha^2 D_0^{-1} q}{4(7-2X)} , \quad (3.9)$$

As the velocity gradient q increases, λ and $-\mu$ are increased, and the angle χ is decreased from a value 45° .

From the above results the equipotential surface can be again written as the form:

$$(1-\lambda)\xi^2 + (1+\lambda)\eta^2 + \zeta^2 = \text{constant} . \quad (3.10)$$

The eccentricity of the ellipsoidal surface, e , is given by the next formula,

$$e = (\lambda/1 + \lambda)^{1/2} \approx \lambda^{1/2} (1 - \frac{1}{2}\lambda + \dots) , \quad (3.11)$$

and when $\lambda (= -\mu)$ is very small, this is written approximately as

$$e \approx 2^{-1}(7-2X)^{-1/2} \alpha D_0^{-1/2} q^{1/2} . \quad (3.12)$$

According to our recent discussions^{2,3)} the quantity, kTX , represents the maximum or minimum value of the mean intermolecular potential, and for some polymer solutions⁴⁾ X assumes the values less than at most the order of unity, and also α^2 is proportional to the mean square end to end distance L of the polymer chain in the solution, as given by the relation:

$$\alpha^2 = 0.81 \cdot 2/9 \cdot L^2 \approx (0.42L)^2 \quad (3.13)$$

From this Eq. (3.12) can be also written as

$$\begin{aligned} e &\approx 2^{-1} \cdot 0.42 \cdot (7-2X)^{-1/2} L D_0^{-1/2} q^{1/2} , \\ &\approx 10^{-1} L D_0^{-1/2} q^{1/2} . \end{aligned} \quad (3.12')$$

Several experimental results in ordinary polymer solutions show that L has the order of about 10^{-6} cm, and D_0^{-1} has the order of about 10^{-7} cm² sec⁻¹. So, according to Eq. (3.12'), in order that the eccentricity e attains to a value of the order of 10^{-1} , the velocity gradient q should have a value of the order of about 10^3 , which is rather a high value as the velocity gradient. Therefore in ordinary order of the velocity gradient the non-spherical symmetry of the radial distribution function should be small. But, usually L and D_0^{-1} increase with the molecular weight of polymer in the same solvent, and D_0^{-1} is considered to have larger value for more viscous solvent. Consequently it is considered that the non-spherical character of the radial distribution function increases with the molecular weight of polymer and with the viscosity of solvent, and moreover it may become more appreciable for greater value of the velocity gradient.

§ 4. Discussions

In our present discussions the internal freedom or configuration of polymer molecule is not taken into consideration, and we adopt the spherically symmetric intermolecular force between two polymer molecules, which depends only on the molecular distance and so acts along the line connecting the two molecular centers of gravity. However, it is considered that the polymer molecule consists usually of large number of molecular segments, and can take various configurations in the solution, and so in more detailed discussions their interaction property should be described by their total internal coordinates.

Also, when the solution has the velocity gradient, the solute polymer molecule performs a rotational motion as a whole about the axis perpendicular to the flow direction and the velocity gradient, in addition to its translational motion following the flow of solvent. This rotational motion may produce another component of intermolecular force which acts in the tangential direction of two molecules, as it were a rotational friction between two molecules.

Besides these, as we can see in the several theoretical treatments⁶⁾ for the flow birefringence or the viscosity of polymer solutions, the velocity gradient causes the statistical orientation for the solute particle having the non-spherically symmetric configuration, and moreover it may deform the internal configuration for the chain polymer molecule owing to the frictional force exerting on the molecular segments from the solvent. Consequently we can consider that such molecular orientation and the deformation effects also affect the intermolecular interaction between two polymer molecules, and deform the intermolecular potential function into the non-spherical symmetry.

However, such rotational or intramolecular effects are considerably small compared with the intramolecular effect, and they can be appreciable for very large velocity gradient, for it is supposed that the order of the intermolecular binding force is far greater than that of the intermolecular interaction, and also the internal diffusion of a polymer molecule is more rapid than that of the translation of the whole molecule. On such considerations the rotational and intramolecular effects are neglected in our calculation. But, it is considered that these effects may become more greater in case of the very large velocity gradient.

Moreover, in the calculation in section 3, we did not consider the hydrodynamic interaction between polymer molecules, and also adopted a model of the free-draining polymer molecule. In the recent various theoretical calculations^{6,7)}, the hydrodynamic intermole-

cular interaction is often considered between molecular segments in a chain polymer molecule, and in order to explain the observed relations between molecular weight of polymer and the intrinsic viscosity of the solution, this effect has been utilized by some authors⁷⁾. The hydrodynamic intramolecular interaction in a polymer molecule, as shown in these treatment, would perturb or deform the streaming lines of the solvent near the polymer molecules as well as in the inside of them, and thus the velocity function $v(r)$ would have more complicated form than that of Eq. (3.2). But, in our present calculations, taking account of the intermolecular potential of chain polymer molecules, the property of the effect of the velocity gradient on the radial distribution of the polymer molecules was considered in a simple calculation.

Paramagnetic Resonance Spectrum of Mn^{++} in NaCl Single Crystal

By Kazuo MORIGAKI, Minoru FUJIMOTO and Junkichi ITOH

Department of Physics, Osaka University, Osaka

(Received June 10, 1958)

The paramagnetic resonance spectrum of Mn^{++} ions contained in NaCl single crystal with concentrations of $1\sim 3\times 10^{-4}$ in mole fraction has been investigated. From the analysis of the spectrum the existence of $Mn^{++}-Na^+$ vacancy complex, in which a Na^+ vacancy is at one of the nearest neighbor positions with respect to the Mn^{++} ion, has been verified at room temperature in crystals quenched from high temperatures. However, this state of Mn^{++} ion is unstable at room temperature, and such complexes diffuse through the lattice to form aggregates of Mn^{++} ions. The ground level splitting parameters of a Mn^{++} ion accompanying a Na^+ vacancy at one of its nearest neighbor positions have been obtained as follows: $D=137.9\pm 1$ gauss, $E=51.4\pm 0.4$ gauss, where D and E represent the parameters in the spin Hamiltonian, $D[S_z^2-1/3\cdot S(S+1)]+E(S_x^2-S_y^2)$, in which z axis is in the direction of $Mn^{++}-Na^+$ vacancy and y axis along the cubic axis perpendicular to it.

§ 1. Introduction

By investigating the paramagnetic resonance spectra of paramagnetic impurities in diamagnetic crystals, certain informations about their electronic states in crystals will be derived. Since the electronic states strongly depend upon the crystalline field, the state of the environment around the paramagnetic ions may be informed by analyzing the structure of their resonance lines. When the valency of the impurity ions is different from that of the ions in the base crystal, additional vacancies would be produced by the principle of charge compensation. For example, if Mn^{++} ions are added to a monovalent ionic crystal, a positive ion vacancy is produced for each Mn^{++} ion. In this case, relative positions between these divalent ions and positive ion vacancies will be known by paramagnetic resonance studies, and a basic knowledge may be obtained concerning complex formation between them.

From this point of view, the paramagnetic resonance of added paramagnetic impurities in alkali-halide crystals has been investigated by several workers.¹⁾⁻⁹⁾ Schneider and Caffyn¹⁾ first investigated the paramagnetic resonance spectrum of a NaCl- Mn^{++} single crystal, and observed fine structures in Mn^{++} resonance when the crystal was quenched from a high temperature while only broad single line was observed before quenching. This shows that, when the crystal is quenched

from high temperature, some $Mn^{++}-Na^+$ ion vacancy pairs, "complexes", are formed and then a crystalline field of a lower symmetry is produced at each Mn^{++} ion by a Na^+ ion vacancy associated with it. However, detailed analysis of the fine structure has not yet been published.* The change of the line shape and line width with heat treatment of the crystals has been reported also by Oshima et al.,²⁾ who did not observe any fine structure of the resonance line. On the other hand, Low³⁾ observed weak h.f.s. lines superposed on a strong bell-shaped line even without heat treatment. He concluded that these h.f.s. lines originated from isolated Mn^{++} ions still remaining in the crystal, so that only cubic crystalline field acted upon them.

Later, Watkins and Walker⁴⁾ have made an experiment at high temperatures, and found that when the temperature was raised to about 200°C, fine structures of the resonance lines which originated from two different states of Mn^{++} in the crystal were observed (one being in axial symmetric, another in orthorhombic crystalline field). They interpreted these crystalline fields as those originating from Na^+ ion vacancies in the next nearest neighbor position and in the nearest neighbor position to Mn^{++} ions respectively. Also

* A brief report of the analysis of the fine structure was given by Schneider at the Conference on the Radio & Microwave Spectroscopy, Duke University, November 1957.

they observed only six h.f.s. lines at 450°C, which meant that at this temperature Mn^{++} ions did not accompany any vacancies, so that the crystalline field at them was of cubic symmetry. They also made an experiment with quenched crystals.¹⁰⁾

In this paper the results of the paramagnetic resonance of Mn^{++} in NaCl single crystals grown from aqueous solutions are reported. When the crystals were quenched from high temperatures, fine structures were observed at room temperature in accordance with Schneider and Caffyn's result. Analyzing the fine structure, it was found to be explainable as the effect of a Na^+ ion vacancy associated with a Mn^{++} ion. So the existence of $Mn^{++}-Na^+$ vacancy complex is verified in the crystal quenched from high temperatures. The crystals before quenching showed no such structure. It is interesting to compare these results with that of the existence of two kinds of $Mn^{++}-Na^{++}$ vacancy complexes at high temperatures observed by Watkins and Walker. Analysis of the fine structure together with the discussion is given in section 3.

§ 2. Experimental Method

Measurements were made at a wavelength of 3.17 cm and at room temperature, using a TE₁₁₄ circular reflection cavity. The signal detected by a standing wave detector was amplified with a pre-amplifier and then with a narrow band amplifier, and finally detected by a phase sensitive detector and recorded as the first derivative of the absorption line. The frequency of the magnetic field modulation was 60 c/s or 315 c/s. The magnetic field measurement was made with proton resonance. The g -factor was determined by comparison with the absorption line of α - α diphenyl β -picryl hydrazyl ($g=2.0036$).

NaCl- Mn^{++} single crystals were obtained by slow vaporization of aqueous solutions of NaCl containing small amounts of $MnCl_2$ at 60°C. By spectroscopic analysis the concentration of Mn^{++} was found to be $1\sim 3\times 10^{-4}$ in mole fraction. With the base NaCl crystal alone, no resonance lines were observed.

The procedure of the quenching was as follows. The specimen kept at a high temperature for about three hours was dropped into dry ice as rapidly as possible. It took about

five seconds. In this procedure the specimens cracked into several parts occasionally, but some parts of the crystal remained uncracked. They were used in the measurement with the static magnetic field parallel to [100] or [110]. The specimen used in the measurement with the magnetic field parallel to [111] was the crystal cut along a (110) plane before the quenching, and for this specimen many cracks appeared after the quenching, probably due to strains produced by the cutting. Therefore, the results of the experiments in this case may include some ambiguities in the line shape, the line width, the intensity, and others. The resonance measurements were started about thirty minutes after the quenching. Since the fine structures decayed with time, as will be shown in section 3, the quenching of the crystal was repeated before each resonance measurement. The fine structures observed were quite reproducible.

§ 3. Experimental Results and Discussions

Experiments are divided into two parts. One is the measurements of the resonance line with the crystals without heat treatment. The other is the measurements of many lines with the single crystals quenched from high temperatures.
